There are two precise repairs. If only the ind-object is wanted, use the full subcategory $T_{\leq t_0} \subseteq T$ on objects admitting some arrow to t_0. Its preorder is exactly the lower ideal of P. Its inclusion is cofinal on associated preorders: given t, choose a common lower bound of t and t_0. It is cofiltered as a preorder for the same reason. Restriction therefore leaves H_C unchanged. The actual slice T/t_0 can instead be used when T is cofiltered in the categorical sense. Given $u : a \to t_0$ and $v : b \to t_0$, first choose $r \to a, b$, then precompose once more to equalize the resulting two arrows $r \rightrightarrows t_0$. This supplies a common predecessor in the slice. Parallel arrows in the slice can likewise be equalized in T, and the resulting equality still lies over t_0. Thus the slice is then cofiltered.

We checked the standard filtering results in The Stacks Project Authors (2026i, Categories, §4.19) and the homotopy-colimit comparison discussed below; we did not find this particular correction to manuscript page 103 stated there. The example and the two repairs are recorded as a local development of the argument, without a claim of priority.

ⓓ De toutes façons, si T' est une autre catégorie filtrante à gauche, et

$$\alpha : T' \longrightarrow T$$

un foncteur cofinal à gauche, de sorte que C sur T, et $C' = C \times_T T'$ sur T', définissent essentiellement le 'même' objet de Ind Cat hot, et que la catégorie C'_∞ pour C' sur T' fait partie des catégories C_∞ pour C sur T - on peut se demander si le foncteur canonique

[page 105]

$$C' \longrightarrow C$$

est également toujours un isomorphisme dans Cat hot, ou sinon, du moins dans Hot.

Un intérêt particulier s'attache à $\pi_0(C)$, et de plus à sa variance pour C sur T variable de la façon suivante. Si S est dans Cat, on regarde les catégories

$$\underline{\mathrm{Hom}}_{\mathrm{Cat}}(S, C_t) \qquad (t \in T),$$

on trouve un foncteur

$$t \longmapsto \underline{\mathrm{Hom}}_{\mathrm{Cat}}(S, C_t), \qquad T^o \longrightarrow (\mathrm{Cat}),$$

d'où une catégorie fibrée sur T, que je vais désigner par

$$\underline{\mathcal{H}om}_T(S_T, C)$$

(Sauf erreur, elle s'interprète comme la catégorie fibrée sur T correspondante au champ sur $\mathrm{Top}(T) = T^\wedge$ du morphisme de T-champs de S_T dans C, où $S_T = S \times T$ (considérée comme catégorie fibrée sur T à fibre essentiellement constante S) dans C. Ici j'identifie catégorie fibrée sur T, et champs sur le topos $T^\wedge$.) Il est immédiat que la propriété d'homotopie (p. 99) est stable par passage de C à $\underline{\mathcal{H}om}_T(S_T, C)$. On s'intéresse à la variation de

$$\pi_0(\underline{\mathcal{H}om}_T(S_T, C))$$

comme contrafoncteur en S,

p. 68

$$H : S \longmapsto \pi_0 \underline{\mathcal{H}om}_T(S_T, C) \qquad (\mathrm{Cat})^o \longrightarrow (\mathrm{Ens}),$$

[page 106]

et à une éventuelle expression de ce contrafoncteur H en termes de l'ind-objet H_C de Cat hot, par la formule hypothétique

$$H(S) \simeq \mathrm{Hom}_{\mathrm{Ind}(\mathrm{Cat\,hot})}(\gamma(S), H_C),$$

où

$$\gamma : \mathrm{Cat} \longrightarrow \mathrm{Cat\,hot}$$

est le foncteur canonique. Si on avait un tel isomorphisme canonique fonctoriel en S, cela donnerait une description (à isomorphisme unique près) de l'ind-objet H_C en termes du foncteur précédent H sur Cat.

Il me vient un doute ici, en vue de l'exemple $T = \underline{\mathrm{Ty}}$, $C = \underline{\mathrm{Ch}}_\Sigma(X; a, b)$. Les trois types d'objets a) b) c) ont le même π_0, et il est sûr que 'c'est le bon'. D'autre part, pour une catégorie paramètre variable S, il est sûr aussi que le bon foncteur en S est

$$S \longmapsto \pi_0(\underline{\mathrm{Hom}}_T(S_T, C)) \simeq \mathrm{Hom}_{\mathrm{Ind\,Cat\,hot}}(S, H_C),$$

isomorphe aussi, *si S est finie,* à

$$\mathrm{Hom}_{\mathrm{Cat\,hot}}(S, C_\infty),$$

ce qui montre que, du moins pour des arguments $S \in (\mathrm{Cat})$ qui sont des catégories *finies*, les objets C_∞ et H_C sont 'bons', il nous permettent de décrire un foncteur important qui domine la situation envisagée. Moyennant une hypothèse très forte, mais satisfaite dans les cas importants, on peut dans ces deux formules remplacer Cat hot par Hot. [page 107]

Commentary · Exposition [ms. 106]

The functor represented by the ind-object

Grothendieck's parameter category S restores information that the connected components of a single fibre cannot carry. The proposed formula for $H(S)$ is valid under the hypotheses already imposed, and its proof explains both the ind-object and the restriction to finite S in the next formula.

For any strict diagram $A : T^{\mathrm{op}} \to \mathrm{Cat}$, the connected components of its fibred total category are

$$\pi_0\left(\int_T A\right) \cong \operatorname*{colim}_{T^{\mathrm{op}}} \pi_0 A(t).$$

Indeed, the total category is generated by vertical arrows and cartesian transport arrows. Vertical arrows impose exactly the component relation inside each $A(t)$; a cartesian arrow imposes exactly the relation identifying a class with its restriction along an arrow of T. Those are the generators and relations defining the colimit of sets, with no further relation. Apply this observation to $A(t) = \underline{\mathrm{Hom}}(S, C_t)$. A zigzag between two reindexing functors induces a zigzag after postcomposition with functors from S, so the diagram of component sets factors through P^{op}. We obtain, naturally in S,

$$\begin{aligned} H(S) &= \pi_0 \underline{\mathcal{H}om}_T(S_T, C) \\ &\cong \operatorname*{colim}_{P^{\mathrm{op}}} \mathrm{Cat\,hot}(S, C_t) = \mathrm{Hom}_{\mathrm{Ind(Cat\,hot)}}(S, H_C). \end{aligned}$$

The last equality is the defining formula for maps from a constant object into an ind-object. The usual fully faithful embedding of ind-objects into set-valued presheaves then gives the asserted uniqueness of H_C. Setting $S = e$ proves the equality of the three component sets in the text.

To compare with C_∞, suppose S has finitely many objects and arrows. A functor $S \to \mathrm{colim}_n C_n$ involves finitely many objects, arrows, and composition equations. Represent its objects and arrows at a common stage, then move to a later stage where all the finitely many required equations hold. It therefore descends to some C_n. A natural transformation between two such functors also consists of finitely many arrows and naturality equations and descends in the same way. Finally, if two descended functors lie in the same component, a witnessing homotopy is a *finite* zigzag of such transformations; the whole zigzag descends to one later stage. This proves the bijection

$$\operatorname*{colim}_n \mathrm{Cat\,hot}(S, C_n) \xrightarrow{\sim} \mathrm{Cat\,hot}(S, C_\infty).$$

It is an instance of the finite-presentation argument underlying filtered colimits, not a fibrancy assertion.

The finiteness cannot simply be omitted. Let C_n be the discrete category on $\{0, \dots, n\}$ and let S be the discrete category on $\mathbf{N}$. Then C_∞ is discrete on $\mathbf{N}$. The left side consists of functions $\mathbf{N} \to \mathbf{N}$ with bounded image; the right side consists of all functions. The identity function lies only in the latter. The ind-object retains the information that a whole S-family must occur at one stage, while the ordinary colimit allows the stage to vary with the individual element of S.

Par contre, sauf pour le cas où S est réduit à un point et où $\mathrm{Hom}_{\mathrm{Cat\,hot}}$ ou $\mathrm{Hom}_{\mathrm{Hot}}$ de S dans C n'est autre que $\pi_0(C)$ ($\simeq \pi_0(C_\infty) \simeq \pi_0(H_C)$), donc effectivement 'bon', je ne sais pas si

$$\underbrace{\mathrm{Hom}_{\mathrm{Cat\,hot}}(S, C)}_{=\pi_0 \underline{\mathrm{Hom}}(S,C)} \qquad \text{ou} \qquad \mathrm{Hom}_{\mathrm{Hot}}(S, C)$$

est lié de façon raisonnable aux ensembles précédents (déterminés par H_C, resp. par C_∞), p. ex. s'ils lui sont isomorphes de façon naturelle, et s'ils ont une signification géométrico-topologique raisonnable. Je commence à suspecter que *non* - donc qu'on aurait ici un cas où une relation de type très général concernant un π_0, ici donc

$$\pi_0(C) \simeq \pi_0(C_\infty) \simeq \pi_0(H_C),$$

ne se prolonge pas en un isomorphisme sur les π_i supérieurs, et en une propriété de Hot-équivalence.

Je ne trouve d'ailleurs aucune flèche directe entre C et l'un des objets C_∞, H_C; tout ce que je vois dans ce sens, c'est p. 69 [page 108]

$$\begin{array}{ccc} C_{\mathbf{N}^o} & \xrightarrow{\substack{\text{foncteur de} \\ \text{localisation}}} & C_\infty \\ \downarrow & & \\ C, & & \end{array}$$

où la flèche verticale est la flèche de projection de $C_{\mathbf{N}^o} = C \times_T \mathbf{N}^o$ (avec $\mathbf{N}^o \xrightarrow{t} T$). Ceci n'établit une relation topologique étroite entre C (en tant qu'objet de Cat hot ou de Hot simplement) et C_∞, que si les deux flèches précédentes sont tout au moins des Hot-équivalences. Et le cas-type (problématique) où la question de la relation entre C et C_∞ se pose, est donc celui où $T = \mathbf{N}^o$, i.e. celui d'un système inductif quelconque de (petites) catégories, indexé par $\mathbf{N}$, et interprété comme défini par une catégorie fibrée $C = C_{\mathbf{N}^o}$ sur $\mathbf{N}^o$. Dans ce cas particulier, on a du moins une flèche canonique

$$C \longrightarrow C_\infty$$

sur laquelle on peut se poser la question si c'est une Hot-équivalence. Sinon, cela prouvera que dans le cas général, le Hot-type de C (et a fortiori sa classe d'isomorphie dans Cat hot) n'a pas de sens géométrique intéressant. C'est à dire que C est intéressante uniquement *en tant que catégorie fibrée sur* T, permettant notamment de construire l'ind-objet H_T de Cat hot ou de Hot, mais pas en tant que 'catégorie nue'. [page 109]

Commentary · Examples [ms. 107]

A finite category need not be a finite homotopy probe

Grothendieck explicitly reserves the passage from Cat hot to Hot for an additional hypothesis. The reservation is necessary. The finite-presentation proof above counts objects, arrows, and equations in a category. Compactness in the homotopy category of spaces concerns the whole nerve, and a finite category can have nondegenerate simplices in arbitrarily high degrees.

Let $S = \mathbf{B}(\mathbf{Z}/2)$, which has one object and two arrows, and put $K = NS$, $K_n = \mathrm{sk}_n K$. Let $D_n = \Delta/K_n$ be the category of simplices of K_n. Every simplex of K belongs to one skeleton, so

$$D_\infty = \operatorname*{colim}_n D_n = \Delta/K.$$

The simplex-category resolution gives $|ND_n| \simeq |K_n|$ and $|ND_\infty| \simeq |K|$, naturally for the inclusions. The precise last-vertex statement for an arbitrary simplicial set is Kerodon (2026, Corollary 11.9.11.5). Thus the filtered colimit has the homotopy type of $B(\mathbf{Z}/2)$, while each stage has an n-dimensional realization.

The identity of $B(\mathbf{Z}/2)$ cannot factor in Hot through any $|K_n|$. Such a factorization would make its identity map on cohomology factor through a group vanishing in degrees greater than n. But

$$H^*(B(\mathbf{Z}/2); \mathbf{F}_2) \cong \mathbf{F}_2[u], \qquad |u| = 1.$$

For completeness, the normalized group cochains with trivial $\mathbf{F}_2$ coefficients have one basis element in each degree: a normalized cochain is determined by its value on the string consisting entirely of the nonidentity group element. Its differential is zero, since the two end terms cancel and every interior product gives the identity, on which a normalized cochain vanishes. The degree-one generator and its cup powers take value one on these strings. This proves the displayed calculation and the obstruction.

Consequently the canonical map

$$\operatorname*{colim}_n \mathrm{Hom}_{\mathrm{Hot}}(S, D_n) \longrightarrow \mathrm{Hom}_{\mathrm{Hot}}(S, D_\infty)$$

is not surjective, although S is finite as a category. There is no contradiction with the preceding Cat hot formula. Finite CW homotopy types are compact probes for filtered homotopy colimits, but the nerve of this finite group is not one. This is the point at which the two meanings of "finite" must be separated when reading the notation $\mathrm{Hot}_0^\wedge$ later on these pages.

Commentary · Later developments [ms. 108]

The sequential total category is a homotopy colimit

Grothendieck has reduced one part of the comparison to a single sequence. That part has a uniform answer: the canonical functor from its fibred total category to its ordinary filtered colimit is a weak equivalence of nerves. No full-faithfulness assumption on the transition functors is needed.

Write $E = \int_{\mathbf{N}^{\mathrm{op}}} C_n$ and $D = \operatorname{colim}_n C_n$. With the variance of this manuscript, an arrow $(m, y) \to (n, x)$ over $m \to n$, where $m \geq n$, is an arrow $y \to F_{n,m}x$ in C_m. The canonical functor $q : E \to D$ sends it to the corresponding arrow in D. Cartesian transport arrows become identities. The localization description in the text is understood in the usual categorical sense: after inverting those arrows, E becomes *equivalent* to D. Literal equality of its object set with that of D is neither needed nor generally true.

The homotopy-colimit theorem of Thomason (1979, Theorem 1.2), in its dual form for a fibration, identifies $|NE|$ with $\operatorname{hocolim}_n |NC_n|$. The convention for a contravariant diagram and the comparison map are displayed explicitly in Cegarra (2020, §3, equation (9)). Two elementary filtered-colimit facts complete the argument. First,

$$ND \cong \operatorname*{colim}_n NC_n :$$

an r-simplex is a finite string of composable arrows, and finitely many representatives and equalities can all be realized at one stage. Second, for a filtered diagram of simplicial sets K_n, the augmentation

$$\operatorname{hocolim}_n K_n \longrightarrow \operatorname*{colim}_n K_n$$

is a weak equivalence. One way to see the second fact is to use the simplicial replacement. In each fixed simplicial degree, the fibre over a simplex of the colimit is the category of its representatives at the different stages. Any two representatives eventually agree, and finitely many such agreements hold simultaneously at a later stage. This category is nonempty and filtered, hence its nerve is contractible: every finite diagram admits a cone, which contracts each finite simplicial sphere. Thus

the augmentation is a weak equivalence in each row of the bisimplicial replacement, and diagonal realization preserves these rowwise weak equivalences. The composite is the map induced by q.

This identifies the genuine issue in the span on manuscript page 108. The horizontal arrow is always a weak equivalence. Whether the vertical arrow is one depends on how the chosen sequence sits inside T, including the homotopy carried by its parallel arrows. Passing to the preorder has deliberately forgotten that information.

Commentary · Exposition [ms. 108]

The total category and the telescope

Grothendieck wants a path category that carries composition and at the same time has the intended homotopy type. The two objects in this opening comparison solve different parts of that problem. The total category remembers how the types of paths vary; the filtered colimit forgets the stages at which paths were represented. We write $BC = |NC|$, and call a functor a weak equivalence when its nerve is a weak homotopy equivalence. This is the meaning of an isomorphism in Hot. It is stronger than a bijection on connected components and different from an isomorphism in Cat hot, where morphisms are connected components of ordinary functor categories.

Here is a proof of the assertion announced on the following page. Let $F_0 \to F_1 \to \cdots$ be a strict sequence of small categories, let $E \to \mathbf{N}^o$ be its fibred Grothendieck construction, and let $L = \operatorname{colim}_n F_n$. The canonical functor $q : E \to L$ is a weak equivalence. For clarity, a morphism $(n, x) \to (m, y)$ in E, with $n \geq m$, is a morphism $x \to F_{m,n}y$ in F_n.

To prove the assertion, fix $z \in L$ and consider the comma category q/z. Any finite collection of its objects, arrows, and commuting triangles can be represented at one sufficiently large stage r: filtered colimits of categories are computed from finite diagrams and their eventual relations. We may also represent z at stage r. Transporting the finitely many objects to that stage gives a diagram in F_r/z_r. Its projection to q/z has a natural transformation to the original diagram, supplied by the cartesian arrows in E. It has a natural transformation to the constant diagram $(r, z_r, 1)$, supplied by the arrows to z_r. Thus every finite simplicial diagram in $N(q/z)$ contracts after passing to a stage. The same argument with a chosen vertex proves connectedness and vanishing of all homotopy groups; the comma category is nonempty because z has a representative. Quillen's Theorem A now gives the assertion (Quillen, 1973, §1, Theorem A). This argument does not require the transition functors to be faithful or injective on objects.

The second leg of the displayed roof is a separate matter. Take a nontrivial group G, let $T = BG$ be its one-object category, and take $C = T$ over itself. The preorder obtained by forgetting the distinction between parallel arrows is a point. A sequence constant on the identity arrow is therefore cofinal in that preorder, whereas the comparison is $* \to BG$. Its fundamental group is $1 \to G$, so it is not a weak equivalence. This proves exactly the limitation noticed on manuscript page 109: cofinality in the preorder of objects does not account for the automorphisms of the indexing category. It does not predict failure for the particular category of interval types, which has additional structure.

Mais je viens de me convaincre que $C_{\mathbf{N}^o} \longrightarrow C_\infty$ est bien une Hot-équivalence. Donc la flèche $C_{\mathbf{N}^o} \longrightarrow C$ définit une flèche *dans* Hot

$$C_\infty \longrightarrow C$$

(en composant avec l'inverse dans Hot de la précédente). Est-ce un isomorphisme? Donc pour cette question, on est ramené à la question pour $C_{\mathbf{N}^o} \longrightarrow C$. Mais si on prend $C = T$, cela pose déjà la même question pour $\mathbf{N}^o \longrightarrow T$, donc la question si T est asphérique, sous la seule hypothèse que T_o soit filtrante à gauche et dénombrable à l'infini (à gauche). Mais bien sûr c'est faux (p. ex. si T n'a qu'un seul objet, il n'est pas pour autant asphérique !).

Cela me convainc donc qu'à défaut d'hypothèse supplémentaire draconienne sur T, la catégorie C 'nue' n'offre pas d'intérêt particulier, à part son π_0 (qui est donné aussi par C_∞, et par H_C). Il n'est pas dit, certes, que Ty ne satisfasse pas à ces 'conditions draconiennes'. Mais comme C 'nue' ne s'insère pas dans un formalisme sympathique (p.ex. on n'a pas d'interprétation géométrique de $\operatorname{Hom}_{\text{Cat hot}}(S, C)$, ou de $\operatorname{Hom}_{\text{Hot}}(S, C)$), je crois que par la suite je peux en faire abstraction. Exit a) !

p. 70

[page 110]

Commentary · Examples [ms. 109]

What a one-object base can retain

Grothendieck's one-object example can be made completely explicit, and it shows exactly which information is absent from the ind-object. Let G be a nontrivial discrete group and let $T = \mathbf{B}G$ be the category with one object and endomorphism group G. Take $C = T$ with its identity projection. This is a split fibration with terminal fibre and identity reindexing functors. Its homotopy hypothesis holds strictly; its associated preorder is the one-point category, which is cofiltered and has a countable cofinal family.

Choose the constant chain at that object, with identity transition arrows. Every C_n and C_∞ is the terminal category, and H_C is the constant terminal ind-object. The total category remains $\mathbf{B}G$. Consequently the comparison in Hot is

$$* \longrightarrow BG,$$

where $BG = |N\mathbf{B}G|$. Its source has trivial fundamental group and its target has fundamental group G. It is a bijection on components and is not a weak equivalence. More generally the constant fibration with fibre D has total category $T \times D$, so it retains the product $BG \times |ND|$ while its sequential colimit is D.

There is also a direct answer to the mapping-set question of manuscript page 107. Set $G = \mathbf{Z}/2$ and $S = \mathbf{B}G$. Since the fibres of $C \to T$ are terminal, $H(S)$ is a singleton. The identity and the trivial functor $S \to C$ are not homotopic in Cat hot: natural transformations between functors of one-object groupoids express conjugacy of the corresponding homomorphisms, and these two homomorphisms are not conjugate. They remain distinct in Hot, because their maps on π_1 differ. Thus neither of the proposed mapping sets into the bare total category recovers $H(S)$ in this generality.

The example concerns the abstract hypotheses of §10. It does not decide the special path-category comparison over $\underline{\mathrm{Ty}}$. That case has additional geometric structure, used later in the chapter. Nor does it make C topologically meaningless: C remembers the base monodromy, which is precisely the datum suppressed by the thin reflection. The warning is against identifying two different invariants.

5.11.90

J'ai quand même passé la journée entière hier à essayer de comprendre la relation de C et de son type dans Hot, à celui de C_∞. En effet, comme on a finalement une flèche dans Hot

$$C_\infty \longrightarrow C,$$

déduite du diagramme dans (Hot)

$$\begin{array}{ccc} C_{\mathbf{N}^o} & \xrightarrow{\sim} & C_\infty \\ \downarrow & & \\ C, & & \end{array}$$

de prouver que $C_\infty \longrightarrow C$ est un isomorphisme dans Hot semble la façon la plus simple, et peut-être unique, de prouver que l'image de C_∞ dans Hot ne dépend pas, à isomorphisme [page 111] unique près, des choix faits pour construire C_∞. Sans compter que dans le cas motivant, $C = \underline{\mathrm{Ch}}_\Sigma(X)$ ou $\underline{\mathrm{Ch}}_\Sigma(X; a, b)$, $T = \underline{\mathrm{Ty}}$, c'est la catégorie des chemins C qui donne lieu à une loi de composition des chemins impeccable, fonctorielle, associative et tout, alors qu'il n'en est rien pour C_∞. On ne trouve pas une loi de composition

$$C_\infty \times C_\infty \longrightarrow C_\infty$$

p. 71

dans Cat, ni même dans Cat hot ou dans Hot - ou plutôt, si on arrive pourtant à construire une flèche $C_\infty \times C_\infty \longrightarrow C_\infty$ dans Cat, c'est encore laborieusement à coups de choix ± arbitraires, [page 112]

cran par cran, et sans savoir si ce qu'on obtient a une propriété d'unicité, ne serait ce que dans Hot; on ne trouve une interprétation géométrique tangible de cette composition que dans $\mathrm{Hot}_0^\wedge$ (où on a une véritable loi de groupoïde), ou dans H_T en tant qu'objet de $\mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}$ ou de $\mathrm{Ind}\,\mathrm{Hot}$. (Donc la limite inductive dans $\mathrm{Hot}_0^\wedge$ n'est autre que l'élément de $\mathrm{Hot}_0^\wedge$ défini par C_∞.)

Mes efforts pour prouver que

$$C_\infty \longrightarrow C$$

était un isomorphisme dans Hot, ou ne serait-ce qu'un 1-isomorphisme (i.e. un isomorphisme non seulement pour les π_0, ce qui est toujours vrai, mais aussi pour les π_1 de toutes les composantes), ont échoués. J'ai trouvé qu'il suffisait que le foncteur

$$T \longrightarrow T_{\mathrm{o}}$$

soit ou bien lisse et coasphérique, ou bien propre et asphérique - donc tout est OK si $T = T_{\mathrm{o}}$, i.e. si T est ordonnée. Mais dans le cas $T = \underline{\mathrm{Ty}}$, le foncteur $T \longrightarrow T_{\mathrm{o}}$ n'est ni propre, ni lisse (pas même 0-propre ou 0-lisse).

Finalement j'en suis arrivé à la conviction que dans le cas qui nous occupe ($T = \underline{\mathrm{Ty}}$, $C = \underline{\mathrm{Ch}}_\Sigma(X; a, b)$), la flèche $C_\infty \longrightarrow C$ n'est en général *pas* un isomorphisme dans Hot. En effet, dans le cas $a = b$, si cela `[était vrai]`, on aurait une description du Hot-groupe $\Omega(X, a) = \underline{\mathrm{Ch}}(X, a)$ ([23]) en termes d'une catégorie C munie d'une loi de composition *associative* (et unitaire) *dans* Cat, redonnant la loi de groupe de Ω en passant de (Cat) à Hot. Prenant le nerf de C, on trouverait un monoïde semi-simplicial qui, dans Hot, donnerait la loi de groupe de $\Omega(X, a)$. Or je me rappelle ([24]) qu'on m'a expliqué qu'en général, la loi de groupe de $\Omega(X, a)$ ne pourrait pas être obtenue par une loi *associative* sur un ensemble semi-simplicial. Ainsi, l'insuccès de mes efforts semble tenir, non à ma maladresse, mais à la nature des choses. [page 113]

Commentary · Exposition [ms. 112]

The cofinality condition that controls total categories

Grothendieck is seeking a hypothesis that allows the base to be replaced without changing the total homotopy type. The appropriate general test is a condition on comma categories, stronger than cofinality of the associated preorders. It gives a precise sufficient criterion without requiring every reindexing functor between fibres to be a weak equivalence.

Let $\alpha : J \to T$ be a functor. If every comma category α/t has contractible nerve, then for every Grothendieck fibration $C \to T$ the projection

$$C \times_T J \longrightarrow C$$

is a weak equivalence of nerves. To prove this, fix $x \in C_t$ and consider the comma category of the displayed projection over x. Its objects are triples consisting of $j \in J$, $y \in C_{\alpha j}$, and an arrow $y \to x$ over some $u : \alpha j \to t$. Forgetting y gives a functor to α/t. Cartesian lifting supplies a right adjoint: send (j, u) to the cartesian arrow $u^* x \to x$. The adjunction follows from the unique factorization of an arrow through a cartesian lift. Hence these two comma categories have equivalent nerves. The dual of Quillen's Theorem A now applies; see Lurie (2009, Corollary 4.1.3.3), applied to the opposite functor, for a precise modern formulation.

The condition is also necessary if the conclusion is required for *every* fibration over T. Use the discrete fibration $T/t \to T$. Its total category has a terminal object, and its pullback is α/t. Universal invariance of total homotopy types therefore forces α/t to be contractible. This elementary converse explains why a criterion expressed only in terms of which pairs of objects admit arrows cannot suffice.

For a cofiltered preorder P and a decreasing cofinal sequence t_n, the category α/t is the nonempty tail of indices for which $t_n \leq t$. It has a terminal object, the least such index. Thus the criterion

23. On fait ici $\Sigma = \mathrm{Fl}(X)$.

24. C'est un erreur - ça doit être pour d'*autres* objets groupe de Hot que les groupes de lacets. J'ai vu dans Quillen que $\Omega(X, x)$ doit se décrire par un groupe semi-simplicial (quand X est un ensemble semi-simplicial, x un sommet). Donc le problème si $C_\infty \simeq C$ dans Hot reste entier.

proves the positive assertion in the text when $T = P$. For $T = \mathbf{B}G$ and the constant identity sequence, by contrast, α/t is a disjoint union of copies of $\mathbf{N}^{\mathrm{op}}$ indexed by G, so it is not contractible when $G \neq 1$. These are the same two cases that the preceding examples separate. This comma criterion characterizes invariance for every fibration. The properness and smoothness conditions in the source instead exploit its hypothesis on parallel pullbacks, as the following proof shows; they need not imply the universal comma criterion.

Commentary · Later developments [ms. 112]

Why the smooth and proper criteria suffice

The two sufficient conditions asserted here do follow from the earlier homotopy hypothesis. They are conditions on the base together with this particular class of coefficients; they need not make the chosen sequence cofinal for every fibration. The distinction matters because the hypothesis on parallel pullbacks supplies exactly the local constancy needed in the proof.

Write $q : T \to P = T_{\mathrm{o}}$, let $\alpha : \mathbf{N}^{\mathrm{op}} \to T$ be the chosen sequence, and replace the fibration by a strict diagram $F : T^{\mathrm{op}} \to \mathrm{Cat}$ as above. Put $K = NF$, regarded as a diagram of spaces, and $k = q^{\mathrm{op}}$. The fibre $E_p = q^{-1}(p)$ has the single object p and endomorphism monoid $\mathrm{End}_T(p)$. Every endomorphism $u : p \to p$ is parallel to id_p. Hence $F(u)$ is homotopic to the identity, so its nerve is a weak equivalence. Thus $K|_{E_p^{\mathrm{op}}}$ is a locally constant diagram: every one of its structure maps is a weak equivalence.

Use smoothness and properness for the localizer of weak equivalences of nerves. The fibre criterion of Maltsiniotis (2005, Theorem 1.2(b), printed p. 4) says that smoothness makes

$$j_p : E_p \longrightarrow p\backslash q$$

aspherical, meaning that every j_p/z has contractible nerve. By the smooth–proper duality on pp. 4–5, properness makes

$$j_p : E_p \longrightarrow q/p$$

coaspherical, meaning that every $z\backslash j_p$ has contractible nerve. In the first case coasphericity of q says that $p\backslash q$ is contractible; in the second case asphericity of q says that q/p is contractible. Quillen's Theorem A and its dual therefore show that E_p is contractible in either case.

We shall use the following precise local-constancy fact. If I has contractible nerve and $L : I \to \mathrm{sSet}$ sends every arrow to a weak equivalence, then for every $i \in I$ the canonical maps

$$L(i) \longrightarrow \mathrm{hocolim}_I L, \qquad \mathrm{holim}_I L \longrightarrow L(i)$$

are weak equivalences. The first is Cisinski (2009, Corollary 1.18, printed p. 599); the second is its dual, applied to the opposite index category and opposite model category. The pointwise homotopy Kan-extension formula is Proposition 1.14 of the same paper, with the right-extension formula obtained by the same duality. These are statements about coherent diagrams, so no choice of mutually compatible homotopies between parallel pullbacks is required.

Smooth and coaspherical. Let $G = \mathbf{L}k_!K$ be the left homotopy Kan extension. Its value at p is

$$G(p) \simeq \mathrm{hocolim}_{(p\backslash q)^{\mathrm{op}}} K \simeq \mathrm{hocolim}_{E_p^{\mathrm{op}}} K.$$

Here the second equivalence follows because j_p^{op} is homotopy final: its under-comma categories are the opposites of the contractible categories j_p/z. The local-constancy fact shows that the adjunction unit $K \to k^*G$ is an objectwise weak equivalence. Let $v = (q\alpha)^{\mathrm{op}} : \mathbf{N} \to P^{\mathrm{op}}$. Cofinality of the chosen sequence in the preorder makes v homotopy final: for $p \in P$, the category p/v is the nonempty tail of indices for which $t_n \leq p$, and it has a least element. Consequently

$$\mathrm{hocolim}_{\mathbf{N}} K\alpha^{\mathrm{op}} \xrightarrow{\sim} \mathrm{hocolim}_{\mathbf{N}} v^*G \xrightarrow{\sim} \mathrm{hocolim}_{P^{\mathrm{op}}} G \simeq \mathrm{hocolim}_{T^{\mathrm{op}}} K.$$

The last equivalence is composition of left homotopy Kan extensions. By the unit and its adjunction identity, this composite is the canonical comparison of homotopy colimits.

Proper and aspherical. Instead take $G = \mathbf{R}k_*K$. The pointwise formula and the proper fibre criterion give

$$G(p) \simeq \mathrm{holim}_{(q/p)^{\mathrm{op}}} K \simeq \mathrm{holim}_{E_p^{\mathrm{op}}} K \xrightarrow{\sim} K(p).$$

Now j_p^{op} is homotopy initial, which justifies restricting the homotopy limit, and the final arrow is the local-constancy equivalence. These maps are the components of the counit $k^*G \to K$, so this counit is an objectwise weak equivalence. Asphericity of q also makes k homotopy final, since $p/k \cong (q/p)^{\mathrm{op}}$. Both k and $v = k\alpha^{\mathrm{op}}$ therefore give homotopy-colimit equivalences to $\mathrm{hocolim}_{P^{\mathrm{op}}} G$. It follows by two-out-of-three that

$$\mathrm{hocolim}_{\mathbf{N}}\, \alpha^{\mathrm{op}*} k^* G \longrightarrow \mathrm{hocolim}_{T^{\mathrm{op}}}\, k^* G$$

is a weak equivalence. The counit transfers this conclusion to K.

Finally, the natural fibred form of Thomason's homotopy-colimit theorem identifies the comparison just proved with $C \times_T \mathbf{N}^{\mathrm{op}} \to C$. The sequential comparison already proved identifies its source with C_∞ in Hot. Thus each of the source's two conditions indeed makes its canonical $C_\infty \to C$ an isomorphism in Hot.

This proof also identifies the exact limit of the statement. It used local constancy on E_p^{op}, supplied by the homotopy hypothesis on F. For example, let T be the one-object category of the monoid $\{1, 0\}$ with absorbing zero. The natural transformation from the identity functor to the constant functor whose component is 0 contracts its nerve. The map $q : T \to *$ is both smooth and proper, by the fibre criterion, and both aspherical and coaspherical. But for the constant identity sequence α, the category α/t is a disjoint union of two copies of $\mathbf{N}^{\mathrm{op}}$. Thus these conditions do not imply the universal comma criterion for arbitrary fibrations; the coefficient hypothesis cannot be dropped from the argument.

Commentary · Examples [ms. 112]

Two disconnected lifting categories

The assertion about the projection to the preorder has a small, concrete explanation. Passing to the preorder remembers that a change of type exists and forgets how many such changes there are. For smoothness or properness, those forgotten choices must be connected by commuting triangles of lifts. Natural transformations between interval functors do not by themselves provide such triangles.

Write $q : \underline{\mathrm{Ty}} \to T_o$ for the projection, with T_o retaining the same objects and having one arrow whenever the corresponding Hom set in $\underline{\mathrm{Ty}}$ is nonempty. A necessary condition for 0-smoothness is the following connected lifting property. Given $a \in \underline{\mathrm{Ty}}$, $b \in T_o$, and an arrow $b \to q(a)$, consider the category of arrows $x \to a$ with $q(x) = b$ lying over that arrow; morphisms are commuting triangles over id_b. This category must be nonempty and connected. The dual condition, with fixed source, is necessary for 0-properness. These are the W_0 specializations of the smoothness criterion and its dual, where W_0 consists of functors inducing bijections on connected components (Maltsiniotis, 2005, Theorem 1.2(b), p. 4).

For smoothness take $b = + - +$ and $a = +$. The interval of type b has four vertices $0, 1, 2, 3$, and the interval of type a has two. An increasing endpoint-preserving functor $b \to a$ is forced to collapse the middle, negative edge. There are exactly two such functors, with vertex lists

$$(0, 0, 0, 1) \qquad \text{and} \qquad (0, 1, 1, 1).$$

On the other hand, the only endpoint-preserving increasing endofunctor of $+ - +$ is its identity. To see this, its first internal value must be at most 1, since a nonconstant image of the first positive edge cannot cross the following negative edge. Its second internal value must be at least 2, by the same argument at the last positive edge. The middle negative edge can then be preserved only when these two values are 1 and 2. As q is the identity on objects, the strict fibre over b has this one object and only its identity arrow. The lifting category therefore has precisely two objects and only their identities. It is disconnected, proving that q is not 0-smooth.

For properness take the fixed source $a = ++$ and target $b = +$. There are exactly two endpoint-preserving increasing functors $a \to b$, with vertex lists

$$(0, 0, 1) \qquad \text{and} \qquad (0, 1, 1).$$

The only endpoint-preserving increasing endofunctor of $+$ is the identity. The fixed-source lifting category is consequently another discrete category with two objects. Thus q is not 0-proper.

Both examples are compatible with the earlier contractibility theorem for nonempty categories of interval functors. In that theorem the morphisms are endpoint-fixed natural transformations.

Here they are factorizations through endofunctors of a fixed type. The distinction explains why connectedness of every mapping category cannot supply the lifting property required on this page.

Commentary · Examples [ms. 112]

What the preorder forgets about a lift

Grothendieck's proposed sufficient criterion fails for the category of types for a concrete reason: its preorder identifies distinct changes of parameter which cannot be connected inside a lifting category. The definition on manuscript page 99 retains the same objects in $\underline{\mathrm{Ty}}_o$ and replaces every nonempty set of morphisms by a singleton. It does not identify different objects whose images happen to be isomorphic in that preorder.

Take

$$S = (0 \longrightarrow 1 \longleftarrow 2 \longrightarrow 3), \qquad T = (0 \longrightarrow 1).$$

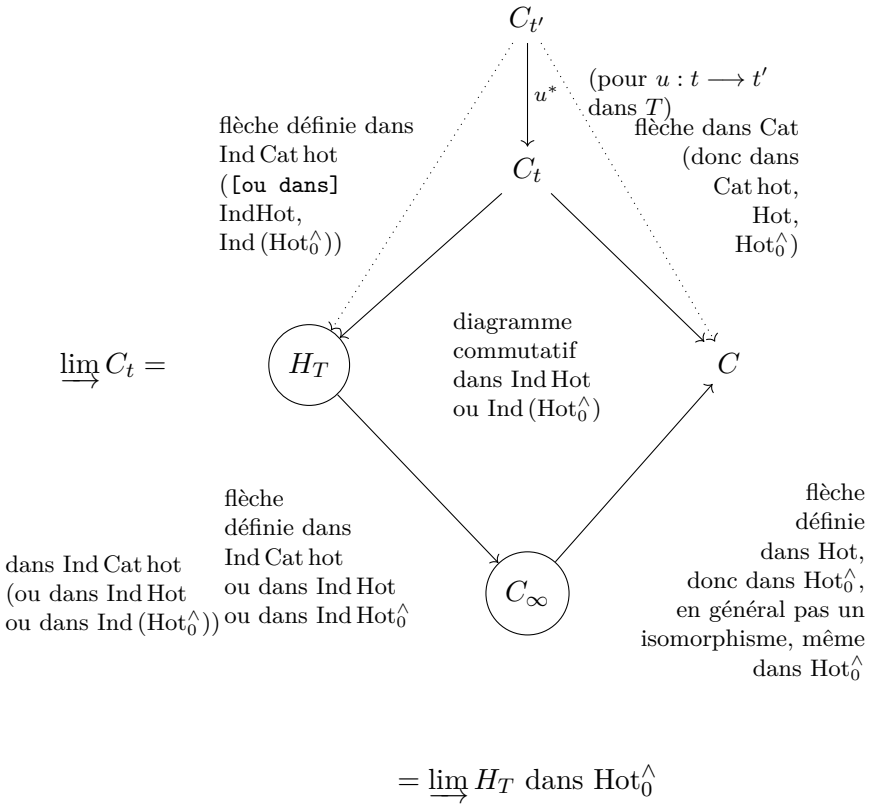
An endpoint-preserving monotone type map $S \to T$ changes its vertex value from 0 to 1 at exactly one of the two forward edges. There are precisely two such maps, with vertex lists

$$(0,1,1,1), \qquad (0,0,0,1).$$

Both S and T have only the identity endomorphism in $\underline{\mathrm{Ty}}$. For S, a monotone endomorphism can advance by at most one vertex on each edge, since its alternating target has no nonidentity composite of two consecutive edges. Its three increments must sum to three because the endpoints are fixed, so each increment is one. The assertion for T is immediate.

Let $p : \underline{\mathrm{Ty}} \to \underline{\mathrm{Ty}}_o$ and consider the unique base arrow $pS \to pT$. An incoming lift with target T has source exactly S, and its morphisms are endomorphisms of S commuting with the lifted arrow. Its lifting category is therefore the discrete category on the two displayed maps. The outgoing lifting category with source S is likewise discrete on those maps, now because its morphisms are endomorphisms of T. Neither category is connected. The incoming and outgoing lift criteria consequently show that p is neither 0-smooth nor 0-proper, and hence neither smooth nor proper. This verifies the source's assertion; failure of a sufficient criterion still does not imply failure of the geometric comparison itself.

Je vais résumer les faits positifs auxquels je suis arrivé dans le diagramme suivant, qui a lieu dans la situation générale $C \longrightarrow T$ envisagée au début du présent paragraphe :



Commentary · Context [ms. 113]

The obstruction withdrawn in the footnote

Grothendieck is trying to explain why an associative composition is easy on all finite paths but elusive on a chosen infinite refinement. The proposed explanation on this page is withdrawn in footnote 24, and the withdrawal is mathematically decisive. A based loop space does admit a strictly associative model. One elementary topological model consists of Moore loops: a loop is a pair (ℓ, γ), where $\ell \geq 0$, $\gamma : [0, \ell] \to X$, and both endpoints are the basepoint. Concatenation adds lengths and joins the maps without rescaling their domains. Its associativity is an equality, and the loop of length zero is a strict unit. Reversal is an inverse up to homotopy, which is exactly the group law required in Hot; a strict monoid model does not require strict inverses.

The simplicial statement is stronger. For a reduced simplicial set K, Kan's loop-group construction gives a simplicial group GK and a weak equivalence $K \to \overline{W}GK$. Consequently $|GK|$ models the based loop space of $|K|$. We checked the precise reducedness hypothesis and the unit equivalence in Stevenson (2012, Theorem 21), which gives a modern proof of Kan's theorem. The word "semi-simplicial" in this part of the manuscript includes the simplicial formalism with degeneracies; it must not be read as a claim about an arbitrary semisimplicial object without them.

These constructions settle the alleged obstruction, but do not by themselves identify either of Grothendieck's particular categories with the model. That identification is the work still to be done. For $\Sigma = \mathrm{Fl}(X)$, section 13 of the present fragment eventually compares the all-types category with $\underline{\mathrm{Ch}}_\infty$ and restores the strict concatenation model. The footnote should therefore be read as a correction to an inference, not as an incidental qualification of a theorem. The unsuccessful search described in the surrounding prose is part of the discovery of the later proof. [page 114] p. 72

Commentary · Present state [ms. 113]

Strict loop multiplication and the later comparison

Grothendieck wants to retain the strictly associative composition already constructed on the total category of paths. His hesitation here concerns whether that useful algebraic structure can live on a correct model of the loop space. Footnote 24 retracts the proposed obstruction, and the retraction is mathematically decisive. A multiplication that is associative only in the homotopy category need not come equipped with the coherent data needed for a strict model. A loop space, however, already has those data; its origin as a space of loops supplies much more than an isolated group object in the homotopy category.

There is a precise classical replacement. For a reduced simplicial set K, Kan constructs a simplicial group GK and a principal GK-bundle over K with weakly contractible total space (Kan, 1958, Definition 6.3 and Theorem 7.1). After passage to a reduced Kan model, this identifies GK with the based loop homotopy type. Its multiplication and inverses are strict in every simplicial degree. Thus the existence of a strictly associative simplicial model cannot disprove the comparison proposed here. This assertion concerns the existence of a model, rather than a claim that a particular category of paths is that model; the latter still requires a comparison argument.

The same manuscript subsequently supplies that argument for unrestricted paths. In Chapter VII, §13, manuscript pages 157–170, Grothendieck returns to the case $\Sigma = \mathrm{Fl}(X)$ and obtains the comparison through the two projections from the sequential Grothendieck construction. The endpoint functors and their fibres are essential; a weak equivalence of total categories alone would not justify a statement about their strict fibres. The elementary lemma that constant paths induce a homotopy equivalence $X \to \mathrm{Fun}(I_\tau, X)$ is left without a written proof at manuscript page 170. The doubts recorded on the present page therefore belong to the progress of the argument, not to its final conclusion (Grothendieck, 1990–1991o, Ch. VII, §13).

That remaining lemma has a direct proof. Delete the last vertex of a nontrivial oriented interval, retract it to its neighbour, and let j denote the inclusion of the remaining interval. The retraction r is a functor, rj is the identity, and either $jr \Rightarrow \mathrm{id}$ or $\mathrm{id} \Rightarrow jr$ is a natural transformation, according to the direction of the deleted edge. Iterating gives a finite zigzag between the identity of I_τ and its constant functor at the initial vertex. Precomposition gives the corresponding zigzag between the identity of $\mathrm{Fun}(I_\tau, X)$ and the composite of evaluation at that vertex followed by the constant-path

functor. The other composite is strictly the identity of X. Thus constant paths give a categorical homotopy equivalence, and hence a weak equivalence of nerves.

For the audit this distinction has two consequences. The inference from an alleged impossibility of strict loop multiplication is false as written, and is explicitly withdrawn by the author. The unrestricted path comparison must be recorded with its later positive treatment, whereas the unrestricted *general-fibration* comparison of §10 still has the counterexamples discussed above. These statements have different hypotheses. Neither footnote 24 nor the later path argument removes the base-category obstruction for an arbitrary $C \to T$.

`[Les annotations dans ce diagramme concernent les flèches en traits pleins.]`

Les objets importants sont H_T et C_∞, alors que C (sur T) et les C_t prennent un rôle technique intermédiaire, pour construire H_T et C_∞. On peut considérer C_∞ comme une catégorie (objet de (Cat)), mais dont la construction dépend de nombreux arbitraires, à l'inverse de H_T dans Ind Cat hot. C'est l'objet de $\mathrm{Hot}_0^\wedge$ déduit de C_∞ qui a un sens canonique, et peut être décrit comme la limite inductive de H_T comme objet de $\mathrm{Ind}\,\mathrm{Hot}_0^\wedge$, i.e. comme représentant le même foncteur sur Hot_0 que H_T.

Dans le cas géométrique $T = \underline{\mathrm{Ty}}$, et C de la forme $\underline{\mathrm{Ch}}_\Sigma(X; a, b)$, donnant lieu à $C_\infty(a,b)$, on *n'a pas* de définition naturelle d'un bifoncteur de composition des chemins [page 115]

$$C_\infty(a,b) \times C_\infty(b,c) \longrightarrow C_\infty(a,c).$$

On peut définir, certes, des accouplements

$$\underline{\mathrm{Ch}}_{\Sigma,\tau}(a,b) \times \underline{\mathrm{Ch}}_{\Sigma,\tau'}(b,c) \longrightarrow \underline{\mathrm{Ch}}_{\Sigma,\tau\tau'}(a,c),$$

ou, avec les notations relatives à la donnée de

$$\underline{t} : \mathbf{N}^o \longrightarrow \underline{\mathrm{Ty}},$$
$$\underline{\mathrm{Ch}}_n(a,b) \times \underline{\mathrm{Ch}}_m(b,c) \longrightarrow \underline{\mathrm{Ch}}_{n+m}(a,c),$$

mais ces accouplements *ne sont pas* compatibles avec les morphismes de transition des trois p. 73
systèmes inductifs de catégories $(\underline{\mathrm{Ch}}_n)_{n\in\mathbf{N}}$, ils ne le sont *qu'à homotopie près.* Cela suffit cependant pour avoir des accouplements parfaits

$$H_T(a,b) \times H_T(b,c) \longrightarrow H_T(a,c),$$

avec associativité, et (si $\Sigma = \mathrm{Fl}(X)$ tout entier) existence de *vrais* inverses, i.e. de flèches (dans Ind Cat hot) de 'passage au chemin opposé'

[page 116]

$$(*) \qquad H_T(a,b) \longrightarrow H_T(b,a), \qquad c \longmapsto c^o,$$

donnant lieu au diagramme commutatif exprimant que c'est bien un inverse pour la composition. Une autre façon de le dire, c'est que pour tout objet Y de Cat hot (ou de Ind Cat hot), les ensembles

$$\mathrm{Hom}_{\mathrm{Cat\,hot}}(Y, H_T(a,b)) \overset{\text{déf}}{=} H_T^Y(a,b)$$

forment, pour $a, b \in X$ variables, les flèches d'un *groupoïde* ([25]) $\mathrm{Ch}_\Sigma^Y(X)$ ayant pour ensemble de sommets $\mathrm{Ob}\,X$, et $H_T^Y(a,b)$ étant formé des flèches de a vers b. L'application

$$H_T^Y(a,b) \longrightarrow H_T^Y(b,a), \qquad c \longmapsto c^o,$$

25. Si $\Sigma = \mathrm{Fl}(X)$. Si Σ est plus petit, au lieu d'un groupoïde, on trouve une *catégorie* sans plus.

déduite du foncteur $(*)$ plus haut n'est autre que l'application de passage à l'inverse. Cette catégorie n'est d'ailleurs autre que celle déduit de

$$X(Y)\Sigma_Y^{-1}, \qquad \text{où} \begin{cases} X(Y) = \underline{\mathrm{Hom}}_{\mathrm{Cat}}(Y, X) \\ \Sigma_Y \subseteq \mathrm{Fl}(X(Y)), \\ \text{défini en termes de } \Sigma \text{ 'argument par argument'}, \end{cases}$$

à l'aide du foncteur

$$X \longrightarrow X(Y), \qquad a \longmapsto a_Y,$$

associant à tout $a \in X$ le foncteur *constant* sur Y de valeur a, en prenant

$$H_T(a, b) \simeq \mathrm{Hom}_{X(Y)\Sigma_Y^{-1}}(a_Y, b_Y) \ . \qquad \text{[page 117]}$$

Commentary · Development (commentators') [ms. 115]

The stage of a concatenation

Grothendieck's ind-object accommodates concatenation because a sufficiently refined type can dominate any two given types and their concatenation. The notation $n + m$ is convenient for a multiplicative standard sequence, but does not follow from an arbitrary cofinal sequence alone. The following small calculation locates the missing convention.

A slow cofinal sequence. [ours] There is a cofinal decreasing sequence of types t_n for which no type map $t_{n+m} \to t_n t_m$ exists for some n, m.

Proof. Put $w = \Delta_+\Delta_-$ and

$$t_n = w^{k(n)}, \qquad k(n) = \lfloor \log_2(n + 1) \rfloor.$$

Use identity maps when $k(n + 1) = k(n)$ and collapse the final copies of w otherwise. This gives $t_{n+1} \to t_n$. It is cofinal: every finite signed word is obtained from a sufficiently long alternating word by deleting unwanted edges and expanding the selected edges into its maximal constant-sign runs. For $n = m = 3$, however, $t_6 = w^2$, whereas $t_3 t_3 = w^4$. A type map from a word to a reduced alternating target must use at least one source edge for every target edge, since the image of a single source edge is a constant-sign run. Four source edges cannot cover the eight edges of w^4. Thus there is no such map. □

The obstruction is visible on path categories themselves. Take $X = I_{w^4}$, with endpoints a, b, and let c be its middle vertex. The inclusions of its two four-edge halves give objects of $\underline{\mathrm{Ch}}_{t_3}(X; a, c)$ and $\underline{\mathrm{Ch}}_{t_3}(X; c, b)$. The category $\underline{\mathrm{Ch}}_{t_6}(X; a, b)$ is empty: every nonidentity arrow of this alternating interval joins adjacent vertices, so four transitions cannot cover the graph distance eight between its endpoints. Hence a pairing with target stage 6 cannot exist in this example, even with $\Sigma = \mathrm{Fl}(X)$.

For a general chain the correct target is a chosen $k = k(n, m)$ admitting $t_k \to t_n t_m$. Cofinality guarantees such a k, and passage to a larger stage or a different chosen map makes no difference in $\mathrm{Cat}_{\mathrm{hot}}$, by the homotopy theorem. Equivalently, one may choose the standard sequence $t_n = w^n$, where $t_n t_m = t_{n+m}$. We checked the type-map description in the preceding part of this chapter and the usual filtered-colimit formalism; we did not find this particular indexing correction recorded in the literature. Its purpose is to make the intended ind-construction exact, not to alter that construction.

Commentary · Exposition [ms. 116]

Parameters turn the ind-object back into localization

Grothendieck ends this part by explaining why the ind-object is geometrically useful: its values on parameter categories recover ordinary localization of diagram categories. The assertion has a direct proof, and it supplies associativity and inverses at the same time.

For an actual small category Y, write $X(Y) = \underline{\mathrm{Hom}}(Y, X)$ and let Σ_Y consist of natural transformations whose components belong to Σ. It contains identities and is closed under composition. A functor

$$Y \longrightarrow \underline{\mathrm{Ch}}_{\Sigma,\tau}(X; a, b)$$

is the same thing as a functor $Y \times I_\tau \to X$ whose endpoints are the constant functors a_Y, b_Y, with identity endpoint components on morphisms in Y, and whose backward arrows belong pointwise to Σ. By exchanging the two variables, it is exactly a Σ_Y-path of type τ in $X(Y)$ from a_Y to b_Y. This identification respects natural transformations and every type-reindexing functor. The two total categories over $\underline{\mathrm{Ty}}$ are therefore isomorphic.

Taking connected components and applying the localization theorem of §7 gives

$$\begin{aligned} H_T^Y(a,b) &:= \mathrm{Hom}_{\mathrm{Ind}(\mathrm{Cat\,hot})}(Y, H_T(a,b)) \\ &\cong \mathrm{Hom}_{X(Y)[\Sigma_Y^{-1}]}(a_Y, b_Y). \end{aligned}$$

This corrects two notational slips in the printed formulas: the ambient category on manuscript page 116 is Ind(Cat hot), and the left side on page 117 needs the superscript Y. No finiteness of Y is required for this formula. The uniform type of a Y-family is retained by the ind-object; replacing it by C_∞ is the separate step for which finite presentation was needed.

Concatenation on either side is the same operation on functors $Y \times I_\tau \to X$, so this bijection respects composition and units. It follows that the sets $H_T^Y(a,b)$ are the hom-sets of the full subcategory of $X(Y)[\Sigma_Y^{-1}]$ on the constant diagrams. They form a groupoid when Σ is all arrows: the reversed path represents the inverse, and the backtracking contractions of §7 are natural in Y. Yoneda in the ind-category turns these pointwise identities into the associativity, unit, and inverse identities of the ind-valued path system. Finite products of ind-objects are represented by the corresponding product diagrams, so the pairings have exactly the domain stated in the manuscript.

If Y itself is an ind-object, the abstract hom-set on the first line still makes sense. For a presentation $Y = (Y_i)$ it is $\lim_i H_T^{Y_i}(a,b)$. The expression $\underline{\mathrm{Hom}}(Y,X)$ on the second line is only the stated functor category when Y is an actual small category; it should not be silently applied to a formal ind-object. The natural extension is the displayed inverse limit on source indices.

Commentary · Exposition [ms. 117]

What the ind-object represents

The ind-object retains a uniform bound on the complexity of a family of paths. This is why it can encode localization before a single category has acquired a satisfactory geometric interpretation. With $[Y,D]_{\mathrm{cat}} = \pi_0 \underline{\mathrm{Hom}}(Y,D)$, the formula is

$$H_T^Y(a,b) = \operatorname*{colim}_n [Y, C_n(a,b)]_{\mathrm{cat}} \cong \mathrm{Hom}_{X(Y)[\Sigma_Y^{-1}]}(a_Y, b_Y).$$

Here Σ_Y consists of natural transformations whose components belong to Σ, and the right side uses the constant diagrams. A morphism on the right is represented by a finite zigzag of natural transformations. Its finite length is a bound shared by every object of Y; it therefore gives a map into one stage on the left. Refinement and the elementary relations of localization give the identifications in the colimit. This is the mechanism already discussed in the commentary on Chapter V, manuscript pages 30–33, concerning the parameter category and ind-representation. The formula printed on page 117 omits the superscript Y from H_T^Y; without it an ind-object is being equated to a set.

For finite Y, the natural map

$$\operatorname*{colim}_n [Y, C_n]_{\mathrm{cat}} \longrightarrow [Y, \operatorname*{colim}_n C_n]_{\mathrm{cat}}$$

is bijective. Indeed a functor uses finitely many objects, arrows, and relations, all of which lift to one stage. A finite zigzag of natural transformations uses finitely many more data, so equality also occurs at one stage. Finite presentation, rather than any topological fibrancy, is doing the work. For infinite Y, a functor to the colimit can have an unbounded range of stages, and this argument stops.

Composition of localized zigzags is associative because juxtaposition of finite strings is associative. When all arrows of X are inverted, reversal supplies the inverse string. Hence the family of sets $H_T^Y(a,b)$ is a groupoid with object set $\mathrm{Ob}(X)$. For a general Σ it is only a category. Passing from this set-valued representation to mapping *spaces* is an additional step: the notation does not identify the ordinary nerve of every functor category with a derived mapping object.

Dans le même cas géométrique, je me suis convaincu d'ailleurs que C_∞ était, en tant

qu'objet de Hot (pas seulement de $\mathrm{Hot}_0^{\wedge}$) *unique à* Hot-*isomorphisme près,* mais (chose étrange) peut-être pas à Hot-isomorphisme *unique* près. De façon générale, revenant aux

Commentary · Later developments [ms. 117]

From path components to mapping spaces

The last formula brings the discussion back to its original purpose: families of paths should describe morphisms after localization, and should continue to do so when an indexing category is introduced. At the level of sets of components, the preceding arguments give a complete description. To retain higher homotopies, a modern treatment keeps the diagram of zigzag categories together with the coherences in its changes of shape.

One precise formulation is the hammock formula. For a relative infinity-category $(\mathcal{C}, \mathcal{W})$, let $\mathrm{Zig}_Z(\mathcal{C}, \mathcal{W})_{x,y}$ denote the infinity-category of zigzags of shape Z with fixed endpoints and pointwise weak-equivalence transformations. Write $|-|$ for groupoid completion, which for an ordinary category is represented by the realization of its nerve. Then, with colimit taken in spaces,

$$\mathrm{Map}_{\mathcal{C}[\mathcal{W}^{-1}]}(x, y) \simeq \operatorname*{colim}_{Z \in \mathrm{Zig}_\partial^{\mathrm{op}}} \left|\mathrm{Zig}_Z(\mathcal{C}, \mathcal{W})_{x,y}\right|.$$

Here Zig_∂ has endpoint-preserving changes of shape. Arakawa and Cnossen prove this formulation in their 2026 preprint, Definition 1.7, Theorem 1.9 and Corollary 1.11; Remark 1.10 identifies composition with concatenation (Arakawa and Cnossen, 2026). Their §4 compares the construction with Dwyer–Kan's original hammock localization.

The notation must not obscure a difference in definitions. Grothendieck's $\underline{\mathrm{Ch}}_{\Sigma,\tau}$ on these pages is a *full* subcategory of the functor category: membership constrains the backward arrows of an object, while morphisms are arbitrary natural transformations with the specified endpoint condition. The hammock construction just quoted also constrains the vertical components of those transformations. A comparison of the two models for general Σ is an additional theorem, not a consequence of recognizing the same words of signs. When all arrows are marked this difference disappears, and the later comparison within Chapter VII is directly relevant. This qualification is particularly useful when passing from X to $X(Y)$: it prevents an equality of localized morphism *sets* from silently being promoted to an identification of mapping *spaces*.

Commentary · Development (commentators') [ms. 117]

Independence of the sequential homotopy type

Grothendieck's final distinction between an isomorphism and a uniquely determined isomorphism can be made precise without solving the comparison with the total category C. The two questions separate: a bad base can obstruct $C_\infty \to C$ while all the sequential models still have the same weak homotopy type. The following argument gives the latter conclusion under the abstract hypotheses of §10. Its ingredients are standard telescope arguments; we include their application here because we did not locate this exact reachability-preorder statement in the sources checked. For the usual sequential homotopy-colimit construction see Dugger (n.d., §14.9, Proposition 14.10 and Corollary 14.11).

Proposition (independence of choices). [ours] Let T be a nonempty small category and let $F : T^{\mathrm{op}} \to \mathrm{Cat}$ be a strict functor. Suppose that $F(u)$ and $F(v)$ are joined by a finite zigzag of natural transformations whenever u, v are parallel arrows of T. Let

$$t_0 \longleftarrow t_1 \longleftarrow \cdots, \qquad s_0 \longleftarrow s_1 \longleftarrow \cdots$$

be two chains whose objects are cofinal to the left in the reachability preorder of T. Then

$$\varinjlim_n F(t_n) \quad \text{and} \quad \varinjlim_m F(s_m)$$

have isomorphic images in Hot. The assertion includes arbitrary choices of the arrows in either chain. It does not assert a preferred isomorphism.

Proof. We first record precisely which properties of sequential homotopy types will be used. For a sequence of small categories A_n, the nerve commutes with its filtered colimit. Indeed, a simplex is

a finite string of objects and arrows subject to finitely many incidence equations; these data, and equalities between two presentations of them, occur at some common stage. Hence

$$N\big(\varinjlim_n A_n\big) = \varinjlim_n NA_n.$$

For a sequence of simplicial sets K_n, the canonical map

$$\mathrm{Tel}(|K_n|) \longrightarrow \Big|\varinjlim_n K_n\Big|$$

is a weak equivalence. Here the telescope glues the upper end of $|K_n| \times [0,1]$ to the next space by its transition map. To check this assertion on homotopy groups, replace simplicial sets by $\mathrm{Ex}^\infty K_n$. This replacement commutes with filtered colimits: $\mathrm{Sd}\,\Delta^r$ is finite for each r, so Ex commutes with them, and the sequential iteration does also. A filtered colimit of Kan complexes is Kan, because every horn is finite. Maps and homotopies defining a homotopy group use finite simplicial data, so homotopy groups, with a basepoint represented at some stage, commute with this filtered colimit. On the telescope side a map or a homotopy from a compact sphere or cylinder has bounded height. Each bounded initial telescope retracts to its final space. Its homotopy groups therefore give the same direct limits. The canonical map induces these identifications, including the statement about components, and is a weak equivalence.

We also need invariance when each transition map is replaced by a homotopic map. Suppose $f_n, g_n : A_n \to A_{n+1}$ are continuous maps with homotopies H_n from g_n to f_n. A map from $\mathrm{Tel}(f)$ to $\mathrm{Tel}(g)$ is the identity on every level A_n. On the cylinder for f_n, it first traverses the cylinder for g_n, then follows H_n in level A_{n+1}. More explicitly it sends (x, r), for $0 \le r \le \frac{1}{2}$, to $(x, 2r)$ in the g_n cylinder, and for $\frac{1}{2} \le r \le 1$ to $H_n(x, 2r-1)$ in level A_{n+1}. The endpoint at $r = 1$ is $f_n(x)$, so these maps glue. Reversing the homotopies gives a map back. Their composites are homotopic to the identities, fixing the levels, by cancelling a path immediately followed by its reverse and reparametrizing the cylinders. These cancellations are defined separately on each cylinder and agree at its ends; they consequently glue on the entire telescope. No compatibility between different H_n is required. Finally, passing to a cofinal subsequence preserves the weak homotopy type of a telescope, by the same bounded-height calculation of homotopy groups.

We now compare the chains. Choose indices, increasing without bound, and arrows in T to obtain an interleaving

$$t_{n_0} \longleftarrow s_{m_0} \longleftarrow t_{n_1} \longleftarrow s_{m_1} \longleftarrow \cdots .$$

At each step this is possible by cofinality of the opposite chain; after finding an index, moving farther down that chain allows the indices to increase. Apply F and take nerves and realizations. The even subsequence has objects $|NF(t_{n_i})|$. Its bonding map is obtained from the composite of two of the newly chosen arrows. That composite and the original transition $t_{n_{i+1}} \to t_{n_i}$ are parallel arrows of T. By hypothesis their pullbacks are connected by natural transformations; taking nerves turns these into a homotopy of continuous maps. The preceding telescope construction therefore identifies the homotopy type of this even subsequence with that of the original t-sequence. The odd subsequence has the corresponding property for the s-sequence. Both are cofinal subsequences of the same interleaved telescope. Combining these comparisons with the telescope-to-colimit weak equivalences proves the proposition. □

Overview · VII-b

Paths, localization, and the information in an indexing category

These pages occupy the middle of Chapter VII. They begin with the end of the combinatorial analysis of path types, establish the ordinary category of fractions by means of path categories, and then examine whether a category containing all shapes of paths has the same homotopy type as a sequentially enlarged model. Their central concern is a compatibility problem. Concatenation is completely satisfactory before taking limits: it is functorial, associative and unital. The sequential models make other calculations accessible, but their transition maps need not respect that composition strictly. Grothendieck is trying to preserve both advantages in one construction.

The category $\underline{\mathrm{Ty}}$ consists of finite oriented intervals, equipped with their spatial order and their two endpoints. Its arrows preserve that order, the categorical direction of each traversed edge, and the endpoints. Concatenation makes it a strict monoidal category. The opening calculation describes its nerve degree by degree as a free monoid: a composable string of type maps splits uniquely over the edges of its initial interval. The data attached to one initial edge are successive finite weightings recording how many edges replace it at each stage. The commentary on the first part of the chapter explains this calculation through manuscript page 57. The commentary here adds the distinction needed for its later use: a face can send an indecomposable generator to a product. Degreewise freeness is therefore not freeness on a simplicial set.

For an ordinary category X, a path of type τ is a functor $I_\tau \to X$. Between paths of the same type one keeps natural transformations, and between different types one also keeps pullback along interval maps. These categories assemble into a category fibred over $\underline{\mathrm{Ty}}$. Fixing endpoints a, b means taking the strict fibre of the endpoint functor: the components of a natural transformation at both ends must be identities. This requirement is responsible for several of the correct diagrams in the text. Dropping it would change the hom-sets obtained after passing to components.

If Σ is a wide subcategory of X, we allow backward edges only when they lie in Σ, and write $\underline{\mathrm{Ch}}_\Sigma(X; a, b)$ for the resulting total fixed-endpoint path category. Closure of Σ under identities and composition is exactly what makes this construction stable under every type map. A source edge can collapse, or cover a consecutive block of target edges; the two possibilities require precisely these two closure conditions. No calculus-of-fractions hypothesis is needed at this stage. The fibres are full subcategories of functor categories, so their internal vertical transformations remain unrestricted.

The first decisive result is

$$\mathrm{Hom}_{X[\Sigma^{-1}]}(a, b) \cong \pi_0 \underline{\mathrm{Ch}}_\Sigma(X; a, b).$$

Concatenation induces the composition on the right. A one-edge path followed by its reversal is connected to a constant path through a ladder with identity endpoint components, and the constant path is connected to the empty path by a type collapse. Thus every arrow of Σ becomes invertible. For a functor $F : X \to Y$ which inverts Σ, evaluation of a zigzag in Y is unchanged under either a ladder or a type change. In a ladder, the equations for its successive squares telescope to

$$\eta_n E_F(c) = E_F(c')\eta_0;$$

the endpoint identities give equality of effects. The argument uses inverses of the backward horizontal edges but never inverses of the internal vertical components. It supplies the omitted well-definedness check for the map β on manuscript page 68. The resulting evaluation has the required unique factorization property. This is the classical localization problem of Gabriel and Zisman (1967, Chapter I, §1), with the witnesses for its relations retained as categorical data.

Two examples make the theorem tangible. Inverting one arm of a span creates the fraction across the span and produces a category with a walking-arrow skeleton. Inverting both arrows of the category $a \rightrightarrows b$ produces a connected groupoid with automorphism group $\mathbf{Z}$; the nerve of the original category is a circle. The complete calculations distinguish cancellation of backtracking from the survival of a genuine loop. They also show why a relative localization need not be a groupoid.

The next task is to establish that concatenation really acts on all morphisms of the total path categories. A ladder can be glued to a second ladder because their common endpoint components are identities. A change of type can be glued to a second change of type because the common endpoint has a specified image. Writing a total morphism as a type map together with a vertical transformation makes the functoriality and strict associativity transparent. The commentary gives this calculation explicitly. It also repairs an edition diagram which glues over the two-element set $\{0, 1\}$ where the construction requires a single identified endpoint.

Sections 8 and 9 then explain why the particular interval map inducing a pullback ceases to matter after categorical homotopy. The relevant homotopy relation joins functors by finite zigzags of natural transformations. Grothendieck proves that every nonempty category of endpoint-preserving interval maps is connected, and asks whether it is contractible. We give a complete categorical contraction. After a forced initial collapse when the first signs disagree, the first target run can be filled by the first source edge. Clamping the remaining vertex images to the end of that run defines an idempotent functor and a natural transformation in the direction determined by the run's sign. The retract is a smaller interval-mapping category. Induction contracts it to a point. This is marked as a development of the present commentary, without a claim of priority.

Precomposition transports these natural transformations to the path categories. Because the endpoint components remain identities, the homotopy takes place over $X \times X$ and restricts to every fixed-endpoint fibre. In modern notation, the diagram of fibres becomes constant on parallel arrows after passage to Cat hot, the category whose morphisms are categorical-homotopy classes of functors. This is the bridge to the abstract discussion of a fibration $C \to T$ in §10.

Here three objects must be distinguished. There is the total category C, the ind-object determined by its fibres in Cat hot, and an ordinary sequential colimit C_∞ formed after choosing a chain cofinal in the reachability preorder T_{o}. The source assumes that this preorder is cofiltered. It does not assume that parallel arrows of T can be equalized. Forgetting that difference would conceal the principal obstruction: for the constant point-valued diagram over a one-object group BG, the ind-object and every sequential model are points, while the total category is BG.

There is a further failure on manuscript page 103. The reachability preorder of a slice T/t_0 need not be the lower ideal of t_0 in T_{o}. The category with two parallel arrows already disproves that assertion. The lower ideal may still be used by restricting to the full subcategory of objects which admit an arrow to t_0, but this is only cofinality on reachability preorders. Comparison of total categories requires the actual comma categories. The commentary formulates and proves the corresponding sufficient-and-necessary condition for base change to preserve the homotopy type of every Grothendieck fibration, using Quillen's Theorem A (Quillen, 1973, §1). The source's separate properness and smoothness criteria are also proved under its hypothesis on parallel pullbacks. Contractibility of the strict fibres of $T \to T_{\mathrm{o}}$, together with local constancy of the coefficients there, allows homotopy Kan extension to descend the diagram to the preorder. This argument explains why those sufficient criteria can hold without the universal comma condition (Maltsiniotis, 2005; Cisinski, 2009).

The sequential colimit itself is less problematic. The nerve preserves filtered colimits, and for a sequence its homotopy colimit maps by a weak equivalence to its ordinary colimit. We prove that two cofinal chains give isomorphic objects of Hot under the source's homotopy

hypothesis: interleave cofinal subsequences, compare their bonding maps by homotopies, and compare the resulting telescopes. This answers the existence part of the independence question. The proof neither chooses a preferred isomorphism nor promotes it to a categorical homotopy equivalence in Cat hot.

Finite probes explain part of the remaining caution. A finite category is finitely presented for ordinary categorical filtered colimits, which gives the asserted formula for Cat hot-morphisms into C_∞. Its nerve need not have the homotopy type of a finite CW complex. The one-object category of the group of order two is a concrete counterexample to unrestricted compactness after passage to Hot: its mod-two cohomology persists in every degree, whereas each finite-dimensional skeleton of its nerve has bounded cohomological dimension. Replacing Cat hot by Hot therefore needs a separate argument. The mapping-set formulas at the end of manuscript page 117 are audited with their parameter Y and their ambient ind-category restored in the commentary.

The proposed obstruction from strict loop multiplication on manuscript page 113 is already withdrawn in footnote 24. Kan's loop-group theorem supplies strict simplicial group models (Kan, 1958, Theorem 7.1). For unrestricted paths, the specific comparison is taken up positively later in this same chapter, §13; it is not a current open problem. The constant-path lemma left unwritten at manuscript page 170 is supplied here by successively retracting the end vertices of an oriented interval. Modern hammock localization gives a separate, precise mapping-space theory. Its requirement that vertical arrows also be weak equivalences must be checked when comparing it with Grothendieck's full path fibres (Dwyer and Kan, 1980a; Arakawa and Cnossen, 2026).

conditions du début du paragraphe, C_∞ doit s'écrire $C_\infty(\underline{t})$, elle dépend du choix du foncteur cofinal p. 74

$$\underline{t} : \mathbf{N}^o \longrightarrow T.$$

Quand $\underline{t}$ varie dans la catégorie

$$\underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T),$$

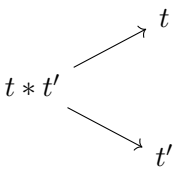
les $C_\infty(\underline{t})$ varient de façon contravariante en $\underline{t}$ (donc définissent une catégorie fibrée sur $\underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T)$). De plus, le foncteur

$$C_\infty(\underline{t'}) \longrightarrow C_\infty(\underline{t})$$

associé à un morphisme de systèmes projectifs

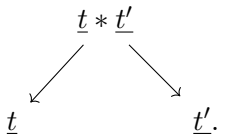
$$\underline{t} \longrightarrow \underline{t'}$$

est un *isomorphisme* dans Hot. Donc le foncteur [page 118]



$$\underline{t} \longmapsto C_\infty(\underline{t}), \qquad \underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T) \longrightarrow (\mathrm{Hot})$$

se factorise par le groupoïde fondamental

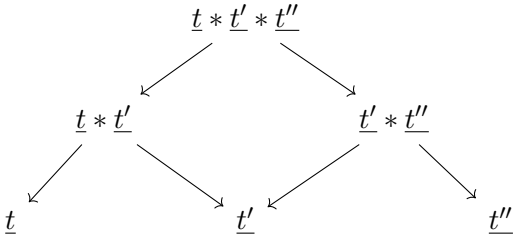


$$\Pi(\underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T)) \longrightarrow (\mathrm{Hot}).$$

Quand ce groupoïde, i.e. quand la catégorie $\underline{\mathrm{Hom\,cof}}$ elle-même est connexe, on peut donc conclure que tous les $C_\infty(\underline{t})$ sont isomorphes entre eux dans Hot. Pour conclure même à un système *transitif* d'isomorphismes entre les $C_\infty(\underline{t})$, i.e. que $C_\infty(\underline{t})$ est 'unique à isomorphisme *unique* près', il faudrait savoir de plus que le groupoïde fondamental est équivalent à la catégorie ponctuelle (groupe fondamental trivial), ou, comme on dit, que $\underline{\mathrm{Hom\,cof}}$ soit *simplement connexe,* ou 1-connexe.

La connexité de $\underline{\mathrm{Hom\,cof}}$ est assurée quand la catégorie T a (comme c'est le cas pour $\underline{\mathrm{Ty}}$) une loi de composition $(t, t') \longmapsto t * t'$, avec des morphismes fonctoriels en t, t'

(cette dernière condition étant automatique si la loi de composition admet l'objet final de T, supposé existant, comme unité bilatère). Dans ce cas, $\underline{t} = (t_n)_n$ et $\underline{t'} = (t'_n)_n$ sont reliés entre p. 75
eux par $\underline{t} * \underline{t'} = (t_n * t'_n)_n$, puisqu'on a un morphisme de systèmes projectifs [page 119]



Je ne sais d'ailleurs pas si la flèche dans Hot

$$C_\infty(\underline{t}) \longrightarrow C_\infty(\underline{t'})$$

associée à $\underline{t'} \longrightarrow \underline{t}$ dans $\underline{\mathrm{Hom\,cof}}$ ne dépend que de $\underline{t}$, $\underline{t'}$, et pas du choix de $\underline{t'} \longrightarrow \underline{t}$. Ce qui est clair, c'est que son image dans $\mathrm{Hot}_0^\wedge$ est unique, c'est l'identité quand on identifie $C_\infty(\underline{t})$ et $C_\infty(\underline{t'})$ au seul et même élément de $\mathrm{Hot}_0^\wedge$ défini par $\varinjlim H_T$. [page 120]

Et pourtant, je m'aperçois à l'instant que, sous l'hypothèse de l'existence de la loi de composition et de son unité bilatère, et admettant de plus que la loi en question est associative à isomorphisme près, *on a transitivité* dans les isomorphismes (canoniques!) entre les $C_\infty(\underline{t})$ qu'on vient d'indiquer !

(Sans avoir pour autant à calculer le groupe fondamental de $\underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T)$!) Si on a trois éléments $\underline{t}$, $\underline{t'}$, $\underline{t''}$ de $\underline{\mathrm{Hom\,cof}}$, il suffit de regarder le diagramme déduit du diagramme commutatif suivant

en lui appliquant le contrafoncteur $\underline{s} \longrightarrow C_\infty(\underline{s})$ de $\underline{\mathrm{Hom\,cof}}$ dans Hot.

Donc dans le cas des $C(a,b) = \underline{\mathrm{Ch}_\Sigma}(X; a, b)$, je n'ai plus aucun scrupule à considérer la catégorie $C_\infty(a,b)$ comme un objet *canonique* de Hot, relié à l'ind-objet canonique $H_T(a,b)$ dans Hot par un homomorphisme canonique

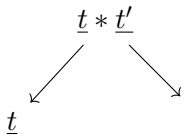
$$(*) \qquad C_\infty(a,b) \longleftarrow H_T(a,b),$$

qui dans $\mathrm{Hot}_0^\wedge$ donne un isomorphisme

$$(**) \qquad C_\infty(a,b) \simeq \varinjlim H_T(a,b),$$

i.e. la flèche $(*)$ induit, pour $\xi \in \mathrm{Ob\,Hot}$, une application ensembliste

$$\mathrm{Hom}_{\mathrm{Hot}}(\xi, C_\infty(a,b)) \longleftarrow \underbrace{\mathrm{Hom}_{\mathrm{Ind\,Hot}}(\xi, H_T(a,b))}_{\varinjlim_n \mathrm{Hom}_{\mathrm{Hot}}(\xi, C_n(a,b))},$$



qui est *bijective* si ξ est dans Hot.

Bien entendu, les flèches

p. 76
[page 121]

$$(*) \qquad C_\infty(\underline{t'}) \longrightarrow C_\infty(\underline{t})$$

dans Hot, associés aux flèches $\underline{t} \longrightarrow \underline{t'}$ dans $\underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T)$, sont en fait des flèches dans (Cat) elle-même - et même des foncteurs pleinement fidèles, dans le cas 'géométrique' et pour les deux flèches canoniques

Elles sont isomorphiques *dans* Hot, parce qu'elles définissent un homomorphisme sur les ind-objets associés de Cat hot, donc aussi pour les ind-objets associés dans Hot et dans $\mathrm{Hot}_0^\wedge$, d'où résulte que

$$\mathrm{Hom}_{\mathrm{Hot}}(Y, C_\infty(\underline{t'})) \longrightarrow \mathrm{Hom}_{\mathrm{Hot}}(Y, C_\infty(\underline{t}))$$

associé à $(*)$ est une bijection si Y *est finie* ([26]), cette flèche s'identifie alors à

$$\varinjlim_n \mathrm{Hom}_{\mathrm{Hot}}(Y, C_{t'_n}) \longrightarrow \varinjlim_n \mathrm{Hom}_{\mathrm{Hot}}(Y, C_{t_n}).$$

26. Ce qui suffit à assurer que $(*)$ est [un] isomorphisme dans Hot : Hot $\longrightarrow \mathrm{Hot}_0^\wedge$ est conservatif!

(Car $Z \longmapsto \mathrm{Hom}_{\mathrm{Hot}}(Y, Z)$ commute aux limites inductives filtrantes, si Y est une catégorie *finie.* Cela provient du fait qu'une $\varinjlim$ filtrante de catégories de Thomason-Kan est itou …) Mais j'ignore par contre si $(*)$ est $\overrightarrow{\texttt{[un]}}$ isomorphisme dans Cat hot. Seulement que pour une catégorie *finie* Y, elle induit

$$\mathrm{Hom}_{\mathrm{Cat\,hot}}(Y, C_\infty(\underline{t}')) \xrightarrow{\sim} \mathrm{Hom}_{\mathrm{Cat\,hot}}(Y, C_\infty(\underline{t})),$$

les deux membres s'identifiant alors à [page 122]

$$H_T(Y)_{\mathrm{Cat\,hot}} = \mathrm{Hom}_{\mathrm{Ind\,Cat\,hot}}(Y, H_T).$$

Pour résumer ces lumières et perplexités sur les $C_\infty(\underline{t})$:

Commentary · Development (commentators') [ms. 120]

Contracting the category of choices

Grothendieck seeks a coherent comparison between different cofinal sequences, so that changing a path parameter does not change the resulting operation in Hot. His three-sequence diagram supplies this comparison, but the natural projections already imply a stronger statement about the space of choices.

Contraction of the refinement category. [ours] Let T be a category with a bifunctor $*$ and natural maps $t * t' \to t$ and $t * t' \to t'$. Let $\mathcal{H}$ be the nonempty category of sequences $\mathbf{N}^o \to T$ cofinal in the preorder of objects. Then $N\mathcal{H}$ is contractible. Consequently every functor $\mathcal{H}^o \to \mathcal{A}$ taking all arrows to isomorphisms has a unique system of comparison isomorphisms induced by arrows and their inverses; these comparisons depend only on their two endpoints and compose transitively.

Proof. Fix $s \in \mathcal{H}$. Define $Q(t) = t * s$ pointwise, on both objects and morphisms of sequences. For every $a \in T$ there is an index n and a map $t_n \to a$. Composing $t_n * s_n \to t_n \to a$ shows that $Q(t)$ is still cofinal. The two natural projections give natural transformations

$$\mathrm{id}_{\mathcal{H}} \longleftarrow Q \longrightarrow \mathrm{const}_s.$$

The nerve of a natural transformation gives a homotopy of the associated maps on realizations: explicitly, a chain of arrows and a cut in that chain use the first functor before the cut, the transformation at the cut, and the second functor afterwards. Thus the identity of $B\mathcal{H}$ is homotopic to the constant map at s, proving contractibility.

A functor taking all arrows to isomorphisms factors through the localization of $\mathcal{H}$ at all its arrows, its fundamental groupoid. Contractibility makes this groupoid equivalent to a point: between any two of its objects there is exactly one morphism. Applying the functor to that morphism proves the uniqueness and transitivity assertions, including independence from the particular arrow of sequences used. The opposite variance changes the direction of the comparisons but not the argument. □

Associativity of $*$ and a terminal unit are unnecessary for this proof once the two natural projections are given. In the interval application, concatenation has these projections by collapsing the other interval, and a cofinal sequence exists. The proposition isolates the formal part of the argument. It does *not* prove that the actual functors $C_\infty(t') \to C_\infty(t)$ are weak equivalences; that premise requires the geometric comparison or a valid relative argument. In particular the conservativity assertion in footnote 26 cannot supply it in the stated generality. We checked the general nerve and cofinality mechanisms in Quillen's §1 and the smooth-functor formulation of Maltsiniotis (2005, Theorem 1.2); we did not locate this explicit application to Grothendieck's category of sequences in those sources. The result is an elementary continuation of his construction, without a claim of priority.

Commentary · Exposition [ms. 121]

Two different finiteness arguments

The comparison on this page must keep finite categorical data separate from a finite homotopy type. The preceding block on ind-representation proves a filtered-colimit formula in Cat hot whenever the source category is finitely presented. In Hot, the corresponding safe hypothesis is that the classifying space of the source has the homotopy type of a finite CW complex, or more generally

is compact for the filtered homotopy colimits in question. A finite poset has a finite nerve and meets this hypothesis. But Grothendieck explicitly defines a finite category by finiteness of both its objects and its arrows in Chapter V, manuscript page 45, and uses these categories to define Hot_0 on pages 51–52 (Grothendieck, 1990a). With that convention, the assertion is false.

For a concrete distinction, let Y be the one-object category of the group $\mathbf{Z}/2$. It is finite, but $BY \simeq \mathbf{RP}^\infty$. Consider the increasing skeleta $\mathbf{RP}^n$. The identity of $\mathbf{RP}^\infty$ cannot factor, up to homotopy, through one skeleton: such a factorization would make the identity on $H^k(\mathbf{RP}^\infty; \mathbf{F}_2)$ factor through zero for every $k > n$, whereas these cohomology groups are nonzero. Thus

$$\operatorname*{colim}_n [BY, \mathbf{RP}^n] \longrightarrow [BY, \mathbf{RP}^\infty]$$

is not surjective. The same example can be expressed entirely in categories by using compatible face-poset models for the finite skeleta, or the categories of simplices of their simplicial models. It is the size of the nerve in all dimensions, not merely the number of arrows, that matters here.

For a finite simplicial source K, the valid filtered-colimit argument is direct. Replace the targets by a functorial Kan replacement built using finite horn data. Such a replacement commutes with filtered colimits. Maps from K and simplicial homotopies between them involve finitely many simplices, so they appear at one stage. Finite CW sources follow by a finite simplicial model up to homotopy. The statement about filtered colimits of Thomason-fibrant categories is also valid, since the relevant horn domains are finite after applying the fixed subdivisions. It does not establish compactness for $B(\mathbf{Z}/2)$.

Accordingly, the literal last sentence of page 120 omits even the intended subscript zero; restoring that subscript would still leave the compactness error. A valid replacement restricts to homotopy-finite tests and thereby changes the stated test category. This repair does not alter the elementary finite-presentation calculation in Cat hot.

Commentary · Present state [ms. 121]

The unpointed detection claim

Grothendieck uses finite tests here to recognize a weak equivalence. In the unpointed homotopy category, the assertion that $\mathrm{Hot} \to \widehat{\mathrm{Hot}_0}$ is conservative is false. The editors already flag the claim in Chapter V, manuscript page 52, and the commentary there gives the symmetric-group shift example; we do not repeat it. The general theorem is stronger: no set of spaces jointly detects all isomorphisms in the unpointed homotopy category (Arlin and Christensen, 2023, Theorem 2.1). Their Theorem 4.3 shows why retaining one more level of data helps: spheres do detect equivalences in the homotopy 2-category, whose morphism categories retain homotopy classes of homotopies.

This defect in the inference does not disprove the particular path comparisons. They can be proved with based or relative information, or, in the all-arrows situation of section 13, by comparing the explicit total path categories over $X \times X$. An audit must separate that geometric theorem from the invalid general detection principle used on this page. For based spaces, all basepoints and their homotopy groups give the usual Whitehead test. For free homotopy classes, the fundamental-group information lost to conjugacy must first be restored.

Commentary · Development (commentators') [ms. 121]

A comparison that fails under the general hypotheses

The preceding distinction can be tested inside the exact fibred setting of section 10, rather than only in the abstract homotopy category. Grothendieck assumes there that parallel reindexing functors are homotopic, that the preorder of the base is cofiltered and has a countable coinitial subset, and that a strict cleavage has been chosen. These assumptions produce the same ind-object, but they do not force every map between the resulting colimits to be a weak equivalence.

A fibred symmetric-group example. [ours] There is a strict fibred category $C \to T$ satisfying these assumptions, with T also admitting an associative product with terminal unit and natural projections, for which a morphism of cofinal sequences induces an isomorphism in Ind Cat hot and a noninvertible map in Hot.

Proof. Let FI be the skeleton of finite sets and injections, with objects $[n] = \{0, \dots, n-1\}$, and set $T = \mathrm{FI}^o$. Write $\mathbf{B}G$ for the one-object category of a group G. Define a strict functor

$$F : T^o = \mathrm{FI} \longrightarrow \mathrm{Cat}, \qquad F([n]) = \mathbf{B}\mathfrak{S}_n.$$

For an injection $j : [n] \hookrightarrow [m]$, send a permutation σ to the permutation $j\sigma j^{-1}$ on $j([n])$, extended by the identity on its complement. Extension along a composite of injections agrees exactly with successive extension, so F is a functor. Its Grothendieck construction is strictly fibred over T.

If $j, k : [n] \hookrightarrow [m]$ are parallel injections, choose $h \in \mathfrak{S}_m$ with $hj = k$, by extending the resulting bijection of their images to the complements. Then $F(k)(\sigma) = hF(j)(\sigma)h^{-1}$ for every σ. Conjugation by h is a natural isomorphism between the associated one-object functors. Thus the homotopy hypothesis is satisfied. The preorder T_o is $\mathbf{N}^o$. Disjoint union provides the required associative operation and the empty set is its terminal unit in T; the two inclusions in FI become its natural projections.

Take $t'_n = [n]$ and $t_n = [n+1]$, with the opposite of the usual initial-segment inclusions as transitions. Both sequences are cofinal. The injections $\delta_n : [n] \hookrightarrow [n+1]$, $i \mapsto i+1$, commute with those inclusions and therefore define a morphism $t \to t'$ in $\mathcal{H}$. The two filtered colimits of the fibres identify with $\mathbf{B}G$, where G is the group of finite-support permutations of $\mathbf{N}$. The induced functor is the homomorphism

$$s : G \longrightarrow G, \qquad (s\sigma)(0) = 0, \quad (s\sigma)(i+1) = \sigma(i) + 1.$$

It is not surjective, since the transposition (0 1) is absent from its image. Consequently Bs does not induce an isomorphism on fundamental groups and is not a weak equivalence.

At each finite stage, however, δ_n and the standard inclusion are parallel injections, so their induced functors are naturally isomorphic. In $\mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}$ the comparison is therefore the ordinary cofinal-shift isomorphism. This proves all assertions. □

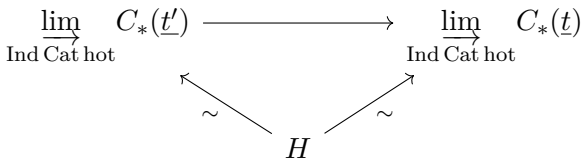
The earlier Chapter V counterexample supplies the shift mechanism; the additional content here is its realization by a strict fibred category satisfying the hypotheses actually used on pages 117–123. We checked those hypotheses against the editors' complete Chapter VII, manuscript pages 99–101, and the detection theorem of Arlin and Christensen (2023); we did not find this indexed realization in those sources. No priority is claimed. The example does not satisfy the stronger full-faithfulness features of the geometric padding maps. It leaves the later all-arrows path theorem intact, while disproving the general inference that an ind-isomorphism of homotopy classes must remain an isomorphism after these ordinary colimits are formed.

a) À tout $\underline{t} = (t_n)_{n \in \mathbf{N}^o} \in \underline{\mathrm{Hom\,cof}}(\mathbf{N}^o, T)$ est associé un système inductif, indexé par $\mathbf{N}$, de catégories $C_n(\underline{t})$ $(= C_{t_n})$, et leur limite inductive

$$C_\infty(\underline{t}).$$

b) Ce système inductif, et aussi sa limite est [un] foncteur contravariant en $\underline{t}$. Si $\underline{t}, \underline{t'} \in \mathrm{Ob}\,\underline{\mathrm{Hom\,cof}}$, alors on peut comparer $C_\infty(\underline{t})$, $C_\infty(\underline{t'})$ et les systèmes inductifs correspondants, grâce à p. 77

$$\begin{array}{ccc} & \underline{t} * \underline{t'} & \\ \swarrow & & \searrow \\ \underline{t} & & \underline{t'}. \end{array}$$



c) L'objet

$$(C_n(\underline{t}))_{n \in \mathbf{N}} \in \mathrm{Ob}\,\mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}$$

défini par le système inductif $(C_n(\underline{t}))_{n \in \mathbf{N}}$ de Cat est (à isomorphisme unique près) indépendant du choix de $\underline{t}$, soit H_C ou H. Les homomorphismes

$$(*) \qquad C_\infty(\underline{t'}) \xrightarrow{u^*} C_\infty(\underline{t}) \qquad \text{associé à } u : \underline{t} \longrightarrow \underline{t'}$$

sont compatibles avec cette donnée, i.e. on a commutativité dans

d) Il s'ensuit que les homomorphismes $(*)$ sont des *isomorphismes* dans Hot, donc tous les $C_\infty(\underline{t})$ sont isomorphes *dans* Hot. L'astuce des $t * t'$ (dans le cas où on a une loi $t * t'$ associative et admettant l'objet final comme objet unité) donne même des isomorphismes *canoniques* [page 123]

$$C_\infty(\underline{t}') \longrightarrow C_\infty(\underline{t}) \qquad \text{dans Hot},$$

et c'est là un système transitif d'isomorphismes. Donc on a dans Hot un objet canonique

$$C_\infty \in \mathrm{Ob}\,\mathrm{Hot},$$

dont la relation à $H \in \mathrm{Ob}\,\mathrm{Ind}\,\mathrm{Hot}$ est déduite de c), c'est une flèche canonique

$$H \longrightarrow C_\infty \qquad \text{dans Ind Hot } ([27]).$$

Cette flèche induit un isomorphisme pour les objets correspondants de $\mathrm{Hot}_0^\wedge$; mais en regardant H non comme ind-objet de $\mathrm{Hot}_0^\wedge$, mais prenant le foncteur H_0 induit sur Hot_0 par le foncteur ind-représentable H sur Hot. Ce foncteur induit est 'représentable' par l'objet C_∞ de la catégorie plus grande

$$H_0 \simeq C_\infty \qquad \text{dans } \mathrm{Hot}_0^\wedge.$$

(Si le foncteur canonique $\mathrm{Hot} \longrightarrow \mathrm{Hot}_0^\wedge$ est pleinement fidèle, alors cette formule décrit C_∞ comme objet de Hot, à isomorphisme unique près, en termes de H_0, donc aussi en termes de $H \in \mathrm{Ob}\,\mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}$.)

e) J'ignore par contre si les flèches [p. 78] [page 124]

$$C_\infty(\underline{t}') \longrightarrow C_\infty(\underline{t})$$

sont des isomorphismes dans Cat hot, bien qu'elles soient définies en termes d'homomorphismes de systèmes inductifs de catégories, qui sont des isomorphismes dans Ind Cat hot. Il en est ainsi, même pour les flèches $C_\infty(\underline{t}), C_\infty(\underline{t}') \rightrightarrows C_\infty(\underline{t} * \underline{t}')$ utilisées pour comparer $C_\infty(\underline{t})$ et $C_\infty(\underline{t}')$ canoniquement. Ainsi, je ne vois pas comment définir des flèches en sens inverse dans Cat, qui seraient candidats à être des isomorphismes inverses dans Cat hot.

Commentary · Examples [ms. 123]

A colimit need not be the same ind-object

Grothendieck's warning in footnote 27 concerns the test objects allowed, not a defect of the colimit. It is already visible for sets. Put $D_n = \{0, \dots, n\}$, viewed as discrete categories, and $D = \mathbf{N}$. For every finite discrete K one has

$$\operatorname*{colim}_n \mathrm{Hom}(K, D_n) = \mathrm{Hom}(K, D),$$

27. **NB** H n'est pratiquement jamais essentiellement constant, donc la flèche ci-contre `[n'est]` pas un isomorphisme dans Ind Hot.

> because the image of a finite set is bounded. The map from the ind-object $(D_n)_n$ to the constant ind-object D is nevertheless not an isomorphism. Applying maps from the constant object $\mathbf{N}$, its source consists of bounded-image functions $\mathbf{N} \to \mathbf{N}$, while the target also contains the identity. These computations are unchanged in Hot: maps between discrete spaces are functions, and no homotopy identifies different functions.
>
> Thus restriction to the finite-test category can identify two presheaves that differ on larger tests. The ind-object records how a family is bounded; the colimit records its pointwise values after the bound has been forgotten. This is the precise content behind "pratiquement jamais essentiellement constant." It is not a universal prohibition: a sequence that is eventually constant is a constant ind-object, and more generally one can have an ind-isomorphism to a constant object without literal eventual constancy.

f) Dans le cas géométrique ($T = \underline{\mathrm{Ty}}$, situation décrite en termes de X, Σ, et $a, b \in \mathrm{Ob}\, X$, d'où des $C_\infty(\underline{t}; a, b)$, $C_\infty(\overline{a, b})$, $H(a, b)$ etc.), on *n'a pas* d'opération de composition de chemins au niveau des *catégories* $C_\infty(\underline{t}; a, b)$ et $C_\infty(\underline{t}; b, c)$, mais seulement au niveau des objets $H(a, b)$, $H(b, c)$ de Ind Cat hot ou de Ind Hot. Suis-je seulement sûr de savoir définir *dans* Hot

$$C_\infty(a, b) \times C_\infty(b, c) \longrightarrow C_\infty(a, c) \quad ?$$

Sûrement, il n'y a pas de problèmes pour les images dans $\mathrm{Hot}_0^\wedge$, puisque là ce sont les mêmes que celles de $H(a, b)$, $H(b, c)$, $H(a, c)$ respectivement, et on a des accouplements parfaits, associatifs, avec unité, et avec inverses là ou il doit y en avoir. Mais pas pour les $C_\infty(a, b)$ eux-mêmes? [page 125]

C'est un peu vexant qu'avec tout ce travail il semblerait qu'on n'ait pas même été foutu de définir l'analogue dans Cat du classique espace des lacets $\Omega(X, x)$ comme un groupe *dans* Hot. (Que fait Thomason?) Mais voilà une idée pensable [?]. Pour définir *quand-même*

$$C_\infty(a, b) \times C_\infty(b, c) \longrightarrow C_\infty(a, c)$$

dans Hot, on va décrire les deux foncteurs $C_\infty(a, b)$ et $C_\infty(b, c)$ par des systèmes projectifs différents $\underline{t}$, $\underline{t'}$. On peut l'expliciter en partant d'un τ_0 de longueur utile ≥ 2, et en prenant dans les deux cas

$$t_n = t'_n = \tau_0^n,$$

mais des morphismes de transition différents

$$(t_{n+p} \longrightarrow t_n) = \pi_p * \mathrm{id}_{\tau_0^n}$$
$$(t'_{n+p} \longrightarrow t'_n) = \mathrm{id}_{\tau_0^n} * \pi_p,$$

où $\pi_p : \tau_0^p \longrightarrow 1$ est la dégénérescence totale. On définira $C_\infty(a, c)$ en termes de $\underline{t''} = \underline{t} * \underline{t'}$, donc

$$\begin{cases} t''_n = \tau_0^{2n} \\ (t''_{n+p} \longrightarrow t''_n) = \pi_p * \mathrm{id}_{\tau_0^{2n}} * \pi_p. \end{cases}$$

Cette fois, les foncteurs de composition p. 79

$$C_n(\underline{t}; a, b) \times C_n(\underline{t'}; b, c) \longrightarrow C_n(\underline{t''}; a, c),$$

sont compatibles avec les foncteurs transition pour n variable, et on trouve [page 126]

$$C_\infty(\underline{t}; a, b) \times C_\infty(\underline{t'}; b, c) \longrightarrow C_\infty(\underline{t''}; a, c),$$

donc une flèche dans Hot

$$\mathrm{comp}_{\tau_0} : C_\infty \times C_\infty \longrightarrow C_\infty.$$

Il faut voir qu'elle ne dépend pas du choix de τ_0, mais si on a τ_0 et τ_0', on les compare par $\tau_0 \times \tau_0' \begin{array}{l} \longrightarrow \tau_0 \\ \longrightarrow \tau_0' \end{array}$, il suffit donc de voir que s'il existe une flèche $\tau_0 \longrightarrow \tau_0'$, alors $\mathrm{comp}_{\tau_0} = \mathrm{comp}_{\tau_0'}$. Mais une telle flèche induit des flèches $\underline{t}_{\tau_0} \longrightarrow \underline{t}_{\tau_0'}$, $\underline{t'}_{\tau_0} \longrightarrow \underline{t'}_{\tau_0'}$, $\underline{t''}_{\tau_0} \longrightarrow \underline{t''}_{\tau_0'}$, d'où un diagramme dans Cat

$$\begin{array}{ccc} C_\infty(\underline{t}_{\tau_0'}; a, b) \times C_\infty(\underline{t'}_{\tau_0'}; b, c) & \xrightarrow{\mathrm{comp}_{\tau_0'}} & C_\infty(\underline{t''}_{\tau_0'}; a, c) \\ \downarrow & & \downarrow \\ C_\infty(\underline{t}_{\tau_0}; a, b) \times C_\infty(\underline{t'}_{\tau_0}; b, c) & \xrightarrow{\mathrm{comp}_{\tau_0}} & C_\infty(\underline{t''}_{\tau_0}; a, c), \end{array}$$

dont on vérifie tout de suite qu'il est commutatif. Or ce diagramme peut se réécrire dans Hot comme

$$\begin{array}{ccc} C_\infty(a, b) \times C_\infty(b, c) & \xrightarrow{\mathrm{comp}_{\tau_0'}} & C_\infty(a, c) \\ \downarrow \mathrm{id} & & \downarrow \mathrm{id} \\ C_\infty(a, b) \times C_\infty(b, c) & \xrightarrow{\mathrm{comp}_{\tau_0}} & C_\infty(a, c), \end{array}$$

d'où $\mathrm{comp}_{\tau_0} = \mathrm{comp}_{\tau_0'}$.

[page 127]

Commentary · Exposition [ms. 126]

Padding at the two outer ends

Grothendieck's construction now solves the binary-composition problem by choosing the locations where new constant segments are inserted. A common stage in each factor is harmless because the diagonal $\mathbf{N} \to \mathbf{N} \times \mathbf{N}$ is cofinal. The location of the padding is what makes the squares commute.

Write a path in the first system as c_n and one in the second as d_n. Under $n \mapsto n + p$, the first becomes a string of p constant blocks followed by c_n, while the second becomes d_n followed by p constant blocks. Concatenation gives

$$(1_a^{\cdot p} * c_n) * (d_n * 1_c^{\cdot p}) = 1_a^{\cdot p} * (c_n * d_n) * 1_c^{\cdot p},$$

which is exactly the transition prescribed for the target system. The equality holds for the vertical transformations as well as for objects, because concatenation is a bifunctor. It therefore induces a functor on the filtered colimits. Products of categories commute with these filtered colimits, again because objects, arrows, and their defining equations are finite data.

A morphism $\tau_0 \to \tau_0'$ gives a commutative square before passage to homotopy; once the refinement maps have been established to be weak equivalences and coherently identified, the square gives equality of the two binary operations in Hot. To compare unrelated types, one can use $\tau_0 * \tau_0'$ and its two collapse maps. The printed $\tau_0 \times \tau_0'$ on this page cannot literally mean their categorical product as interval types: the product of two nontrivial intervals generally has a square rather than a linear underlying shape. Concatenation supplies the common refinement required by the argument.

The remaining associativity issue is real at the level of this proof. A third path has two joining positions, and the two binary constructions use different padding conventions at those positions. One must compare the resulting maps with coherent reparametrizations, or compare with a single strictly associative all-types model. Equality after restriction to finite tests cannot be substituted for that comparison. In the all-arrows case, the comparison established in section 13 is precisely the route back to the strict concatenation which motivated the discussion on page 111.

Je recule devant la vraie difficulté - celle de prouver l'associativité de cette loi de composition. Elle devient associative dans $\mathrm{Hot}_0^\wedge$ - mais pour que deux flèches dans Hot soient égales (ici donc

$$C_\infty(a, b) \times C_\infty(b, c) \times C_\infty(c, d) \rightrightarrows C_\infty(a, d) \quad),$$

suffit-il qu'il en soit ainsi de leurs images dans $\mathrm{Hot}_0^\wedge$ - en d'autres termes, le foncteur

$$\mathrm{Hot} \longrightarrow \mathrm{Hot}_0^\wedge,$$

est-il (en plus d'être conservatif) au moins fidèle (sinon pleinement fidèle)?

Il y a aussi que cette loi de composition est compatible avec celle des $H(a,b)$ dans Ind Hot, p. 80
pour les flèches canoniques

$$H(a,b) \longrightarrow C_\infty(a,b) \qquad \text{dans Ind Hot},$$

si on saurait que ce sont des épimorphismes, et le restent par produits cartésiens, on aurait gagné.

Bien sûr, on saura que c'est associatif, une fois qu'on saura que la composititon définie ici est compatible avec la composition des chemins dans le cadre semi-simplicial. Mais comment fait-on dans ce cadre, pour composer les chemins de longueur non bornée? N'y a-t-il pas là exactement la même difficulté? À moins de s'en tirer en se ramenant tout de suite, pour la [page 128]
théorie des opérations Ω, aux complexes de Kan, et aux chemins de type Δ_+. Mais pour les composer *fonctoriellement,* il me semble y avoir toujours le même problème - on trouvera des chemins de type $\Delta_+\Delta_+ = \mathbf{\Delta}_2^+$, et non pas Δ_+, mais on peut alors composer les homotopies directes (revient à s'induire sur $\Delta_+ \simeq \{0,2\} \subseteq \mathbf{\Delta}_2^+$). Or j'ai fait le formalisme des catégories de chemins sans me soucier de conditions du type Kan. Je présume que dans le cadre semi-simplicial, les $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1, X)$ ne donnent *pas* le bon objet des chemins, pour X pas de Kan. (Car sinon, il semblerait que pour $X = X_0$ à composantes *finies,* le calcul des π_i devrait être fini, ce qui n'est pourtant pas le cas, m'a-t-on toujours assuré …)

Commentary · Examples [ms. 127]

A map invisible at every finite stage

Grothendieck asks whether finite tests determine a morphism and whether the ind-object maps epimorphically onto its colimit. A small telescope gives a negative answer to both questions. We give the calculation because it exhibits the obstruction without relying on an unspecified phantom-map example.

Let T be the mapping telescope of the degree-two maps

$$S^1 \xrightarrow{2} S^1 \xrightarrow{2} S^1 \xrightarrow{2} \cdots .$$

Its finite subtelescopes T_n retract onto circles. Its fundamental group is $\mathbf{Z}[1/2]$, and its higher homotopy groups vanish: a map or nullhomotopy from a compact sphere lies in a finite subtelescope. Thus T is a $K(\mathbf{Z}[1/2], 1)$. After contracting the ray of vertices, a cellular model has one vertex, one loop e_n for each $n \geq 0$, and one two-cell with boundary $e_n - 2e_{n+1}$. Cellular cohomology consequently gives

$$H^2(T;\mathbf{Z}) = \operatorname{coker}\left(\prod_{n\geq 0}\mathbf{Z} \longrightarrow \prod_{n\geq 0}\mathbf{Z}, \quad (b_n) \longmapsto (b_n - 2b_{n+1})\right).$$

This is the standard telescope computation of Hatcher (2002, Examples 3F.7 and 3F.9).

To see nonvanishing directly, take $a_{2j} = 1$ and $a_{2j+1} = 0$. If $a_n = b_n - 2b_{n+1}$, iteration would give

$$b_0 = \sum_{j=0}^{N} 2^j a_j + 2^{N+1} b_{N+1} \qquad (N \geq 0).$$

In the ring of 2-adic integers, this forces $b_0 = 1 + 4 + 16 + \cdots = -1/3$, impossible for an integer b_0. Hence a determines a nonzero cohomology class. By the representation of integral degree-two cohomology, it determines an essential map

$$f : T \longrightarrow K(\mathbf{Z}, 2)$$

(Hatcher, 2002, Theorem 4.57). Each restriction to T_n is nullhomotopic, since $H^2(T_n;\mathbf{Z}) = 0$. Every map from a finite CW complex into T has image in a finite subtelescope up to homotopy, so all finite homotopy tests identify f with the constant map.

Even if the test category includes nerves of all categories with finitely many objects and arrows, this example remains invisible. Each connected component of such a nerve has finitely generated

fundamental group. Any homomorphism from that group to $\mathbf{Z}[1/2]$ has cyclic image, because finitely many denominators have a common power of two. The associated map to $T = K(\mathbf{Z}[1/2], 1)$ therefore factors up to homotopy through $K(\mathbf{Z}, 1) = S^1$, or through a point. Its composite with f is nullhomotopic because $[S^1, K(\mathbf{Z}, 2)] = 0$.

Finally let $H = (T_n)_n$ in $\mathrm{Ind}\,\mathrm{Hot}$. The two maps $f, 0 : T \rightrightarrows K(\mathbf{Z}, 2)$ become equal after precomposition with $H \to T$, since

$$\mathrm{Hom}_{\mathrm{Ind}\,\mathrm{Hot}}(H, K(\mathbf{Z}, 2)) = \lim_n [T_n, K(\mathbf{Z}, 2)] = \{0\}.$$

They are distinct before precomposition. Hence $H \to T$ is not an epimorphism. This example refutes the proposed general inference; it does not contradict associativity of the particular path composition, which requires its own geometric proof.

Je présume pourtant, quand on prend $\Sigma = \mathrm{Fl}(X)$, que les objets $\underline{\mathrm{Ch}}_\infty(X; a, b)$ et $\underline{\mathrm{Ch}}_\infty(\bar{X}; a, b)$ sont isomorphes dans Hot, quand on immerge X dans une enveloppe de Thomason-Kan $\bar{X}$.

Commentary · Exposition [ms. 128] p. 81 [page 129]

Edges and the fibres of the path object

Grothendieck wants the categorical construction to work before fibrant replacement. The distinction needed here concerns the endpoint fibres. For a Kan complex K, the map $K^{\Delta^1} \to K \times K$ is a Kan fibration, and its fibre over two vertices models their space of paths. For an arbitrary simplicial set, the same strict fibre need not compute a homotopy fibre. This does not mean that the total space K^{Δ^1} has the wrong homotopy type: evaluation at an endpoint has the constant-path section and the simplicial interval contraction gives a homotopy from their composite to the identity.

A finite example makes the endpoint problem explicit. Let X be the category with objects $0, 1, 2$ and nonidentity arrows $0 \to 1 \leftarrow 2$. Its classifying space is contractible, so the topological space of paths from 0 to 2 is nonempty and contractible. But there is no morphism $0 \to 2$. The fibre of the functor category $\underline{\mathrm{Hom}}([1], X) \to X \times X$ over $(0, 2)$ is therefore empty. The two-edge zigzag already supplies the missing path, and the refinement formalism is designed to supply all the further homotopies between such representatives.

There is a related distinction in the discussion of composition. Two composable edges of a simplicial set specify the spine $\Delta^1 \cup_{\Delta^0} \Delta^1$, not an entire Δ^2. For a Kan complex a filler produces a third edge, with higher fillers controlling the dependence on choices. In an ordinary category the interval [2] already includes the composite arrow; this explains why the categorical notation for two direct segments can conceal the simplicial filling step. A simplicial loop group, a Moore-path model, or a coherent localization retains the data needed to compare repeated compositions. None requires an algorithm computing all homotopy groups of a finite simplicial set.

The last conjecture on this page is correct for the all-arrows path object: a weak equivalence of categories induces weak equivalences on the corresponding derived path spaces, with their endpoints carried along. The justification for identifying Grothendieck's specific categories with those spaces belongs to the geometric argument in sections 12–13, not to a calculation with one-edge paths.

11 Rapide retour sur les $(\mathcal{M}, \Sigma)$, dans l'optique des dérivateurs

Commentary · Exposition [ms. 129]

What an external Hom must represent

Grothendieck now asks what his paths would have to accomplish in order to serve a theory of derived diagrams. A path from a to b is no longer only a point of a topological mapping space. It must also describe a morphism between the constant diagrams a_Y and b_Y, after objectwise localization of Y-diagrams. This is the reason for testing the path construction against every parameter category Y.

Write

$$\mathbb{D}(Y) = \mathrm{Fun}(Y, \mathcal{M})[\Sigma_Y^{-1}], \qquad F_{a,b}(Y) = \mathrm{Hom}_{\mathbb{D}(Y)}(a_Y, b_Y).$$

The conventions on variance can be reversed together without changing this discussion. The first displayed condition says precisely that $F_{a,b}$ factors through the localization of categories at nerve weak equivalences. It is a necessary invariance property for the proposed representation by a space. It is not by itself a definition of a derivator: existence and pointwise computation of homotopy Kan extensions are additional requirements. For combinatorial model categories these requirements hold by Groth (2013, Proposition 1.30). For their locally constant diagrams, the invariance asserted here is a theorem of Cisinski (2009, Theorem 1.3); constant diagrams are particular locally constant diagrams, and the subcategory in that theorem is full.

The contemporary form of the intended answer is especially transparent when a relative category presents an ∞-category $\mathcal{C}$ and its localized strict diagram categories present $\mathrm{Fun}(NY, \mathcal{C})$. With $K = \mathrm{Map}_{\mathcal{C}}(a, b)$ one then has

$$F_{a,b}(Y) \cong \pi_0 \, \mathrm{Map}_{\mathcal{S}}(|NY|, K).$$

Indeed, a coherent transformation between the two constant diagrams is a coherent Y-indexed family of points of K; this is the limit of the constant K-diagram, hence the mapping space from the groupoid completion $|NY|$ to K. Taking components gives the formula. The diagram-presentation hypothesis is substantive: one cannot replace it by the existence of an arbitrary admissible set Σ.

The comparison between strict model-category diagrams and coherent diagrams is established, under the relevant model-category hypotheses, in Lurie (2009, Proposition 4.2.4.4).

Here the source means finite sets of objects and arrows by a finite category (Grothendieck, 1990a, ms. 45); such a category need not have a finite nerve. Consequently the earlier compactness argument does not establish the comparison for every finite category. The conditional assertion under the additional locality of H is not disproved merely by that observation.

This also clarifies the finite-stage issue. The ind-object $H(a,b)$ records a bound on the length of a zigzag that works simultaneously over the entire parameter. Passing to $\underline{\mathrm{Ch}}_\infty$ can forget this uniformity. It does not follow that modern derived mapping spaces must themselves be ind-objects: in the good diagram presentations just described, one space K represents the functor for every small Y. What fails for a general pair $(\mathcal{M},\Sigma)$ may be the identification of its localized strict diagrams with coherent diagrams, rather than representability of the latter. The example below separates these two issues with a six-object category.

Quand on s'intéresse au formalisme des $\underline{\mathrm{Ch}}_\Sigma(X;a,b)$ en vue d'un *dérivateur* $\mathbf{D}_{X,\Sigma}$ qu'on voudrait définir en termes de X, Σ, il semblerait que le prédérivateur qu'on obtient bel et bien ne mérite le nom de dérivateur que lorsqu'on suppose que pour toute flèche

$$Y \longrightarrow Y'$$

dans Cat qui est une Hot-équivalence, les flèches correspondantes

$$\mathrm{Hom}_{\mathrm{Ind\,Cat\,hot}}(Y', H(a,b)) \longrightarrow \mathrm{Hom}_{\mathrm{Ind\,Cat\,hot}}(Y, H(a,b)),$$

ou encore

$$\varinjlim_n \mathrm{Hom}_{\mathrm{Cat\,hot}}(Y', \underline{\mathrm{Ch}}_{n,\Sigma}(a,b)) \longrightarrow \varinjlim_n \mathrm{Hom}_{\mathrm{Cat\,hot}}(Y, \underline{\mathrm{Ch}}_{n,\Sigma}(a,b))$$

sont des bijections. J'ai regardé dans V ce que ça signifie pour l'objet $H(a,b) = (\underline{\mathrm{Ch}}_{n,\Sigma}(a,b))_n$ de Ind Cat hot. C'est cette condition seulement qui assure, du point de vue des dérivateurs, une interprétation convaincante de $\underline{\mathrm{Ch}}_{\infty,\Sigma}(a,b)$,

$$\underline{\mathrm{Ch}}_{\infty,\Sigma}(a,b) \;=\; \varinjlim_n \underline{\mathrm{Ch}}_{n,\Sigma}(a,b)$$

en tant qu'objet de Hot, ou plus exactement de $\mathrm{Hot}_0^\wedge$, car on a alors pour Y une catégorie *finie*

$$\underbrace{\mathrm{Hom}_{\mathrm{Cat\,hot}}(Y, H(a,b))}_{\simeq \mathrm{Hom}_{X(Y)\Sigma_Y^{-1}}(a_X, b_X)} \;\simeq\; \mathrm{Hom}_{\mathrm{Hot}}(Y, \underline{\mathrm{Ch}}_{\infty,\Sigma}(a,b)),$$

car je veux quand-même que le type dans Hot soit le bon, qu'il correspond bien à l'homotopie des espaces de chemins. Donc on voudrait qu'un morphisme

[page 130]

$$X \xrightarrow{f} X'$$

dans (Cat), qui est une Hot-équivalence, définisse

$$\underline{\mathrm{Ch}}_\infty(X;a,b) \longrightarrow \underline{\mathrm{Ch}}_\infty(X'; f(a), f(b)),$$

qui soient eux aussi des Hot-équivalences. D'autre part, c'est évidemment compatible avec la brillante composition des chemins, que j'ai réussi à définir entre ces objets de Hot. Donc (sous réserve d'avoir vérifié ce que je viens de dire) la vérification de l'associativité se ramenerait au cas où X est de Thomason-Kan. Mais dans ce cas, il y a des chances que, tout comme dans le cas semi-simplicial, les $\underline{\mathrm{Ch}}_\infty(X;a,b)$ peuvent se définir (comme objets de (Hot)) comme étant simplement les chemins de type Δ_+ de a à b, qu'on compose alors de la façon triviale. Mais non, ces catégories sont discrètes!

Je renonce pour l'instant à poursuivre plus la question d'associativité. Demander à Thomason pour les propriétés du foncteur $\mathrm{Hot} \longrightarrow \mathrm{Hot}_0^\wedge$.

Cela signifie, à très peu de choses près, qu'on a une interprétation de $\underline{\mathrm{Ch}}_{\infty,\Sigma}(a,b)$, en tant qu'objet de Hot, comme un 'Hom externe' $\mathrm{Hom}\,\mathrm{ext}(a,b)$ à valeurs dans Hot, défini sur la catégorie $\mathcal{M} = X$ à l'aide du seul ensemble admissible de flèches $\Sigma \subseteq \mathrm{Fl}(\mathcal{M})$, opération satisfaisant la condition p. 82 [page 131]

$$(*) \qquad \boxed{\mathrm{Hom}_{\mathrm{Hot}}(Y, \mathrm{Hom}\,\mathrm{ext}(a,b)) \;\simeq\; \mathrm{Hom}_{\mathcal{M}(Y)\Sigma_Y^{-1}}(a_X, b_X)}$$

(qui peut s'interpréter aussi, soit comme

$$\mathrm{Hom}_{\mathcal{M}}(p_!(a_Y), b)$$

si $p_! : \underbrace{\mathcal{M}(Y)\Sigma_Y^{-1}}_{\mathbf{D}(Y)} \longrightarrow \mathcal{M}$ existe, soit comme

$$\mathrm{Hom}_{\mathcal{M}}(a, p_*(b_Y))$$

si $p_* : \underbrace{\mathcal{M}(Y)\Sigma_Y^{-1}}_{\mathbf{D}(Y)} \longrightarrow \underbrace{\mathcal{M}}_{=\mathbf{D}(*)}$ existe); avec le seul petit ennui que cette formule n'est valable que pour Y *finie.* Si on veut exprimer le second membre pour Y variable quelconque dans Cat, il ne suffit pas d'un objet de Hot ($\mathrm{Hom}\,\mathrm{ext}(a,b)$) dans le premier membre, mais il faut l'ind-objet $H(a,b) = (\underline{\mathrm{Ch}}_n(a,b))_{n\in\mathbf{N}}$ dans Hot. Si donc on tient à travailler dans un 'domaine' Diag du dérivateur $\mathbf{D} = \mathbf{D}_{\mathcal{M},\Sigma}$ aussi grand que possible, en se bornant à des catégories finies, et qu'on veut qu'une formule $(*)$ reste valable pour toute Y dans le domaine, il faut 'en toute rigueur' définir le $\mathrm{Hom}\,\mathrm{ext}(a,b)$ non comme objet de Hot, mais de Ind Hot. Il se décrirait donc alors comme [page 132]

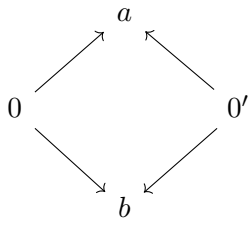
$$\mathrm{Hom}\,\mathrm{ext}(a,b) = (\underline{\mathrm{Ch}}_{n,\Sigma}(a,b))_n \qquad \text{(ind-objet dans Hot)}\ ,$$

et l'objet $\underline{\mathrm{Ch}}_{\infty,\Sigma}$ dans Hot en est une sorte de limite inductive.

Commentary · Context [ms. 131]

The original category and its localized value

Grothendieck wants the same external Hom to explain both homology and cohomology with constant coefficients. This is an adjunction calculation once the ambient categories have been fixed. Put $p : Y \to e$. If the relevant adjoints exist, then



$$\begin{aligned}\mathrm{Hom}_{\mathbb{D}(Y)}(p^*a, p^*b) &\cong \mathrm{Hom}_{\mathbb{D}(e)}(p_!p^*a, b)\\ &\cong \mathrm{Hom}_{\mathbb{D}(e)}(a, p_*p^*b).\end{aligned}$$

Here $\mathbb{D}(e) = \mathcal{M}[\Sigma^{-1}]$, not the original $\mathcal{M}$ unless the notation has been changed. Likewise the a_X, b_X of the displayed formula mean a_Y, b_Y. These small notational adjustments matter because an adjoint to restriction of localized diagrams is a derived operation; an adjoint before localization need not compute it.

The historical motivation is unusually explicit. In the retrospective in *Pursuing Stacks*, Grothendieck (1983, §69, pp. 1–2) relates the inadequacy of an isolated derived category to the trace questions arising from SGA 5, and proposes retaining derived categories of all diagram shapes. The present pages carry that programme into a concrete question: can the dependence on the parameter shape itself be represented homotopically? The adjunction formulas explain why a positive answer belongs simultaneously to the homological and the cohomological sides of the theory. The subsequent calculations concern the geometric adequacy of the proposed representative, rather than another formal manipulation of these adjunctions.

Je me suis demandé si la condition préalable, savoir que les foncteurs $H(a,b)$ sur Cat transforment Hot-équivalences $Y' \longrightarrow Y$ en bijections, était bel et bien une (forte) restriction. Je me suis convaincu que c'est bien le cas, déjà dans le cas particulier où $\Sigma = \mathrm{Fl}(X)$. Il me semble que lorsque les composantes connexes de $\Omega(X,a)$ ne sont pas contractiles, ladite

condition n'est pratiquement jamais satisfaite. J'ai pensé p. ex. au cas où X a le type d'homotopie (dans Hot) d'une 2-sphère, de sorte que son $\Omega(X,a) = \underline{\mathrm{Ch}}_\infty(X,a,a)$ doit avoir un $\pi_1 \simeq \mathbf{Z}$. Prenons Y ayant le type dans Hot d'un cercle, disons

Y : 

,

donc les foncteurs p. 83
[page 133]

$$f : Y \longrightarrow \underline{\mathrm{Ch}}_\infty(X; \bullet, \bullet) \overset{\text{déf}}{=} \Omega(X, \bullet)$$

correspondent à *certains* 'lacets' de $\Omega(X, \bullet)$ (mais lacets à origine non précisée), ils ont un type d'homotopie au sens topologique ('nombre de tours' autour de la sphère X) donné par un entier $n \in \mathbf{Z}$ (le 'degré' du lacet λ). L'intuition évidente, c'est que l'ensemble des degrés δ qu'on peut obtenir ainsi, avec une catégorie *finie* donnée Y qui représente le cercle $S^1 \in (\mathrm{Hot})$, est fini - $|\delta|$ majoré sûrement par le nombre de ces flèches (donc au moins par 4 dans le cas envisagé, chaque flèche de Y faisant faire *au plus* un tour autour du pseudo-cercle $\Omega(S^2, \bullet)$) ([28]). D'autre part, quand on représente S^1 par des catégories Y_n arbitrairement grandes (disons déduites des intervalles $\Phi_n = (\Delta_+\Delta_-)^n$ en identifiant la source et le but), on doit trouver des degrés arbitrairement élevés. Or toute Y_n s'envoie dans $Y(= Y_2)$ par une flèche

$$Y_n = Y' \longrightarrow Y = Y_2$$

qui est de degré 1, donc qui est une Hot-équivalence. Mais l'application correspondante [page 134]

$$\pi_0\underline{\mathrm{Hom}}(Y, \Omega(X, \bullet)) \longrightarrow \pi_0\underline{\mathrm{Hom}}(Y', \Omega(X, \bullet))$$

n'est pas bijective. Ce genre d'argument me semble devoir marcher chaque fois que l'ensemble des groupes d'homotopie $\pi_j(X, x)$, pour $j \geq 2$ (donc l'ensemble des groupes d'homotopie π_i de $\Omega(X, x)$, pour $i \geq 1$) est *infini,* en prenant pour Y, Y' différents représentants Y_n de la sphère S^i, disons les Y_n déduites de Φ_n ($n \geq 2$) en prenant $\Phi_n^i = \Phi_n \times \Phi_n \times \cdots \times \Phi_n$ (qui est une sorte de i-cube combinatoire), et en identifiant son 'bord' à un seul point. Je présume que le nombre d'élements dans $\pi_i(\Omega(X, x))$ qu'on peut obtenir à partir de flèches $Y_n \longrightarrow \Omega(X, x)$ est limité par la taille de Y_n, mais on peut sûrement les obtenir chacun, en prenant n assez grand. Si donc $\xi \in \pi_i(\Omega)$ échappe à Y_{n_0} ($n_0 = 0$, disons), on prend un n' assez grand pour que ξ n'échappe pas à $Y_{n'}$, et on choisit

$$Y_{n'} \longrightarrow Y_n \ ,$$

[$n = n_0$?]

qui soit une Hot-équivalence (p. ex. à l'aide d'une rétraction de $\Phi_{n'}$ sur Φ_n, compatible avec sources et buts). [page 135]

Commentary · Development (commentators') [ms. 134]

A fixed circle already sees every degree

Grothendieck's intuition that localization of strict diagrams can depend on the chosen category presenting a homotopy type is correct. The proposed explanation by a bound on the degree of a four-arrow circle is not. A natural transformation between long paths contains an arbitrarily wide commuting ladder. Its contribution to a two-dimensional homotopy class is not bounded by the number of arrows in the parameter category. We give a finite example that both disproves the suggested bound and proves the desired failure of invariance.

A suspension calculation. [ours] Let Y be the four-object poset with minimal objects r_0, r_1, maximal objects q_0, q_1, and all four relations $r_i < q_j$. Let X be obtained by adjoining two incomparable objects s, n, each greater than every object of Y. Take all arrows of X as weak equivalences. Then $|NY|$ is a circle and $|NX|$ is its suspension, hence a 2-sphere. For the constant diagram s_Y the group

$$G_Y = \mathrm{Aut}_{\Pi\,\mathrm{Fun}(Y,X)}(s_Y)$$

contains an element of infinite order. Moreover, for one fixed four-arrow Y, functors $Y \to \underline{\mathrm{Ch}}_\infty(X; s, s)$ realize every integer in $\pi_1\Omega|NX|$.

Proof. Denote the inclusion by $j : Y \hookrightarrow X$, and choose a vertex $y_0 \in Y$. Since all objects of Y lie below both suspension vertices, there is a loop of natural transformations

(B1) $$s_Y \longleftarrow j \longrightarrow n_Y \longleftarrow (y_0)_Y \longrightarrow s_Y.$$

28. probablement on ne trouve tout au plus que les degrés δ entre -2 et $+2$.

This is a loop in the nerve of the functor category, based at s_Y. Under evaluation it gives a continuous family of loops in $|NX|$: at y the loop travels from s to n along the meridian through y, and returns along the fixed meridian through y_0.

To check its class, let γ be an oriented fundamental 1-cycle of $|NY|$. The two varying portions of the family sweep out the two cones on γ. The fixed return meridian contributes no 2-chain. Thus the image of the fundamental class of $|NY| \times S^1$ is, with a choice of orientation,

$$n * \gamma - s * \gamma,$$

which is the fundamental cycle of the suspension $|NX|$. In particular its degree is 1. Equivalently, collapse the fixed meridian in the suspension: the adjoint of the family becomes the usual suspension map of the identity of $|NY|$. The collapse of that contractible arc induces an isomorphism on H_2, so this gives the same calculation. Consequently (B1) is nontrivial and its k-fold power has degree k. A null-homotopy in the functor category would give a null-homotopy after evaluation and degree zero. All these powers are therefore distinct in G_Y.

The same construction takes place in one finite path stage. For $\rho = \Delta_-\Delta_+\Delta_-\Delta_+$ define

$$F(y) = \big(s \longleftarrow y \longrightarrow n \longleftarrow y_0 \longrightarrow s\big).$$

For an arrow $y \to y'$ use that arrow in the varying position and identities in the other four positions. All squares commute because X is a poset. This defines a functor $F : Y \to \underline{\mathrm{Ch}}_\rho(X; s, s)$. Concatenating k copies pointwise gives a functor into $\underline{\mathrm{Ch}}_{\rho^k}(X; s, s)$ of degree k. Insert identity arrows at the two ends to fit this alternating word into a sufficiently long symmetric stage t_N; this changes only parametrization, not the degree. Reversal gives negative k, and the constant family gives zero. This proves the assertion for $\underline{\mathrm{Ch}}_\infty$, without assuming that its concatenation has already been made into a globally defined bifunctor. □

The example also supplies a genuine change-of-parameter failure. Write $B\mathbb{Z}$ for the one-object category with automorphism group $\mathbb{Z}$. There is a functor $u : Y \to B\mathbb{Z}$ sending one of the four edges to $1 \in \mathbb{Z}$ and the other three to 0. Choose the sign so that the induced map on the circle has degree 1. Its nerve is a weak equivalence: both classifying spaces are $K(\mathbb{Z}, 1)$ and the induced map on fundamental groups is an isomorphism. Every functor $B\mathbb{Z} \to X$ is constant, since a poset has only identity automorphisms; every natural transformation between such functors is exactly one arrow of X. Therefore

$$\mathrm{Fun}(B\mathbb{Z}, X) \cong X, \qquad \mathrm{Aut}_{\prod \mathrm{Fun}(B\mathbb{Z},X)}(s) = 1.$$

Restriction along u maps this trivial group to G_Y, which contains all the powers of (B1). It is not surjective. By the localization interpretation of $H(s, s)$ used on ms. 129, this is precisely a failure of the required invariance of $H(s, s)$.

We checked the relevant diagram-localization and fibrancy results in Cisinski (2009), Thomason (1980), and Raptis (2010). We did not find this finite suspension calculation presented there. It is included as a direct completion of Grothendieck's proposed example, without a claim of priority. The failure proved here concerns localized *strict* diagrams in this relative category. It is consistent with the homotopy invariance of coherent diagrams explained above.

Ceci attire fortement l'attention sur le fait que si Y, C sont deux catégories, la catégorie $\underline{\mathrm{Hom}}(Y, C)$ *n'est pas* un représentant de $\underline{\mathrm{Hom}}_{\mathrm{Hot}}(\mathrm{hot}(Y), \mathrm{hot}(C))$, on a seulement une flèche canonique

$$(*) \qquad \mathrm{hot}(\underline{\mathrm{Hom}}(Y, C)) \longrightarrow \underline{\mathrm{Hom}}_{\mathrm{Hot}}(\mathrm{hot}(Y), \mathrm{hot}(C)),$$

i.e.

$$\underbrace{\mathrm{hot}(\underline{\mathrm{Hom}}(Y, C)) \times \mathrm{hot}(Y)}_{\mathrm{hot}(\underline{\mathrm{Hom}}(Y,C)\times Y)} \longrightarrow \mathrm{hot}(C),$$

p. 84

laquelle flèche est simplement déduite de

$$\underline{\mathrm{Hom}}(Y, C) \times Y \longrightarrow C.$$

Mais la flèche $(*)$ n'a aucune envie d'être `[un]` isomorphisme. C'est parce qu'elle ne l'est déjà pas dans le cas particulier $Y = \mathbf{\Delta}^1$, essentiellement, qui nous oblige, pour faire une théorie

des chemins dans les catégories qui soit topologiquement raisonnable, de ne pas nous borner à $\mathbf{\Delta}^1$ comme type de chemins, mais à prendre des intervalles composés $\tau \in \mathrm{Ty}$.

Commentary · Examples [ms. 135]

The absolute arrow category and its endpoint fibres

Grothendieck is trying to isolate the defect that forced him to lengthen paths. The defect is real, but the specific absolute comparison on this page does not exhibit it. For every category C, put $A = \mathrm{Fun}([1], C)$, let $c : C \to A$ send an object to its identity arrow, and let $e_0 : A \to C$ evaluate at the source. Then $e_0 c = \mathrm{id}_C$. For an arrow $f : x \to y$, the square with vertical arrows id_x and f defines a natural transformation

$$ce_0 \Longrightarrow \mathrm{id}_A.$$

After taking nerves, this is a homotopy from Bce_0 to the identity. Hence Be_0 is a homotopy equivalence. Evaluation at 0 also gives a homotopy equivalence $\mathrm{Map}(|N[1]|, BC) \to BC$, since the interval contracts to 0. The canonical comparison

$$B\,\mathrm{Fun}([1], C) \longrightarrow \mathrm{Map}(|N[1]|, BC)$$

commutes with these evaluations and is consequently a weak equivalence. No fibrancy assumption on C is involved.

What cannot be inferred is the corresponding assertion on *strict* endpoint fibres. The fibre over (a, b) of $A \to C \times C$ is the discrete category $\mathrm{Hom}_C(a, b)$: a square with identity arrows at its two ends can only relate an arrow to itself. The homotopy fibre of the topological path fibration is instead the full path space from a to b. The fork example discussed at ms. 128 already shows that these can differ even on components. Thus the motivation for alternating paths survives, while the sentence claiming failure of the absolute $Y = [1]$ comparison must be corrected.

There is also a direct example of absolute failure for another shape. Let P be any poset with $BP \simeq S^1$, and take $Y = B\mathbb{Z}$. As above, $\mathrm{Fun}(B\mathbb{Z}, P) \cong P$. Its classifying space is connected, whereas $\mathrm{Map}(S^1, S^1)$ has one component for every integer degree. The comparison misses every nonconstant degree. This pinpoints the missing derived dependence on the source, without confusing the total arrow category with its fibres.

[page 136]

Par contre, $(*)$ est [un] isomorphisme quand C est une catégorie de Thomason-Kan. Il suffit de voir que pour tout Z dans (Cat), le Hom de $\mathrm{hot}(Z)$ dans les deux membres est isomorphe par la flèche déduite de $(*)$. Or si C est de Thomason-Kan, de même $\underline{\mathrm{Hom}}(Y, C)$ (immédiat sur la définition de Thomason-Kan en termes de prolongements de $A_0 \xhookrightarrow{i} A$ avec $A_0 \to C$ et $A \dashrightarrow C$ ...([29])), donc

$$\mathrm{Hom}_{\mathrm{Hot}}(\mathrm{hot}(Z), \mathrm{hot}(\underline{\mathrm{Hom}}(Y, C))) \xleftarrow{\sim} \pi_0(\underbrace{\underline{\mathrm{Hom}}_{\mathrm{Cat}}(Z, \underline{\mathrm{Hom}}(Y, C))}_{\underline{\mathrm{Hom}}_{\mathrm{Cat}}(Z \times Y, C)}) \simeq \pi_0 \underline{\mathrm{Hom}}(Z \times Y, C),$$

et

$$\mathrm{Hom}_{\mathrm{Hot}}(\mathrm{hot}(Z), \underline{\mathrm{Hom}}_{\mathrm{Hot}}(\mathrm{hot}(Y), \mathrm{hot}(C))) \simeq \mathrm{Hom}_{\mathrm{Hot}}(\underbrace{\mathrm{hot}(Z) \times \mathrm{hot}(Y)}_{\mathrm{hot}(Z \times Y)}, \mathrm{hot}(C))$$

$$\underbrace{\xleftarrow{\sim}}_{\text{car } C \text{ est de Thomason-Kan}} \qquad \pi_0(\underline{\mathrm{Hom}}_{\mathrm{Cat}}(Z \times Y, C)),$$

O.K.

On voit donc que les catégories $\underline{\mathrm{Ch}}_{\infty,\Sigma}(X; a, b)$ n'ont aucune tendance à être des catégories de Thomason-Kan. Pourtant, son type dans Hot doit être 'le bon', sans avoir d'abord à remplacer X par une enveloppe de Thomason-Kan $\bar{X}$.

29. un peu vif! Il faut savoir que les applications cofibrantes i de Thomason le restent après multiplication cartésienne par Y ...

Commentary · Development (commentators') [ms. 136]

A fibrant target does not derive every source

Grothendieck's next attempt is to impose a Kan condition on the target. His footnote identifies one missing assertion about products of cofibrations, but the displayed proof also replaces arbitrary maps in the localized category by ordinary functors from an arbitrary source. Thomason fibrancy alone does not permit that replacement. The following example makes the issue visible already on components.

A fibrant-poset obstruction. [ours] There are a Thomason-fibrant category P and a finite category Y for which

$$B\,\mathrm{Fun}(Y,P) \longrightarrow \mathrm{Map}(BY,BP)$$

is not a weak equivalence. Here "finite" means finitely many objects and arrows, not a finite nerve.

Proof. Let $G = \mathbb{Z}/2$ and $Y = BG$. By Raptis (2010, Theorem 2.6), Thomason's model structure restricts to posets, with the same weak equivalences and fibrations. Start with a poset representing BG, for example the twofold subdivision construction $c\,\mathrm{Sd}^2\,N(BG)$, and take its fibrant replacement within posets. We obtain a poset P that is fibrant as a category and satisfies $BP \simeq BG$. Every functor $BG \to P$ sends the single object to some p and every element of G to id_p. Natural transformations are exactly the relations $p \le p'$. Hence

$$\mathrm{Fun}(BG,P) \cong P.$$

The source of the comparison is therefore connected. Its image consists of constant maps $BG \to BP$. But the target has at least two components: a constant map induces the zero homomorphism on π_1, whereas a homotopy equivalence $BG \to BP$ induces an isomorphism. These maps cannot be homotopic, even without specified basepoints, since conjugation cannot turn a trivial homomorphism into an isomorphism. The comparison fails on π_0. □

This also supplies an immediate test of the first isomorphism asserted in the proof on ms. 136: take its $Z = e$. The claimed bijection would identify the connected set $\pi_0\,\mathrm{Fun}(Y,P)$ with $[BY,BP]$, which has the two distinct classes just exhibited. One cannot repair that step merely by proving that the functor category is fibrant. In Thomason's model structure the source has to be handled as well; in particular every cofibrant category is a poset (Thomason, 1980, Proposition 5.7), so this BG is not cofibrant.

The literal product claim in footnote 29 would also be too strong for arbitrary cofibrations: multiplying the cofibration $\varnothing \to e$ by Y would make every category cofibrant. The next development also rules out preservation of all trivial cofibrations under product with arbitrary Y: the lifting adjunction would otherwise force every such functor category to be fibrant.

A safe model for the desired derived mapping space is the simplicial function complex

$$\mathrm{Map}_{\mathrm{sSet}}(NY, RNP),$$

where RNP is a Kan replacement. Every simplicial set is cofibrant, and this construction derives the target in the cartesian model category of simplicial sets. The ordinary nerve identity $N\,\mathrm{Fun}(Y,P) = (NP)^{NY}$ explains precisely what the uncorrected formula omits. We checked the model structure and the poset replacement in the cited papers; we did not find this particular $B(\mathbb{Z}/2)$ application there. The result is recorded as an elementary application, not a priority claim.

p. 85
[page 137]

Commentary · Development (commentators') [ms. 136]

Fibrancy is not preserved by strict diagram categories

The failure of the preceding mapping-space formula does not logically decide the separate assertion that $\mathrm{Fun}(Y,C)$ is fibrant whenever C is. That assertion also fails, but it needs a different example. An equivariant construction makes the obstruction precise: ordinary horn filling need not respect an action on the diagram.

A finite parameter with a nonfibrant functor category. [ours] There are a countable Thomason-fibrant category E and a finite category Y such that $\mathrm{Fun}(Y,E)$ is not Thomason-fibrant.

Proof. Let D be the four-object crown used above, so $BD \simeq S^1$. It is not Thomason-fibrant. Indeed, $\mathrm{Ex}^2\,ND$ has finitely many 1-simplices: they are the functors from the finite poset $c\,\mathrm{Sd}^2\,\Delta^1$ to D. In a Kan complex every element of a based fundamental group is represented by one loop

edge, since horn fillers compose and invert edge paths. If $\mathrm{Ex}^2\, ND$ were Kan, its fundamental group would therefore be finite, contrary to its being isomorphic to $\pi_1(BD) = \mathbb{Z}$.

Put $G = \mathbb{Z}/2$ and give D the trivial action. We first construct a G-poset Q whose underlying category is fibrant and whose fixed subposet is exactly D. Start with $Q_0 = D$. At step r, for every generating Thomason horn inclusion

$$A = c\,\mathrm{Sd}^2\,\Lambda^n_i \;\longrightarrow\; B = c\,\mathrm{Sd}^2\,\Delta^n$$

and every ordinary functor $F : A \to Q_r$, attach the free G-cell $G \times B$ along $G \times A$, using the equivariant attaching map $(g, a) \mapsto gF(a)$. Here G in a product denotes the discrete set of its two elements. Take all these pushouts simultaneously and put $Q = \varinjlim_r Q_r$.

These horn inclusions are Dwyer inclusions of finite posets. The pushout description in May et al. (2017, Lemmas 4.7–4.8) shows that the old poset stays full and that the new objects are exactly the disjoint sets $G \times (B \setminus A)$. All new objects have free G-action. Thus $Q^G = D$, with its original order. Every horn map into Q factors through some finite stage, because its domain is finite, and it obtains a filler at the next stage. Consequently Q is Thomason-fibrant. There are only countably many finite horn shapes and, at each countable stage, countably many maps from them. Hence Q is countable.

Define the transport category $E = Q \rtimes G$ as follows. Its objects are those of Q, and an arrow $x \to y$ labelled $g \in G$ exists exactly when $gx \le y$; composition multiplies labels. There is a projection $E \to BG$. We claim that E is Thomason-fibrant. Given a horn diagram $F : A \to E$, write g_{ab} for the label of an arrow $a \to b$. Since BA is contractible, its fundamental groupoid is equivalent to a point. The projected functor $A \to BG$ is therefore naturally isomorphic to a constant functor: choose labels h_a with

$$h_b g_{ab} = h_a.$$

Replacing $F(a)$ by $h_a F(a)$ turns every arrow label into 1 and gives a functor $A \to Q$. Extend it to $B \to Q$ by fibrancy of Q. Extend the assignments h_a arbitrarily to the remaining objects of B, and undo the replacement: at b use $h_b^{-1} F'(b)$, and label $b \to c$ by $h_c^{-1} h_b$. The inequalities defining F' make this a functor $B \to E$, and it restricts exactly to the original horn diagram. This proves the claim.

Finally set $Y = BG$. A functor $BG \to E$ induces a homomorphism $\phi : G \to G$, either trivial or the identity. The trivial case is the identity action at an arbitrary object of E. In the identity case, an endomorphism labelled by the nontrivial g requires $gx \le x$; applying g gives the reverse inequality, so $gx = x$. Its objects are therefore precisely $D = Q^G$. A natural transformation labelled by h must satisfy $h\phi(g) = \psi(g)h$. Since G is abelian, this forces $\phi = \psi$. For the identity case the remaining condition is just $x \le y$, and every $h \in G$ is allowed. We obtain an actual decomposition

$$\mathrm{Fun}(BG, E) \cong E \amalg (D \times BG).$$

The category D is a retract of this coproduct: project the second summand onto D, send the first constantly to a chosen object of D, and use identity labels for the section. A retract of a fibrant category is fibrant. Since D is not fibrant, neither is $\mathrm{Fun}(BG, E)$. □

Thus both claims on ms. 136 fail: arbitrary strict diagram categories need not preserve Thomason fibrancy, and even when a particular functor category is fibrant, it need not represent the derived mapping space. The equivariant cell and fixed-point ingredients above are standard and are cited at their use. We did not locate this application to strict diagram categories in the primary sources checked, including the published equivariant-poset paper; the argument is supplied here without a claim of priority.

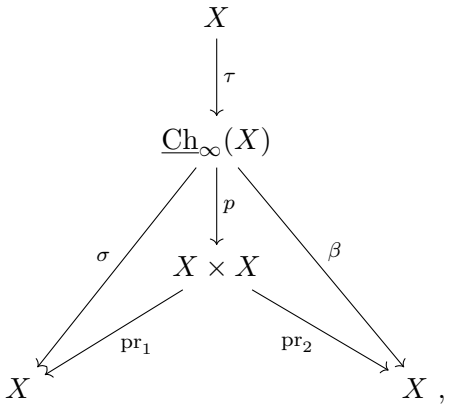
12 Retour sur les ‘catégories de chemins’ dans Cat, comme catégorie de modèles pour Hot

Je vois exactement deux applications intéressantes du formalisme des chemins dans les catégories. L’une, qui m’a surtout forcé la main, est pour pouvoir construire des Hom ext, Hom *externes* à valeurs dans Hot, pour tout prédérivateur **D** défini par un couple $(\mathcal{M}, \Sigma)$ (et

je ne connais pas de prédérivateur qui ne soit défini ainsi).

L'autre application est pour avoir dans (Cat) une *construction fonctorielle,* en termes d'un objet X quelconque ou d'une flèche $X \longrightarrow Y$, de l'analogue du formalisme de Cartan-Serre sur les espaces de chemins. Dans ce cadre, il est entendu qu'on prend toujours $\Sigma_X = \mathrm{Fl}(X)$, ensemble de *toutes* les flèches de X. Pour construire fonctoriellement en X dans (Cat)

$$\begin{array}{c} \underline{\mathrm{Ch}}_\infty(X) \\ \downarrow \\ X \times X, \end{array}$$



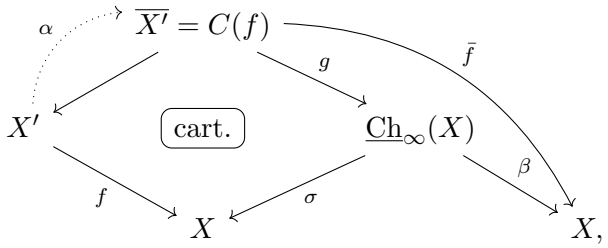
il faut avoir fixé un système projectif

$$\underline{t} = (t_n)_{n \in \mathbf{N}}$$

dans $\underline{\mathrm{Ty}}$ qui soit cofinal dans $\underline{\mathrm{Ty}}$, ce qui signifie simplement que parmi les t_n il y en a de [page 138] longueur utile arbitrairement grande (et comme

$$n \longmapsto \text{long.ut.}(t_n)$$

est croissante, cela implique que long.ut.(t_n) tend vers $+\infty$ pour $n \longrightarrow +\infty$). Les faits principaux à vérifier ensuite (si faire se peut) sont les propriétés essentielles des flèches dans le diagramme p. 86



$$\left|\begin{array}{l} \sigma\tau = \beta\tau = \mathrm{id}_X \\ p\tau = \mathrm{diag}_X \end{array}\right.$$

et plus généralement, pour une flèche

$$X' \xrightarrow{f} X$$

dans Cat, des flèches dans le diagramme correspondant

$$\bar{f}\alpha = (\beta g)\alpha = f,$$

et plus particulièrement de βg. La flèche en pointillés α est la section de $\overline{X'}$ sur X' déduite de [page 139]

la section τ de $\underline{\mathrm{Ch}}_\infty(X)$ sur X qui réalise la décomposition de f en

$$X' \xrightarrow{\alpha} \overline{X'} \xrightarrow{\bar f} X,$$

où $\bar f$ devrait être une flèche *'fibrante'* et une Hot-équivalence, α une flèche *'cofibrante'* au sens de Thomason. (Mais s'il en est ainsi, est à voir!) Voici pour le moment les propriétés essentielles que je voudrais vérifier.

Commentary · Exposition [ms. 139]

The two maps in a mapping-path factorization

Grothendieck turns from representing an external Hom to replacing a map by its homotopy fibres. This change of purpose makes the endpoints decisive. Put $E = \underline{\mathrm{Ch}}_\infty(X)$, with source σ, target β, and constant-path section i. Then

$$C(f) = X' \times_{X,\sigma} E, \quad r : C(f) \longrightarrow X', \quad \bar f = \beta\,\mathrm{pr}_E, \quad \alpha(x') = (x', i(fx')).$$

The strict identities are $r\alpha = \mathrm{id}$ and $\bar f\alpha = f$. Geometrically, r forgets a path whose initial point is prescribed; its fibre should be contractible. The other map remembers the final point; its fibre should be the homotopy fibre of f. Thus the weak equivalence is α, whereas $\bar f$ is a weak equivalence exactly when f is. The sentence on ms. 139 that attaches the unconditional weak-equivalence assertion to $\bar f$ is contradicted by item 3° immediately below it.

Once r is known to be a weak equivalence, the rest of this assertion uses only two-out-of-three. Since $r\alpha = \mathrm{id}$, the section α is a weak equivalence. Since $\bar f\alpha = f$, the maps f and $\bar f$ are weak equivalences simultaneously. Neither inference says that α is a Thomason cofibration, or that $\bar f$ is a Thomason fibration. Smoothness and properness concern the homotopy exactness of base change, while Thomason's chosen fibrations are tested by $\mathrm{Ex}^2 N$. Their definitions must not be interchanged.

The cofibration expectation actually fails for the unaltered constant-path inclusion. Take $f = \mathrm{id}_X$ with $X = [1]$. A nonconstant alternating path from 0 to 1, padded by identity arrows, admits a natural transformation to the constant path at 1: at a vertex labelled 0 use $0 \to 1$, and at a vertex labelled 1 use its identity. Hence the image of $\alpha : X \to E$ is not a sieve. Every Thomason cofibration is a pseudo-Dwyer map and therefore a sieve (Raptis, 2010, §2, following Proposition 2.4). Thus α need not be a Thomason cofibration. This does not damage the intended homotopy-fibre replacement; it limits the proposed identification with a particular model-category factorization.

The expectation that $\bar f$ is always a Thomason fibration also fails directly. Take $X = e$. Since $\underline{\mathrm{Ch}}_\infty(e) = e$ strictly, the construction gives $C(f) = X'$ and $\bar f = f : X' \to e$. Choosing $X' = D$, the nonfibrant crown of the preceding development, gives a counterexample. The homotopical lifting properties proved later do not impose Thomason fibrancy on an arbitrary category mapping to e.

The properties in items 1°–3° are requirements at this stage of the manuscript. Their proofs begin only after the concrete symmetric model is fixed on ms. 145. We will use them in that order, rather than reading the list as an already established theorem for an unspecified projective system.

1°) p est lisse et propre, et est une HOT-fibration.

2°) Donc il en est de même de $\sigma = \mathrm{pr}_1 p$ et $\beta = \mathrm{pr}_2 p$. De plus, ce sont des HOT-fibrations *triviales,* i.e. à fibres asphériques.

3°) Plus généralement (pour ce qui concerne β), $\overline{X'} \xrightarrow{\bar f} X$ devrait encore être propre et lisse et une HOT-fibration, mais bien sûr en général pas triviale. (Elle devrait être triviale si et seulement si f est une Hot-équivalence.) ([30]). p. 87

Un mot sur la 'dualité'. Les énoncés sur σ (resp. β) se traduisent en énoncés sur β (resp. σ) par passage de $\underline{t}$ à $\underline{t}^o = (t^o_n)$, où $\tau \longmapsto \tau^o$ est le foncteur dans $\underline{\mathrm{Ty}}$ 'passage à l'intervalle opposé'. On a en effet

un isomorphisme fonctoriel en X (passage au chemin opposé)

$$\boxed{\begin{array}{ccc} c & \longmapsto & c^o \\ \underline{\mathrm{Ch}}^t_\infty(X) & \longrightarrow & \underline{\mathrm{Ch}}^{t^o}_\infty(X) \end{array}} \qquad ([31]) \qquad [\text{page } 140]$$

30. résulte formellement de 1° et 2°, cf. page 170.

qui 'échange source et but'. Bien sûr, on a intérêt à prendre $\underline{t}$ tel qu'on ait $\underline{t} = \underline{t}^o$ (c'est ce que j'avais fait, par un sain instinct, dès le début dans V), de sorte qu'on a un foncteur involutif canonique

$$\begin{array}{ccc} c & \longmapsto & c^o \\ \underline{\mathrm{Ch}}_\infty(X) & \longrightarrow & \underline{\mathrm{Ch}}_\infty(X) \end{array}$$

(je laisse tomber à nouveau l'exposant $\underline{t}$), qui 'échange source et but'. Donc on trouve, à isomorphisme canonique près, la 'même' factorisation de $f : X' \longrightarrow X$ en $\bar{f} \circ \alpha$, si on fait comme dans page 38 pour définir $\overline{X'}$ et α, ou si dans ce diagramme on intervertit les rôles de σ et de β.

Commentary · Exposition [ms. 140]

Two different reversals

Grothendieck needs two symmetries because two different operations are being compared: exchanging the endpoints of a path, and replacing the ambient category by its opposite. For a signed word $\tau = (\varepsilon_1, \dots, \varepsilon_r)$, with $\varepsilon_i \in \{+, -\}$, write

$$\tau^o = (-\varepsilon_r, \dots, -\varepsilon_1), \qquad \tau^- = (-\varepsilon_1, \dots, -\varepsilon_r).$$

The first operation reverses the ordered interval. It is an anti-automorphism of concatenation and interchanges source and target without changing X. The second reverses every categorical arrow while preserving the ordering of the vertices. It is an automorphism of concatenation and is the operation accompanying $X \mapsto X^{\mathrm{op}}$.

At a fixed stage the corresponding identities are obtained by reindexing diagrams and natural transformations:

$$\underline{\mathrm{Ch}}_\tau(X) \cong \underline{\mathrm{Ch}}_{\tau^o}(X), \qquad \underline{\mathrm{Ch}}_\tau(X^{\mathrm{op}}) \cong \underline{\mathrm{Ch}}_{\tau^-}(X)^{\mathrm{op}}.$$

The first identity is understood over the transposition of $X \times X$; the second is over $(X \times X)^{\mathrm{op}}$. Passing through the specified transition maps gives the identities for projective systems. For $\tau_0 = \Delta_+\Delta_-$ one has $\tau_0^o = \tau_0$ but $\tau_0^- = \Delta_-\Delta_+$. This explains why path reversal becomes a strict involution in the symmetric model, while categorical duality initially changes its parity. The translation introduced on ms. 147 supplies the remaining comparison. The commentary at manuscript p. 9 already distinguishes these operations; here their role is to transfer the endpoint and base-change assertions.

Enfin :

4°) Si

$$c : a \longrightarrow b$$

est un chemin quelconque dans X, on voudrait en conclure un isommorphisme dans Hot (de 'transport par c')

$$\overline{X'}_a \xrightarrow[\sim]{\bar{c}} \overline{X'}_b,$$

avec bien sûr transitivité pour la composition,
ce qui donnera aussi

$$\overline{c^{\mathrm{opp}}} = \bar{c}^{-1}$$ [page 141]

(en admettant que les chemins triviaux $a \xrightarrow{\mathrm{id}} a$ donnent l'identité $\overline{X'}_a \xrightarrow[\sim]{\mathrm{id}} \overline{X'}_a$!) ([32, 33]). Bien sûr, $\bar{c}$ ne doit dépendre que de la *classe d'homotopie* de $\bar{c}$ (dans $\underline{\mathrm{Ch}}_\tau(X; a, b)$, ou même dans $C = \underline{\mathrm{Ch}}(X; a, b)$, catégorie de tous les chemins dans X, de a vers b, de type non précisé). En d'autres termes, on doit avoir un foncteur p. 88

$$\begin{array}{ccc} \Pi(X) & \longrightarrow & \mathrm{Hot} \\ a & \longmapsto & \mathrm{hot}(\overline{X'}_a) \end{array}$$

31. cf. page 143 pour le passage de $\underline{t}$ à $\underline{t}^-$.
32. Surtout pas se borner au cas où c serait un des t_n!
33. décrire quand-même l'effet sur les π_0!

du groupoïde fondamental de X dans Hot. À vrai dire, ceci n'a rien à voir avec la situation particulière étudiée ici - ça doit marcher chaque fois qu'on a une HOT-fibration, ici $\overline{X'} \longrightarrow X$, mais aussi $\underline{\mathrm{Ch}}_\infty(X) \longrightarrow X \times X$ ([34]). Et pour une $\mathbf{D}$-fibration $X' \longrightarrow X$ ($\mathbf{D}$ un dérivateur quelconque), et $a \in \mathbf{D}(e)$, on doit avoir de même deux foncteurs

$$\Pi(X) \rightrightarrows \mathbf{D}(e)$$

correspondant à

$$\begin{cases} x & \longmapsto & H^\bullet_{\mathbf{D}}(X'_x, \bullet) \\ x & \longmapsto & H^{\mathbf{D}}_\bullet(X'_x, \bullet). \end{cases}$$

Le cas qui nous occupe ici serait celui où $\mathbf{D} = \mathrm{HOT}$, où on prend $H^{\mathbf{D}}_\bullet$, et $a =$ objet final de $\mathbf{D}(e) =$ Hot.) [page 142]

5°) Si 1°, 2°, 3° sont vérifiés, on est moralement sûr que la construction des $\underline{\mathrm{Ch}}_\infty(X)$ est bel et bien l'équivalent exact du formalisme de Cartan-Serre. Pour en avoir le cœur totalement net, i.e. raccrocher explicitement cette théorie aux constructions classiques, il faudrait prouver un *énoncé de comparaison* avec la théorie semi-simpliciale, qui dirait essentiellement ceci : Si on désigne, pour X dans Cat, par $\tilde{X}$ l'objet associé dans $\mathbf{\Delta}^\wedge$ (le 'nerf' de X), alors la flèche

$$\underline{\mathrm{Ch}}_\infty(X)^\sim \longrightarrow \underbrace{(X \times X)^\sim}_{\simeq \tilde{X} \times \tilde{X}}$$

dans $\mathbf{\Delta}^\wedge/(X \times X)^\sim$, est W-équivalente sur $(X \times X)^\sim$ à la flèche

$$\underline{\mathrm{Ch}}(\tilde{X}) \longrightarrow \tilde{X} \times \tilde{X}$$

de la théorie semi-simpliciale des chemins (à supposer qu'il y ait une telle flèche classique définie pour *tout* objet X de $\mathbf{\Delta}^\wedge$). Ou qu'on ait tout au moins des isomorphismes canoniques dans Hot

$$\mathrm{hot}_{\mathrm{Cat}}(\underline{\mathrm{Ch}}_\infty(X; a, b)) \;\simeq\; \mathrm{hot}_{\mathbf{\Delta}^\wedge}(\underline{\mathrm{Ch}}(\tilde{X}; \tilde{a}, \tilde{b})).$$

Commentary · Later developments [ms. 142]

Transport and the comparison with ordinary path spaces

Grothendieck wants the replacement to remember how its fibres vary, and his marginal request to compute π_0 is the right concrete test. For the ordinary mapping-path construction, a point in the homotopy fibre at a is a pair (x', γ) with $\gamma : f(x') \rightsquigarrow a$. Transport along $c : a \rightsquigarrow b$ sends it to

$$(x', \gamma * c).$$

Homotopic paths give homotopic maps of fibres; concatenation and reversal give composition and inverse in the homotopy category. This produces the functor from the fundamental groupoid requested in item 4°. It is a truncation of the coherent family of fibres. A functor into Hot alone need not retain all that family's higher twisting, a distinction already illustrated in the commentary on Chapter VI, manuscript pp. 7 and 74.

For a connected pointed map $f : (X', x'_0) \to (X, a)$, this transport has an explicit component formula. Set $G = \pi_1(X, a)$ and $H = \operatorname{im} \pi_1(f)$. Then

$$\pi_0 \operatorname{hofib}_a(f) \cong H \backslash G.$$

To see the formula, join x'_0 to x' by a path δ. The pair (x', γ) determines the loop $f\delta * \gamma$. A different δ multiplies its class on the left by an element of H. Conversely, a homotopy of pairs gives precisely this relation, by tracing the path of their first coordinates; any such relation is realized by that construction. A loop c at a therefore acts by right multiplication $Hg \mapsto Hg[c]$. For the inclusion $2\mathbb{Z} \subset \mathbb{Z}$, viewed as a map of one-object groupoids, there are two components and a generator of the

34. Ici aussi, il faudrait décrire l'effet du transport $\bar{c}$ sur les π_0 des fibres.

base interchanges them. This answers the request about π_0 without choosing representatives in a categorical lifting category.

There is a functorial simplicial path object for every simplicial set K, not only for a Kan complex. Choose a functorial Kan replacement $K \to RK$ and put

$$P(K) = (K \times K) \times_{RK \times RK} (RK)^{\Delta^1}.$$

Its endpoint map is a Kan fibration. The constant-path map $K \to P(K)$ is a weak equivalence: right properness first identifies $P(K) \to (RK)^{\Delta^1}$ as a weak equivalence, and evaluation identifies the latter with RK. Apply this with $K = NX$. Once $i : X \to \underline{\mathrm{Ch}}_\infty(X)$ has been proved a weak equivalence, the span

$$N\underline{\mathrm{Ch}}_\infty(X) \longleftarrow NX \longrightarrow P(NX)$$

is already a zigzag of weak equivalences over $NX \times NX$. This gives the first form of comparison in item 5°. Identifying the *strict* endpoint fibres with ordinary path spaces still requires the homotopy-fibre property of the categorical endpoint map; a weak equivalence of total spaces over a base does not by itself identify strict fibres.

For a general coefficient $A \in \mathbb{D}(e)$, the analogous homology transport is covariant; cohomology transport uses pullback along the inverse fibre equivalence. These constructions require the homotopy base-change isomorphisms appropriate to the stated $\mathbb{D}$-fibration.

The later theory of locally constant diagrams makes the distinction between a coherent family and its monodromy systematic (Cisinski, 2009, Theorem 1.3 and the discussion preceding it). The language of straightening provides a higher-categorical model of the family itself (Lurie, 2009, Theorem 2.2.1.2). These results explain the final form of the construction; the elementary fibre comparison remains the work that this chapter undertakes.

Dans 1° et 3°, on veut prouver que certaines flèches (p et $\bar{f}$) sont à la fois *propre* et *lisse* - ce qui est vraiment idéal ! Je dis qu'il suffit à chaque fois de prouver l'un des deux, que l'autre s'en déduit (comme 'cas particulier') par dualité. Pour ceci, notons p. 89 [page 143]

$$\tau \longmapsto \tau^-$$

l'automorphisme (*pas anti*-automorphisme) de $\underline{\mathrm{Ty}}$ qui consiste à changer de signe toutes les flèches de transition - c'est donc, au niveau des objets, l'unique automorphisme du monoïde libre Ty, qui échange Δ_+ et Δ_-. Au système projectif $\underline{t}$ dans $\underline{\mathrm{Ty}}$ correspond le système projectif $\underline{t}^-$. Ceci dit, on a un isomorphisme de catégories

$$\boxed{\underline{\mathrm{Ch}}^{\underline{t}}_\infty(X^o) \simeq (\underline{\mathrm{Ch}}^{\underline{t}^-}_\infty(X))^o} \tag{35}$$

et le diagramme commutatif

$$\begin{array}{ccc} \underline{\mathrm{Ch}}^{\underline{t}}_\infty(X^o) & \xrightarrow{\sim} & \underline{\mathrm{Ch}}^{\underline{t}^-}_\infty(X)^o \\ \downarrow{\scriptstyle p^{\underline{t}}_{X^o}} & & \downarrow{\scriptstyle (p^{\underline{t}^-}_X)^o} \\ X^o \times X^o & = & (X \times X)^o. \end{array}$$

Ainsi, dire que $p^{\underline{t}}_X$ `[plutôt` $p^{\underline{t}^-}_X$`]` est lisse, i.e. que $(p^{\underline{t}}_X)^o$ `[plutôt` $(p^{\underline{t}^-}_X)^o$`]` est propre, équivaut à dire que $p^{\underline{t}}_{X^o}$ est propre.

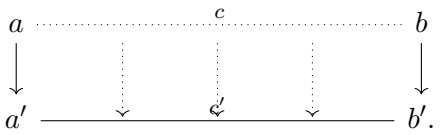
Il nous reste donc, à ce sujet, que deux faits à vérifier : la lissité de $p : \underline{\mathrm{Ch}}_\infty(X) \longrightarrow X \times X$, et celle de $\bar{f} : \overline{X'} \longrightarrow X$. [page 144]

a) Lissité de $p : \underline{\mathrm{Ch}}_\infty(X) \longrightarrow X \times X$. On se donne une flèche

$$w : (a, b) \longrightarrow (a', b'), \qquad \text{i.e.} \quad \begin{cases} u : & a & \longrightarrow & a' \\ v : & b & \longrightarrow & b', \end{cases}$$

35. cf. page 140 pour le passage de $\underline{t}$ à $\underline{t}^o$.

sur la base, un objet c' au dessus du but, i.e.



$$c' \in \underline{\mathrm{Ch}}_\infty(X; a', b'),$$

et on regarde la catégorie des flèches dans $\underline{\mathrm{Ch}}_\infty(X)$, de but c', qui relèvent w,

$$\begin{array}{ccc} \underset{\text{variable}}{c} & \xrightarrow{\varphi} & \underset{\text{fixe}}{c'} \\ \Big| & & \Big| \\ (a,b) & \xrightarrow{w} & (a',b'), \end{array}$$

i.e. la catégorie des couples (c, φ), où p. 90

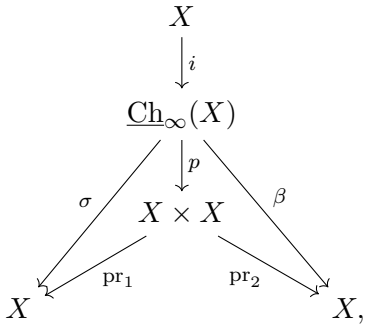
$$\begin{cases} c \in \underline{\mathrm{Ch}}_\infty(X; a, b) \\ \varphi : c \longrightarrow c' \quad (\in \underline{\mathrm{Ch}}_\infty(X; a', b')) \\ \text{une flèche induisant} \quad \begin{array}{ll} u & \text{sur les sources} \\ v & \text{sur les buts,} \end{array} \end{cases}$$

[page 145]

9.11.90

Commentary · Exposition [ms. 144]

Why a category of lifts is the right test



Grothendieck now replaces the geometric word "smooth" by a calculation that can be carried out on paths. Fix an arrow $w : b \to b'$ in a base B and an object e' above b'. For $p : E \to B$, the relevant category has objects (e, φ) with $p(e) = b$ and $\varphi : e \to e'$ satisfying $p(\varphi) = w$. A morphism from (e, φ) to (e_1, φ_1) is a vertical map $h : e \to e_1$ with $\varphi_1 h = \varphi$. Thus one must control both existence of lifts and the homotopy type of the space of choices.

This is exactly a comma category for the inclusion $E_b \to b\backslash E$. Requiring it to be contractible for every (e', w) says that this inclusion is aspherical. The equivalence with smoothness is the criterion of Maltsiniotis (2005, Theorem 1.2). In the present case $B = X \times X$ and $w = (u, v)$. The annotation placing φ inside $\underline{\mathrm{Ch}}_\infty(X; a', b')$ cannot be literal: its source has endpoints (a, b), so it is a morphism of the total path category over (u, v).

The next construction is designed to make these comma categories manageable. At a finite interval whose two endpoint arrows point into the interior, a lift is obtained by changing the two endpoints and composing with u and v. This is a Cartesian lift, hence a terminal object in the corresponding category of lifts. To deal with a path already lying in some stage, enlarge its support to a stage with the required endpoint parity. The filtered union then accommodates every finite diagram in the lifting category. This is why the two-index system introduced next is useful: it permits the same infinite path category to be approached by finite stages suited separately to incoming and outgoing lifts.

The proof of properness uses the opposite variance, as the duality formula on ms. 143 indicates. It does not follow from the mere existence of one lift, nor from a statement about the homotopy type of the total path category. The full calculation is carried out on ms. 150–153.

Pour la question précédente, relative aux flèches dans le diagramme

il faut préciser absolument la déscription de $\underline{\mathrm{Ch}}_\infty(X)$ *dans* Cat, donc il faut préciser le système projectif $\underline{t} = (t_n)_{n\in\mathbf{N}}$. Nous allons prendre en effet

$$t_n = (\underbrace{\Delta_+\Delta_-}_{\tau_0})^{2n},$$

avec les morphismes de transition décrits par ailleurs

$$\underbrace{t_{n+p}}_{=\tau_0^{2n+2p}} \longrightarrow \underbrace{t_n}_{\tau_0^n},$$

étant donnés par $\delta_p * \mathrm{id}_{\tau_o^{2n}} * \delta_p$, où $\delta_p : \tau_0^p \longrightarrow 1$ est la dégénérescence de τ_0^p. Ainsi on peut considérer $\underline{\mathrm{Ch}}_\infty(X)$ comme étant la catégorie des chemins biïnfinis dans X p. 91

$$\overbrace{\overbrace{\overbrace{\cdots \longrightarrow a_{-5} \longleftarrow a_{-4} \longrightarrow a_{-3} \xleftarrow{u_{-2}} a_{-2} \xrightarrow{u_{-1}} a_{-1} \xleftarrow{u_0} a_0 \xrightarrow{u_1} a_1 \xleftarrow{u_2} a_2 \xrightarrow{u_3} a_3 \longleftarrow a_4 \longrightarrow a_5 \longleftarrow \cdots,}^{\underline{\mathrm{Ch}}_0}}^{\underline{\mathrm{Ch}}_1}}^{\underline{\mathrm{Ch}}_2}$$

avec les u_i des identités pour $|i|$ assez grand.

La sous-catégorie (pleine)

$$\underline{\mathrm{Ch}}^W_{t_n}(X) \;=\; \underline{\mathrm{Ch}}^W_{(\Delta_+\Delta_-)^{2n}}$$

s'identifie à celle pour laquelle on a

> u_i une identité pour $i \notin [-2i+1, 2i]$, i.e. les seuls u_i 'significatifs' sont les $4i$ flèches u_{-2i+1}, u_{-2i+2}, …, u_{2i}.

Mais il sera plus commode de regarder $\underline{\mathrm{Ch}}_\infty(X)$ comme la limite inductive d'une famille à deux indices de sous-catégories pleines [page 146]

$$\underline{\mathrm{Ch}}_{n,m}(X), \qquad n, m \in \mathbf{Z},$$

en définissant cette catégorie comme *vide* si $n > m$, et pour $n \le m$ comme formée des objets

$$\begin{cases} (a_i, u_i)_{i\in\mathbf{Z}} \in \underline{\mathrm{Ch}}^W_{n,m}(X) \iff u_i \text{ une identité pour } i \notin [n, m-1] \\ \overset{\mathrm{id}}{\cdots} a_{n-1} \xrightarrow{\mathrm{id}} \underbrace{a_n \xrightarrow{u_n} a_{n+1} \cdots \longrightarrow a_{m-1} \xrightarrow{u_{m-1}} a_m}_{\text{'partie utile' du chemin}} \xrightarrow{\mathrm{id}} a_{m+1} \overset{\mathrm{id}}{\cdots}. \end{cases}$$

Donc pour $n = m$, on trouve la sous-catégorie pleine isomorphe à X, formée des chemins infinis 'totalement dégénérés', i.e. tels que *toutes* les u_i soient des identités. (Cette sous-catégorie de $\underline{\mathrm{Ch}}_\infty$ ne dépend donc pas du choix de $n = m$.)

$$\xrightarrow{\mathrm{id}} \underbrace{a_{-1}}_{=a} \xleftarrow{\mathrm{id}} \underbrace{a_0}_{=a} \xrightarrow{\mathrm{id}} \underbrace{a_1}_{=a} \xleftarrow{\mathrm{id}}$$

Tous les sommets d'un tel chemin sont égaux à un même objet de X, et les flèches de transition entre eux sont identiques.

La structure de $\underline{\mathrm{Ch}}^W_{n,m}(X) \simeq \underline{\mathrm{Ch}}^W_{\tau_{n,m}}(X)$ ne dépend que de la longueur $m-n$ de $\tau_{n,m}$ et de la *parité* de n. Si n est pair, la direction initiale de $\tau_{n,m}$ est positive, et

$$\tau_{n,m} = \underbrace{\Delta_+\Delta_-\cdots}_{m-n \text{ facteurs en alternance}} = \begin{cases} (\Delta_+\Delta_-)^{\frac{m-n}{2}} & \text{si } m \text{ pair} \\ (\Delta_+\Delta_-)^{\frac{m-n}{2}-1}\Delta_+ & \text{si } m \text{ impair} \end{cases}$$

[plutôt $\frac{m-n-1}{2}$ au lieu de $\frac{m-n}{2}-1$], tandis que pour n impair c'est juste l'inverse

p. 92
[page 147]

$$\tau_{n,m} = \underbrace{\Delta_-\Delta_+\cdots}_{m-n \text{ facteurs alternés}} = \begin{cases} (\Delta_-\Delta_+)^{\frac{m-n}{2}} & \text{si } m \text{ impair} \\ (\Delta_-\Delta_+)^{\frac{m-n}{2}-1}\Delta_- & \text{si } m \text{ pair} \end{cases}$$

[plutôt $\frac{m-n-1}{2}$ au lieu de $\frac{m-n}{2}-1$]. La direction initiale est conforme à la parité de n, i.e. égale à $(-1)^n$, tandis que la direction terminale est opposée à la parité de m, i.e. égale à $(-1)^m$ [plutôt $(-1)^{m+1}$].

Commentary · Exposition [ms. 147]

Finite support and endpoint parity

Grothendieck's two-sided sequence makes the eventual constancy of a path concrete. Its advantage is that support may be enlarged independently at the two ends. To avoid the shift in edge numbering between ms. 145 and ms. 146, write e_i for the edge joining a_i and a_{i+1}, directed forwards for even i and backwards for odd i. Thus e_i is the u_{i+1} of the large diagram on ms. 145. A path supported on $[n,m]$ has e_i equal to an identity outside $n \le i < m$.

For $n < m$, the source-end sign is $(-1)^n$ and the target-end sign is $(-1)^{m-1} = (-1)^{m+1}$. The four cases are

n mod 2	m mod 2	initial sign	terminal sign
0	0	+	−
0	1	+	+
1	0	−	−
1	1	−	+

For an odd length $m-n$, the number of full two-letter blocks is $(m-n-1)/2$; this is the correction already supplied by the editors in both displayed formulas. When $n = m$ there are no endpoint arrows and the subcategory is the constant-path copy of X; the sign table is not intended for that degenerate case.

The inclusion for $n' \le n \le m \le m'$ extends a diagram by identity arrows. It is fully faithful, since a natural transformation is forced to be constant on each identity tail. Every eventually constant path and every natural transformation between two such paths belongs to a sufficiently large common support interval. Hence the filtered colimit of these full subcategories is the asserted category of two-sided paths, on morphisms as well as objects. The even-even intervals form a cofinal family of support intervals, and so do the odd-odd intervals. The first family has both endpoint arrows pointing into the interval and is adapted to Cartesian lifts; the second has both pointing out and is adapted to coCartesian lifts. Cofinality here is the ordinary directedness of support intervals, not an assertion that a fixed inclusion of categories is a weak equivalence.

Je note que l'on a $\tau_0 = (\tau_0)^o$, d'où

$$\underline{t} = \underline{t}^o, \qquad \text{mais } \underline{t} \neq \underline{t}^-,$$

et pourtant on a des isomorphismes fonctoriels en X

$$\underline{\mathrm{Ch}}_{\underline{t}}(X) \simeq \underline{\mathrm{Ch}}_{\underline{t}^-}(X)$$

respectant source et but, à cause d'un isomorphisme

$$\underline{t} \simeq \underline{t}^- \qquad \text{dans } \mathrm{Pro}(\underline{\mathrm{Ty}}).$$

On peut dire p. ex. que le *foncteur translation* T^p d'amplitude p (pour $p \in \mathbf{Z}$) est défini sur $\underline{\mathrm{Ch}}^W_{\underline{t}}(X)$, par

$$\left\{ \begin{array}{l} T^p(((a_i),(u_i))_{i\in\mathbf{Z}}) = ((b_j),(v_j))_{j\in\mathbf{Z}} \\ \text{avec} \left\{ \begin{array}{lcl} b_j & = & a_{j-p} \\ v_j & = & u_{j-p} \end{array} \right. \end{array} \right.$$

et que

$$T^p : \left\{ \begin{array}{lcl} \underline{\mathrm{Ch}}_t(X) & \xrightarrow{\sim} & \underline{\mathrm{Ch}}_{-t}(X) \\ \underline{\mathrm{Ch}}_{-t}(X) & \xrightarrow{\sim} & \underline{\mathrm{Ch}}_t(X) \end{array} \right\} \text{ si } p \text{ impair}$$

$$T^p : \left\{ \begin{array}{lcl} \underline{\mathrm{Ch}}_t(X) & \xrightarrow{\sim} & \underline{\mathrm{Ch}}_t(X) \\ \underline{\mathrm{Ch}}_{-t}(X) & \xrightarrow{\sim} & \underline{\mathrm{Ch}}_{-t}(X) \end{array} \right\} \text{ si } p \text{ pair.}$$

En d'autres termes, on peut formellement regarder la catégorie somme [page 148]

$$\underline{\mathrm{Ch}}_{\pm}(X) = \underline{\mathrm{Ch}}_{+}(X) \amalg \underline{\mathrm{Ch}}_{-}(X)$$

et l'opération translation T comme un automorphisme qui échange les deux morceaux, et T^p n'est autre que son itéré p-ème, qui échange les morceaux $+$ et $-$ si p impair, qui les stabilise si p pair.

Il y a aussi l'automorphisme involutif de passage au chemin opposé, qui échange source et but, et que je définis (conformément à l'isomorphisme canonique identique p. 93

$$\underline{t} \xrightarrow{\sim} \underline{t}^o \quad)$$

comme la symétrie S

$$\left\{ \begin{array}{l} S((a_i),(u_i)) = ((b_j),(u_j)) \ \text{ avec} \\ \quad b_j \ = \ a_{-j} \\ \quad u_j \ = \ u_{-j+1}. \end{array} \right.$$

Si je le regarde comme opérant sur $\underline{\mathrm{Ch}}^W_{\pm}(X)$, il est lié au foncteur T par

$$\left\{ \begin{array}{rcl} S^2 & = & \mathrm{id} \\ STS^{-1} & = & T^{-1}, \end{array} \right.$$

de sorte que c'est le groupe semidirect de $\mathbf{Z}/2\mathbf{Z}$ par $\mathbf{Z}$ (groupe affine de dimension 1 de l'anneau $\mathbf{Z}$) qui opère sur $\underline{\mathrm{Ch}}_{\pm}$.

Commentary · Examples [ms. 148]

The dihedral action on a two-sided path

Grothendieck introduces translations to compare the two parity choices without changing either endpoint. In the edge convention of the preceding block, translation and reversal are

$$(T^p a)_j = a_{j-p}, \quad (T^p e)_j = e_{j-p}, \qquad (Sa)_j = a_{-j}, \quad (Se)_j = e_{-j-1}.$$

These formulas apply equally to the components of a natural transformation, so they define functors, not merely permutations of the objects. Since paths are eventually constant, translation leaves both eventual values unchanged; reversal exchanges them. Odd translation reverses parity, whereas even translation preserves it. Reversal preserves each parity convention because reversing the direction of an edge also reverses the parity of its index.

The group relations are identities of functors. On vertices,

$$(S^2 a)_j = a_j, \qquad (STSa)_j = a_{j+1} = (T^{-1}a)_j,$$

and substitution in the edge formula gives the same equalities on edges and natural transformations. The acting group is therefore

$$D_\infty = \mathbb{Z} \rtimes \mathbb{Z}/2, \qquad (\epsilon, k) : j \longmapsto \epsilon j + k, \quad \epsilon \in \{1, -1\}.$$

The integer subgroup is the translation subgroup and reflection acts on it by inversion. This specifies the semidirect-product convention independently of the order of the groups in the French phrase.

For example, a path with one nonidentity edge $e_0 : x \to y$ is carried by T^2 to the same edge at position 2, with two additional identity positions on one side and two fewer on the other. Both have source x and target y, but they are different objects of the strict path category. The formulas above prove an isomorphism of categories and the dihedral relations. They do not by themselves prove that T^2 is the identity after passage to Hot. This is the specific coherence question taken up on the next page. It should be resolved by a homotopy or a comparison of the relevant diagrams, not by treating coordinate translation as literal equality.

[page 149]

On est embarassé de trouver un automorphisme T^2 de la situation $\underline{\mathrm{Ch}}_\infty(X) \longrightarrow X \times X$, sans qu'il soit évident que dans Hot, ce foncteur induise l'identité! Je ne vois aucun moyen de relier un chemin c et T^2c par une flèche dans $\underline{\mathrm{Ch}}_\infty$, ni même pas un chemin 'canonique'. Mais je me dis que cet automorphisme est décrit par un automorphisme, non pas du système projectif

$$(\tau_{n,m})_{n,m \in \mathbf{Z}^o \times \mathbf{Z},\ n \le m}$$

(où $\mathbf{Z}^o$ désigne l'ensemble ordonné *opposé* de $\mathbf{Z}$), mais du *pro-objet* de $\underline{\mathrm{Ty}}$ qu'il définit (qui est bien sûr 'le même' pour tous les systèmes projectifs cofinaux à gauche dans $\underline{\mathrm{Ty}}$). Il en résulte déjà que T^2 induit l'identité sur l'ind-objet de Cat hot, $\underline{\underline{\mathrm{Ch}}}_\infty(X)$, et a fortiori sur l'ind-objet correspondant de Hot, ou de $\mathrm{Hot}_0^\wedge$, ou enfin pour l'objet de $\mathrm{Hot}_0^\wedge$ lui-même. De même pour les $\underline{\mathrm{Ch}}_\infty(X; a, b)$. Il s'ensuit, revenant à $\underline{\mathrm{Ch}}_\infty(X)$ lui-même et aux $\underline{\mathrm{Ch}}_\infty(X; a, b)$, que l'automorphisme induit par T^2 est l'identité dans $\mathrm{Hot}_0^\wedge$. J'espère que Hot $\longrightarrow \mathrm{Hot}_0^\wedge$ est tout au moins fidèle, de sorte que ça prouvera que T^2 induit l'identité dans Hot également. [page 150]

Je reviens aux questions 1° à 4° d'il y a quelques jours.

Pour 1°), il faut prouver que

$$p : \underline{\mathrm{Ch}}_\infty(X) \longrightarrow X \times X$$

est lisse et propre et une Hot-fibration. Par dualité, p propre résultera de p lisse. Mais $\underline{\mathrm{Ch}}_\infty(X)$ est $\varinjlim$ des $\underline{\mathrm{Ch}}_{n,m}(X)$, avec $n \longrightarrow -\infty$, $m \longrightarrow +\infty$, et où on peut se borner à n et m *pairs.* Or on voit que pour n, m pairs, i.e. $\tau_{n,m}$ à flèche initiale directe, à flèche finale

rétrograde, $\underline{\mathrm{Ch}}_{n,m}(X) \simeq \underline{\mathrm{Ch}}_{\tau_{n,m}}(X)$ est Cat-*fibrée* sur $X \times X$, donc lisse (i.e. HOT-lisse), p. 94
et cela passe aux $\varinjlim$ ([36]).

Ainsi $\underline{\mathrm{Ch}}_\infty(X) \xrightarrow{p} X \times X$ est à la fois propre et lisse ([37]). Dire que c'est une HOT-fibration, revient p. ex. à dire que pour

$$(a, b) \xrightarrow{(u,v)} (a', b')$$

dans $X \times X$, la flèche correspondante

$$\underline{\mathrm{Ch}}_\infty(X)/(a, b) \longrightarrow \underline{\mathrm{Ch}}_\infty(X)/(a', b')$$

est une Hot-équivalence. Or, comme p est propre, les inclusions des fibres en (a, b) et en (a', b') dans l'un et l'autre membre sont des Hot-équivalences : [page 151]

36. **NB** $\underline{\mathrm{Ch}}_\infty(X)$ n'est ni fibrée ni cofibrée sur $X \times X$ - car les foncteurs d'inclusion entre les $\underline{\mathrm{Ch}}_{n,m}$ ne sont pas cartésiens resp. cocartésiens.

37. 12.11. Mais ça implique déjà que c'est une fibration !

$$(*)\qquad \begin{array}{ccc} \underline{\mathrm{Ch}}_\infty(X)/(a,b) & \xrightarrow{\rho} & \underline{\mathrm{Ch}}_\infty(X)/(a',b') \\ \wr\uparrow & & \wr\uparrow \\ \underline{\mathrm{Ch}}_\infty(X;a,b) & \xrightarrow{\varphi} & \underline{\mathrm{Ch}}_\infty(X;a',b') \end{array}$$

Ainsi on trouve une flèche en pointillés dans Hot, dont il faut prouver que c'est une Hot-équivalence. Mais en considérant

$$u : a \longrightarrow a' \qquad v : b \longrightarrow b'$$

comme des *chemins* dans X, et

$$u^o : a' \longleftarrow a$$

comme un chemin rétrograde de a' à a, la théorie de variance générale (dans IX) nous donne bel et bien un isomorphisme dans (Hot) :

$$\underline{\mathrm{Ch}}_\infty(X;a,b) \longrightarrow \underline{\mathrm{Ch}}_\infty(X;a',b'),$$

on a envie de dire que c'est φ, i.e. qu'en l'insérant à la place de φ, le carré ci-dessus devient commutatif (ce qui prouverait ce qu'on veut). Je pense que si on travaille avec les ind-objets $\underline{\underline{\mathrm{Ch}}}_\infty(X)/(a,b)$, $\underline{\underline{\mathrm{Ch}}}_\infty(X;a,b)$ etc., pour lesquels on a des accouplements qui s'explicitent agréablement aux crans finis, et donnent naissance aux φ, cela devrait être facile (quoiqu'un peu fastidieux). Cela ne prouverait pas pour autant la commutativité de $(*)$ dans Hot, mais seulement dans $\mathrm{Hot}_0^\wedge$, ce qui n'est peut-être pas suffisant. Mais cela suffit pour prouver que la flèche ρ dans $(*)$ devient `[un]` isomorphisme dans $\mathrm{Hot}_0^\wedge$, donc elle est `[un]` isomorphisme. p. 95 [page 152]

Commentary · Exposition [ms. 150]

Why both parities give the endpoint fibration

Grothendieck wants the categorical path object to carry the same geometric information as an ordinary path fibration, before any fibrant replacement of X. The two ends of a finite zigzag already explain how this can happen. For a positive-length interval, when both endpoints are sources in the interval category, changing their values contravariantly only composes the two outer arrows; this gives a Grothendieck fibration over $X \times X$. When both endpoints are sinks, the analogous operation is covariant and gives an opfibration. The two parity choices, with positive length imposed, are cofinal among the finite supports of an eventually constant path. The zero-length case is the diagonal functor and must not be used in the fibration claim.

The passage to the filtered union deserves a proof, since the inclusion functors need not preserve Cartesian arrows. For a functor $q : E \to B$, an object $e \in E$, and an arrow $h : b \to q(e)$, put

$$L_q(e,h) = \{(d,\gamma) : q(d) = b,\ \gamma : d \to e,\ q(\gamma) = h\},$$

with morphisms over 1_b commuting with γ. Smoothness means that every such category is weakly contractible; properness has the dual outgoing-lift test. These are the fibre-to-comma criteria of Maltsiniotis (2005, Theorem 1.2 and its dual). Suppose $E = \varinjlim_i E_i$ over a filtered category, with all functors over B. Once e is represented at one stage, its lift category is the filtered colimit of the corresponding lift categories at later stages. Every object, arrow, and equation defining a finite simplex occurs at a stage, and every equality holds at some later stage. Nerves preserve these filtered colimits. A filtered colimit of weakly contractible simplicial sets is weakly contractible: after Ex^∞, which also commutes with filtered colimits, the assertions about based homotopy groups involve only finitely many simplices. Consequently smoothness and properness pass separately to this filtered colimit. Preserving Cartesian arrows is unnecessary.

It follows that $\underline{\mathrm{Ch}}_\infty(X) \to X \times X$ is smooth and proper. We can also justify directly the later marginal observation that these two conditions imply the required homotopy-fibre property. For $h : b \to b'$ in B, let M_h be the category of arrows $d \to d'$ in E over h, with its two projections to E_b and $E_{b'}$. Properness and smoothness show that these projections are weak equivalences. For example, the comma category under an object $d_0 \in E_b$ retracts, by precomposition, onto its outgoing-lift

category; the dual argument uses postcomposition. Quillen's Theorem A applies. The arrows defining M_h then give a natural transformation between its two maps into $b\backslash E$, the second obtained by precomposition from $b'\backslash E$. Since smoothness identifies each strict fibre with its under-comma category, precomposition

$$b'\backslash E \longrightarrow b\backslash E$$

is a weak equivalence. Quillen's Theorem B identifies the strict fibres with homotopy fibres (Quillen, 1973, §1, Theorem B). This proof also survives every base change. It establishes what the manuscript needs without the finite-test conservativity invoked on the following pages.

Commentary · Examples [ms. 151]

A homotopy fibration without Cartesian lifts

The warning in footnote 36 can be seen in the walking-arrow category $X = [1]$. It explains why a contractible category of choices is the appropriate conclusion, even when no best choice exists.

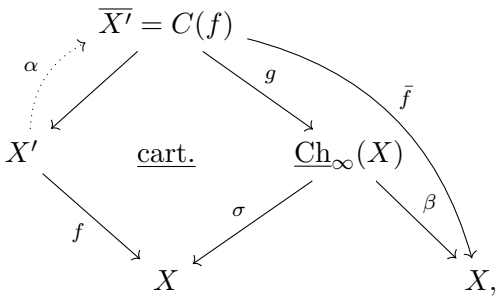
Consider the constant eventual path $c = 1$ and the base arrow $(0 \to 1, 1_1) : (0, 1) \to (1, 1)$. An incoming lift is precisely an eventual alternating path d from 0 to 1: its natural transformation to the constant path 1 is unique. If the endpoint map were a Grothendieck fibration, this lifting category would have a terminal object. Its arrows are pointwise inequalities between the 0–1 diagrams. For any candidate d, choose a direct edge far enough to the left that d is still constantly 0 there. Let e change from 0 to 1 across that edge and remain 1 afterwards. This is an allowed alternating path, because all its other edges are identities. At a vertex immediately after the chosen edge, e is 1 and d is 0, so there is no natural transformation $e \to d$. No terminal lift exists.

Dually, take the constant path 0 and the outgoing base arrow $(1_0, 0 \to 1)$. A cocartesian lift would give an initial object among paths from 0 to 1. For any candidate d, choose a single-step path whose direct transition is farther right than the point where d has become constantly 1. There is no arrow from d to this later-step path. Thus no initial lift exists either. The incoming and outgoing lift categories are nevertheless weakly contractible by the filtered-stage proof. This is the exact distinction between the two homotopical lifting properties proved here and an ordinary fibration or opfibration.

2°) Il faut montrer que les HOT-fibrations

$$\underline{\mathrm{Ch}}_\infty(X) \underset{\beta}{\overset{\sigma}{\rightrightarrows}} X$$

sont triviales, ou ce qui revient au même, qu'elles sont à fibres asphériques. Il suffit de le voir pour σ, donc que



$$\underline{\mathrm{Ch}}_\infty(X; a, ?)$$

est asphérique. Mais cette catégorie est la limite inductive des $\underline{\mathrm{Ch}}_n(X; a, ?)$, i.e. des

$$\underline{\mathrm{Hom}}^{\text{source fixée}}(\tau^n, X).$$

Mais comme l'intervalle I_{τ^n} se rétracte par déformation sur son origine, il est immédiat que cette catégorie $\underline{\mathrm{Hom}}$ est même contractile.

3°) Considérons

[page 153]

je voudrais prouver que $\bar{f}$ est une **D**-fibration propre et lisse ([38]).

Commentary · Exposition [ms. 152]

The contraction with one endpoint fixed

The next task is to make a path starting at a disappear while keeping its starting point fixed. This is stronger than knowing merely that the interval has contractible nerve, because an arbitrary weak equivalence of interval categories need not induce a weak equivalence of strict functor categories. Here the interval has an explicit categorical deformation, and that is enough.

Write its vertices as $0, \dots, r$, in their geometric order, with either orientation on each edge. For $0 \le k \le r$, define $r_k(j) = \min(j, k)$. Each $r_k : I \to I$ is a functor. Successive r_k, r_{k+1} are connected by a natural transformation in the direction of the edge between k and $k+1$: on the tail $j \ge k+1$ use that edge, and elsewhere use identities. Naturality follows on the generating edges, hence on all arrows. Every r_k fixes 0, while r_0 is constant and $r_r = 1_I$. Precomposition therefore joins the identity of $\mathrm{Fun}(I, X)_{a,?}$ to the constant functor at the constant path a_I, through a finite zigzag of natural transformations which is relative to the source. Its nerve is contractible.

Filtered colimits of these one-endpoint categories are weakly contractible by the finite simplicial argument just given. Thus both σ and β have weakly contractible strict fibres. Since they are smooth and proper, their pullbacks along arbitrary functors are weak equivalences. In the mapping-path construction, this universal statement is precisely what allows the category X' to replace X at the source endpoint. No supposition that X itself is a Thomason fibrant category enters this argument.

$\overline{X'}$ est la catégorie des couples

$$(x', c) \ \in \ \mathrm{Ob}\, X' \times \mathrm{Ch}_\infty(X)$$

tels que

$$\sigma(c) = f(x')$$

et

$$\bar{f}(x', c) = \beta(c), \qquad \text{but de } c.$$

La fibre de $\overline{X'}$, $\bar{f}$ en $x_0 \in X$ est donc la catégorie des couples $(x', c) \in \mathrm{Ob}\, X' \times \mathrm{Ch}_\infty(X)$, tels que

$$\sigma(c) = f(x'), \qquad \beta(c) = x_0.$$

On peut regarder encore $\overline{X'}$ comme limite inductive des sous-catégories $\overline{X'}_{n,m}$, correspondante aux couples (x', c) avec $c \in \mathrm{Ch}_{n,m}(X)$. On trouve que pour m pair (direction terminale de $\tau_{n,m}$ rétrograde) les $\overline{X'}_{n,m}$ sont Cat-fibrées sur X, pour m impair (direction terminale de $\tau_{n,m}$ directe) elles sont Cat-cofibrées. Donc on conclut encore comme tantôt, $\overline{X'}$ étant (au choix) limite inductive filtrante de sous-catégories lisses sur X, ou propres sur X. p. 96

Il faut prouver enfin que $\overline{X'} \xrightarrow{\bar{f}} X$ est une **D**-fibration ([39]), ce qui revient p. ex. à dire que pour une flèche [page 154]

$$a \xrightarrow{v} b$$

dans X, la flèche induite

$$\overline{X'}/a \xrightarrow{\bar{v}} \overline{X'}/b$$

est une Hot-équivalence. On sait déjà comme tantôt que l'on a un diagramme à flèches verticales des Hot-équivalences

$$\begin{array}{ccc} \overline{X'}/a & \longrightarrow & \overline{X'}/b \\ \wr\uparrow & & \wr\uparrow \\ \overline{X'}_a & \dashrightarrow & \overline{X'}_b, \end{array}$$

38. Ça résulte formellement de ce qui a été déjà vu, cf. pages 170-171.
39. Cela résulte déjà du fait que c'est propre et lisse!

et tout revient à montrer qu'une certaine flèche entre $\overline{X'}_a$ et $\overline{X'}_b$ dans Hot est [un] isomorphisme. J'ai envie de définir directement une telle flèche dans Hot, voire dans Cat. Or pour les m impairs, les $\overline{X'}_{n,m}$ sont Cat-cofibrées sur X. Pour $\overline{X'}_{-m,m}$ (m impair) on trouve donc

$$(\overline{X'}_{-m,m})_a \xrightarrow{v_*} (\overline{X'}_{-m,m})_b,$$

l'ennui est qu'elles ne sont pas compatibles avec les morphismes de transition pour m variable. [page 155]
Elles le sont cependant *à homotopie près* sûrement, donc on trouvera au moins une flèche d'ind-objets dans Cat hot

$$\overline{\overline{X'}}_a \xrightarrow{v_*} \overline{\overline{X'}}_b,$$

ce qui par passage à $\mathrm{Hot}_0^\wedge$ donne quand-même une flèche

$$\overline{X'}_a \xrightarrow{v_*} \overline{X'}_b.$$

En travaillant avec les m impairs, on trouve de même des foncteurs en sens inverses

$$(\overline{X'}_{-m,m})_a \xleftarrow{v^*} (\overline{X'}_{-m,m})_b,$$

qui ne se recollent pas pour m variable, mais qui se recollent à homotopie près, pour donner p. 97
une flèche dans Ind Cat hot

$$\overline{\overline{X'}}_a \xleftarrow{v^*} \overline{\overline{X'}}_b,$$

d'où aussi

$$\overline{X'}_a \xleftarrow{v^*} \overline{X'}_b \qquad \text{dans } \mathrm{Hot}_0^\wedge.$$

D'autre part, on doit pouvoir montrer soritalement, cran par cran, que v_*v^* et v^*v_* dans [page 156]
Ind Cat hot sont égales à l'identité, donc v_* et v^* sont des isomorphismes inverses l'un de l'autre. On doit vérifier d'autre part soritalement que

$$\begin{array}{ccc} \overline{\overline{X'}}/a & \xrightarrow{\bar v} & \overline{\overline{X'}}/b \\ \uparrow & & \uparrow \\ \overline{\overline{X'}}_a & \xrightarrow{v_*} & \overline{\overline{X'}}_b, \end{array}$$

dans Ind Cat hot est commutatif. Passant au diagramme correspondant dans $\mathrm{Hot}_0^\wedge$, en prenant les limites inductives, on trouve un carré commutatif dans $\mathrm{Hot}_0^\wedge$

$$\begin{array}{ccc} \overline{X'}/a & \xrightarrow{\bar v} & \overline{X'}/b \\ \uparrow\wr & & \uparrow\wr \\ \overline{X'}_a & \xrightarrow[\sim]{v_*} & \overline{X'}_b, \end{array}$$

d'où résulte que $\bar v$ est [un] isomorphisme dans $\mathrm{Hot}_0^\wedge$, donc aussi dans Hot.

Commentary · Later developments [ms. 153]

Evrard's categorical cocylinder

Grothendieck is seeking an explicit factorization of an arbitrary functor by adjoining paths. The same purpose already appears in Evrard (1975, §I.1), whose variable-length zigzags carry both natural transformations and maps which insert identity segments. The indexing conventions differ from those used here; an identification of the two categories would therefore require a comparison functor, not just the observation that their objects look alike.

A precise modern theorem is Shoikhet (2016, Theorem 2.8): the categorical cocylinder gives a functorial factorization by a weak equivalence followed by a homotopy-fibred functor, and there is a

dual construction. Its relation with the manuscript is the role of the second map: after applying the nerve, ordinary fibres compute homotopy fibres. Shoikhet's Proposition 1.14 formulates a stronger, base-change-stable version through simplicial sharp maps, under the prefibration hypotheses stated there. We use Quillen's comma-category theorem directly when those strict prefibration hypotheses have not been established. These distinctions matter for the total category $\underline{\mathrm{Ch}}(X)$, whose type-changing arrows will obstruct properness below, even though its fixed-endpoint categories still have the correct homotopy types.

Pour vérifier que la HOT-fibration $\bar{f}$ est triviale si et seulement si f est une HOT-équivalence, il faudrait avoir développé dans Cat le formalisme de la suite exacte des lacets - on est tout près visiblement !

p. 98

Commentary · Exposition [ms. 156] [page 157]

When the replacement is trivial

The desired test for triviality is already formal once the mapping-path construction has been established. Put $r : C(f) \to X'$ for the projection which forgets the path. It is the pullback of the universally weakly equivalent source map σ, so r is a weak equivalence. Its section i_f is consequently a weak equivalence as well. The equality $\bar{f} i_f = f$ gives

$$\bar{f} \text{ is a weak equivalence} \quad \Longleftrightarrow \quad f \text{ is a weak equivalence}$$

by two-out-of-three. If triviality is expressed instead by weakly contractible fibres, the homotopy-fibre theorem gives the same criterion. One can see both directions by replacing the realized map by a Serre fibration: a weak equivalence has contractible homotopy fibres, and a fibration with such fibres induces isomorphisms on every based homotopy group and a bijection on components.

Thus an independently developed long exact sequence for categorical loop objects is not needed for this particular conclusion. Nor should the preceding finite-test inference bear its proof. The claimed conservativity of the unbased restricted Yoneda functor is false in the generality used in the manuscript; the commentary on the finite-test obstruction in Chapter V, manuscript p. 52, explains this. The two-out-of-three argument, together with the actual endpoint-fibration theorem, proves exactly the assertion required here.

13.11.90

13 Où on prouve enfin que $\underline{\mathrm{Ch}}(X; -, -)$ est aussi bon (voire meilleur) que $\underline{\mathrm{Ch}}_\infty(X; -, -)$.

Je crois finalement que les catégories $\underline{\mathrm{Ch}}(X)$, $\underline{\mathrm{Ch}}(X; a, b)$ (sans indice ∞!) sont 'bonnes', que les flèches canoniques dans Hot

$$\begin{cases} \underline{\mathrm{Ch}}_\infty(X) & \xrightarrow{\sim} \quad \underline{\mathrm{Ch}}(X) \\ \underline{\mathrm{Ch}}_\infty(X; a, b) & \xrightarrow{\sim} \quad \underline{\mathrm{Ch}}(X; a, b) \end{cases}$$

sont des isomorphismes. (La première est même [un] isomorphisme dans $\mathrm{HOT}(X \times X)$, ce qui implique la deuxième relation, en passant aux fibres …) Je crois que je suis à présent (après XI) en mesure de le prouver. Cela résultera des deux résultats-clef suivants :

1) Le foncteur canonique
$$X \longrightarrow \underline{\mathrm{Ch}}(X)$$
(associant à tout $x \in \mathrm{Ob}\, X$ le chemin vide de source et but X) est une Hot-équivalence, et :

2) Le foncteur source-but
$$\underline{\mathrm{Ch}}(X) \longrightarrow X \times X$$
est *lisse* et *propre* (donc une 'Hot-fibration parfaite').

Cela doit donner ce qu'on cherche. Comme la $X \times X$-flèche $\underline{\mathrm{Ch}}_\infty(X) \longrightarrow \underline{\mathrm{Ch}}(X)$ (et les flèches déduites $\underline{\mathrm{Ch}}_\infty(X;a,b) \longrightarrow \underline{\mathrm{Ch}}(X;a,b)$) a été définie par l'intermédiaire de la catégorie

$$\mathcal{C}_{\mathbf{N}^o} = \mathbf{N}^o \times_{\underline{\mathrm{Ty}}} \mathcal{C}$$

(où $\mathcal{C} = \underline{\mathrm{Ch}}(X)$ `[est]` considérée comme catégorie fibrée sur $\underline{\mathrm{Ty}}$, et $\mathbf{N}^o \longrightarrow \underline{\mathrm{Ty}}$ est le système projectif des $\underbrace{(\Delta_+\Delta_-)^{2n}}_{t_n}\dots$)

à l'aide des deux flèches canoniques [page 158]

$$\begin{array}{ccc} \mathcal{C}_{\mathbf{N}^o} & \longrightarrow & \underline{\mathrm{Ch}}_\infty(X) \\ \downarrow & & \\ \underline{\mathrm{Ch}}(X), & & \end{array}$$

Commentary · Development (commentators') [ms. 157]

A properness claim which the empty path disproves

The return to paths of arbitrary type is motivated by their strictly associative concatenation. Their geometric usefulness is real, but the proposed proof gives them a stronger lifting property than they possess. We isolate the error before using the comparison diagram.

The empty-path obstruction. [ours] For $X = [1] = (0 \xrightarrow{w} 1)$, neither

$$\underline{\mathrm{Ch}}(X) \longrightarrow X \times X \qquad \text{nor} \qquad \mathcal{C}_{\mathbf{N}^o} \longrightarrow X \times X$$

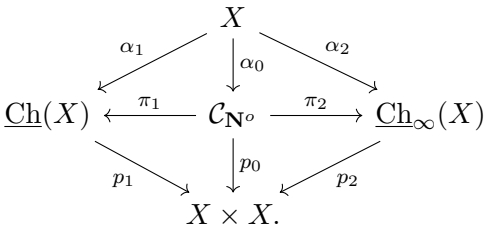
is proper, with the morphisms defined in this chapter.

Proof. Let z be the empty path at 0, lying above $(0,0)$, and consider the base arrow $(1_0, w) : (0,0) \to (0,1)$. Properness requires the category of its outgoing lifts with source z to be weakly contractible. In $\underline{\mathrm{Ch}}(X)$, a morphism from a path of type e to a path of type τ lies over an endpoint-preserving type map $e \to \tau$. The single vertex of e would have to map to both endpoints of τ. Hence $\tau = e$. But an empty path has equal endpoints and cannot lie above $(0,1)$. The lift category is empty. For $\mathcal{C}_{\mathbf{N}^o}$ the same argument is even more immediate: an arrow from stage 0 can only end at stage 0, because its image in $\mathbf{N}^o$ has source 0. Again its target must have equal endpoints. This proves both failures. □

The opposite of a total Grothendieck construction reverses the arrows in its indexing category as well as the arrows inside its fibres. Reversing a path or replacing X by X^o does not perform that operation on $\underline{\mathrm{Ty}}$ or on $\mathbf{N}^o$. This is the missing distinction in the deductions of properness on pp. 161 and 169. The same lifting test is the dual of Maltsiniotis (2005, Theorem 1.2).

This counterexample does not contradict the comparison of fixed-endpoint homotopy types which opens the section. That conclusion has a repair: smoothness of $\underline{\mathrm{Ch}}(X)$, together with explicit cancellation of a path and its reverse, gives the homotopy-fibre theorem by Quillen B. The intermediary $\mathcal{C}_{\mathbf{N}^o}$ can then be compared with $\underline{\mathrm{Ch}}_\infty(X)$ using its filtered-colimit construction. We give the full argument below. We did not find this empty-path counterexample or this precise repair of the present pages in the primary sources checked, namely Evrard, Shoikhet, and Maltsiniotis; the mathematical ingredients of the repair are classical.

on sera obligé de prouver aussi les résultats qui correspondent à 1) 2) pour $\mathcal{C}_{\mathbf{N}^o}$, i.e. p. 99



1′)

$$\begin{array}{ccc} X & \longrightarrow & \mathcal{C}_{\mathbf{N}^o} \\ \wr\downarrow & & \\ \mathcal{C}_{t_0} = \mathcal{C}_0 & & \end{array}$$

(l'inclusion canonique de $\mathcal{C}_0$, fibre de $\mathcal{C}_{\mathbf{N}^o}$ (fibrée sur $\mathbf{N}^o$) en $0 \in \mathbf{N}^o$) est une Hot-équivalence, et :

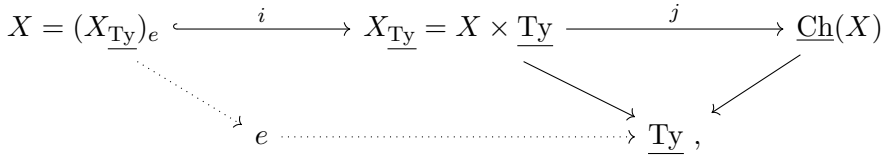
2′) $\mathcal{C}_{\mathbf{N}^o} \longrightarrow X \times X$ est propre et lisse.

Moyennant ces quatre résultats techniques, que je vais prouver tantôt (et 1′ et 2′ ne font aucune surprise pour moi), on gagne. Considérons en effet le diagramme

Par 1) et 1′) (concernant α_1 et α_0) et le résultat similaire déjà connu pour α_2, ces trois foncteurs sont des Hot-équivalences. Donc il en est de même de π_1, π_2. Comme p_1, p_0, p_2 sont des Hot-fibrations (étant propres et lisses), il s'ensuit que π_1 et π_2 induisent des Hot-équivalences sur les fibres [page 159]

$$\underline{\mathrm{Ch}}(X;a,b) \quad \xleftarrow{\pi_1(a,b)} \quad \mathcal{C}_{\mathbf{N}^o}(a,b) \quad \xrightarrow{\pi_2(a,b)} \quad \underline{\mathrm{Ch}}_\infty(X;a,b).$$

Je l'avais vérifié (sans mal) déjà pour π_2 et les $\pi_2(a,b)$, ce qui avait permis, en inversant π_2 dans Hot, de définir *dans* Hot



$$\begin{cases} \underline{\mathrm{Ch}}_\infty(X) & \longrightarrow & \underline{\mathrm{Ch}}(X) \\ \underline{\mathrm{Ch}}_\infty(X;a,b) & \longrightarrow & \underline{\mathrm{Ch}}(X;a,b), \end{cases}$$

et dire que ce sont des isomorphismes signifie justement que π_1 et les $\pi_1(a,b)$ sont des isomorphismes.

Je ne crois pas que $\mathcal{C}_{\mathbf{N}^o}$ ait en lui-même d'autre interêt, que de permettre de comparer les $X \times X$-catégories $\underline{\mathrm{Ch}}_\infty(X)$ et $\underline{\mathrm{Ch}}(X)$, à l'aide du diagramme précédent. Par contre, $\underline{\mathrm{Ch}}_\infty(X)$ et $\underline{\mathrm{Ch}}(X)$ m'aparaissent comme les deux ingrédients essentiels du formalisme des chemins dans Cat.

Je vais prouver 1, 2, 1′, 2′.

1) Considérons le diagramme p. 100 [page 160]

où $X_{\underline{\mathrm{Ty}}}$ et $\underline{\mathrm{Ch}}(X)$ sont considérées comme catégories Cat-fibrées sur $\underline{\mathrm{Ty}}$, et le foncteur j est déduit des foncteurs canoniques

$$X \longrightarrow \underline{\mathrm{Ch}}(X)_\tau \overset{\text{déf}}{=} \underline{\mathrm{Ch}}_\tau(X),$$

associant à $x \in \mathrm{Ob}\, X$ le chemin $p_\tau^*(x)$, où $p_\tau : \tau \longrightarrow e$ est la projection de τ vers l'élément unité (et élément final) $e = 1_{\underline{\mathrm{Ty}}}$ de $\underline{\mathrm{Ty}}$, et $\underline{\mathrm{Ch}}_e(X)$ est identifiée à X. Il faut vérifier le

Lemme. *Pour tout $\tau \in \underline{\mathrm{Ty}}$, le foncteur précédent est une* Hot-*équivalence (et même un homotopisme).*

Mais on sait que pour deux catégories $\mathcal{X}$, $\mathcal{C}$ lisses sur une autre, T, tout T-morphisme de $\mathcal{X}$ dans $\mathcal{C}$ qui induit des Hot-équivalences sur les fibres, est une Hot-équivalence. Ainsi j est est une Hot-équivalence. D'autre part, $\underline{\mathrm{Ty}}$, ayant un objet final, est asphérique, donc $X \times \underline{\mathrm{Ty}} \xrightarrow{\mathrm{pr}_1} X$ est une Hot-équivalence, d'où résulte aussitôt que i est une Hot-équivalence. Donc de même ji, or $ji = \alpha_1$, q.e.d. [page 161]

Commentary · Exposition [ms. 160]

Completing the constant-path lemma

The first comparison is a statement about total homotopy types, and here Grothendieck's argument works. Its useful feature is that it does not ask the chosen sequence of interval types to be homotopy cofinal in $\underline{\mathrm{Ty}}$.

For every finite oriented interval I, evaluation at the initial vertex and the constant-diagram functor give

$$X \xrightarrow{c} \mathrm{Fun}(I, X) \xrightarrow{\mathrm{ev}_0} X, \qquad \mathrm{ev}_0\, c = 1_X.$$

The truncation functors $r_k(j) = \min(j, k)$ constructed above join $c\,\mathrm{ev}_0$ to the identity by a finite zigzag of natural transformations. This proves the lemma promised here and left unwritten on p. 170: c is a categorical homotopy equivalence, not just a weak equivalence of nerves. The argument applies to every sign pattern and to the zero-length interval.

These constant-diagram functors commute strictly with precomposition by type maps. They therefore assemble to the displayed Cartesian functor

$$j : X \times \underline{\mathrm{Ty}} \longrightarrow \underline{\mathrm{Ch}}(X)$$

between Grothendieck fibrations over $\underline{\mathrm{Ty}}$, and each of its fibre functors is a weak equivalence. The standard fibrewise comparison theorem for Grothendieck constructions makes j a weak equivalence. This is also the objectwise invariance behind Thomason's homotopy-colimit theorem; the fibred convention is recalled explicitly in Shoikhet (2016, §1.5). Since $\underline{\mathrm{Ty}}$ has terminal object e, the inclusion $X \to X \times \underline{\mathrm{Ty}}$ at e is a weak equivalence. Their composite is the empty-path section $X \to \underline{\mathrm{Ch}}(X)$.

Exactly the same proof over $\mathbf{N}^o$ proves $X \to \mathcal{C}_{\mathbf{N}^o}$ is a weak equivalence. For $\underline{\mathrm{Ch}}_\infty(X)$ the constant-diagram functors assemble to a levelwise weak equivalence of filtered diagrams; invariance of weak equivalences under filtered colimits gives the corresponding assertion. Consequently the two comparison arrows out of $\mathcal{C}_{\mathbf{N}^o}$ are weak equivalences on total categories, by two-out-of-three. What remains is genuinely relative: a weak equivalence over $X \times X$ need not be a weak equivalence on its strict fibres until those fibres have been identified as homotopy fibres.

2) Prouvons p. ex. la lissité de $\underline{\mathrm{Ch}}(X) \longrightarrow X \times X$, la propriété s'en déduira en appliquant ce résultat à X^{opp}. Soit donc

$$(a', b') \;\longrightarrow\; (a, b), \qquad \text{i.e. } a' \xrightarrow{u} a, \quad b' \xrightarrow{v} b,$$

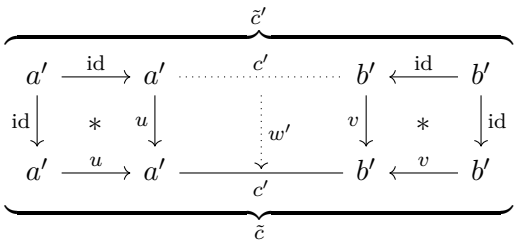
une flèche dans $X \times X$, et c un objet de $\underline{\mathrm{Ch}}(X)$ au dessus de (a, b) :

$$\begin{array}{ccc} a' & \overset{c'}{\underset{\rightarrow}{\cdots\cdots\cdots}} & b' \\ {\scriptstyle u}\downarrow & & \downarrow{\scriptstyle v} \\ a & \xrightarrow[\rightarrow]{c} & b. \end{array}$$

On regarde la catégorie $\mathcal{C}(c; u, v)$ des couples (c', w) qui relèvent $(c, (u, v))$, où donc c' est un chemin (de type non précisé) de a' vers b', et

$$w : c' \longrightarrow c$$

une flèche dans $\underline{\mathrm{Ch}}(X)$ qui sur les objets source induise u, et sur les objets buts induise v (ainsi c' est un chemin de a' vers b'). Il faut prouver que cette catégorie $\mathcal{C}(c; u, v)$ est asphérique. Pour cela, on regarde le chemin composé p. 101 [page 162]



$$\tilde{c} = \mathrm{ch}(u)\ c\ \mathrm{ch}(v)^o,$$

où $\mathrm{ch}(u)$ est le chemin (direct) de a' vers a défini par $u : a' \longrightarrow a$, et $\mathrm{ch}(v)^o$ désigne donc le chemin (rétrograde) de b à b' défini par $v : b' \longrightarrow b$. Si c est de type τ, $\tilde{c}$ est donc de type $\Delta_+\tau\Delta_-$. On va comparer $\mathcal{C}(c; u, v)$ et la catégorie $\underline{\mathrm{Ch}}(X)/\tilde{c}$, à l'aide de deux foncteurs

$$\mathcal{C}(c; u, v) \underset{\psi}{\overset{\varphi}{\rightleftarrows}} \underline{\mathrm{Ch}}(X; a', b')/\tilde{c}\ ,$$

dont on prouvera qu'ils définissent des flèches inverses l'une de l'autre dans Hot. Comme $\underline{\mathrm{Ch}}(X)/\tilde{c}$ est contractile (ayant un objet final), donc asphérique, il en est de même de $\mathcal{C}(c;u,v)$, et on gagnera.

On définit φ par $\boxed{\varphi(c',w')=(\tilde{c}',\tilde{w}'),}$ où (c' étant du type τ') $\tilde{c}'$ est le chemin de type $\Delta_+\tau'\Delta_-$ déduit de c' comme image inverse par la dégénérescence $\Delta_+\tau'\Delta_- \longrightarrow \tau'$, i.e. on prolonge c' d'un 'cran Δ_+' $a' \xrightarrow{\mathrm{id}} a'$ à gauche et d'un 'cran Δ_-' $b' \xleftarrow{\mathrm{id}} b'$ à droite, cf. figure.

On peut dire que [page 163]

$$\tilde{c}' = a'_{\Delta_+} \circ c' \circ b'_{\Delta_-},$$

où de façon générale, si $x \in X$ et $\tau \in \mathrm{Ty}$, x_τ désigne le 'chemin constant' de valeur x, type τ. On a d'autre part des morphismes évidents

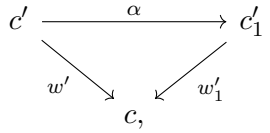
$$a'_{\Delta_+} \longrightarrow \mathrm{ch}(u), \qquad b'_{\Delta_-} \longrightarrow \mathrm{ch}(v)^{\mathrm{opp}},$$

comme montré [?] par les flèches verticales $(\mathrm{id}_{a'}, u)$ et $(v, \mathrm{id}_{b'})$ dans les deux carrés marqués $*$ du diagramme, flèches qui sont l'une dans $\underline{\mathrm{Ch}}_{\Delta_+}(X)$, l'autre dans $\underline{\mathrm{Ch}}_{\Delta_-}(X)$. Ceci dit, on pose

$$\tilde{w}' : \tilde{c}' \longrightarrow \tilde{c}, \qquad \tilde{w} = \lambda(u) * w' * \mu(v),$$

où

$$\begin{cases} \lambda(u) : & a'_{\Delta_+} & \longrightarrow & \mathrm{ch}(u) \\ \mu(v) : & b'_{\Delta_-} & \longrightarrow & \mathrm{ch}(v)^{\mathrm{opp}} \end{cases}$$



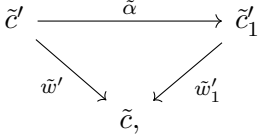
(cf. figure). Le couple p. 102

$$(\tilde{c}', \tilde{w}') \in \mathrm{Ob}\,\underline{\mathrm{Ch}}(X)/\tilde{c}$$

ainsi défini dépend fonctoriellement de (c', w') variable dans $\mathcal{C}(c;u,v)$: Si (c'_1, w'_1) est un deuxième objet de cette catégorie, une flèche du premier dans le second est une flèche

$$c' \xrightarrow{\alpha} c'_1$$

dans $\underline{\mathrm{Ch}}(X; a', b')$, telle qu'on ait commutativité dans



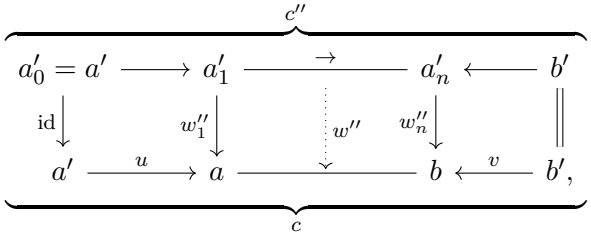
$w' = w'_1\alpha.$

Une telle flèche α définit

$$\tilde{\alpha} = a'_{\Delta_+} * \alpha * b'_{\Delta_-} : \tilde{c}' \longrightarrow \tilde{c}'_1$$

dans $\underline{\mathrm{Ch}}(X; a', b')$, et on vérifie aussitôt que l'on a commutativité dans [page 164]

i.e. $\tilde{w}' = \tilde{w}'_1\tilde{\alpha},$



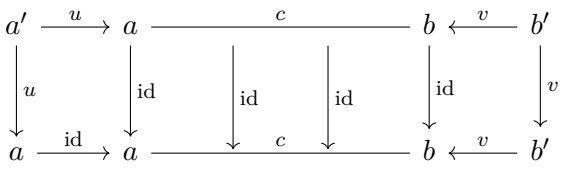
i.e. que $\tilde{\alpha}$ est bien une flèche dans $\underline{\mathrm{Ch}}(X; a', b')/\tilde{c}$. De même, que $\alpha \longmapsto \tilde{\alpha}$ définit une dépendance fonctorielle, i.e. $(\beta\alpha)\tilde{} = \tilde{\beta}\tilde{\alpha}$, est évident sur la définition de $\tilde{\alpha}$. Donc, on a bien défini

$$\mathcal{C}(c; u, v) \xrightarrow{\varphi} \underline{\mathrm{Ch}}(X; a', b')/\tilde{c},$$

définissons maintenant

$$\mathcal{C}(c; u, v) \xleftarrow{\psi} \underline{\mathrm{Ch}}(X; a', b')/\tilde{c}.$$

Soit (c'', w'') un objet de $\underline{\mathrm{Ch}}(X; a', b')/\tilde{c}$,



donc p. 103

$$w'' : c'' \longrightarrow \tilde{c}, \qquad \text{flèche dans } \underline{\mathrm{Ch}}(X; a', b'),$$

notons qu'on a une flèche de rétraction évidente

$$\tilde{c} \xrightarrow{\rho_c} c \qquad \text{associée à } \Delta_+\tau\Delta_- \longrightarrow \tau \text{ (rétraction)},$$

induisant u et v sur la source et le but :

$\Big\} \tilde{c} \qquad \in \underline{\mathrm{Ch}}_{\Delta_+\tau\Delta_-}(a', b')$

$\Big\} \delta^*_\tau(c) \qquad \in \underline{\mathrm{Ch}}_{\Delta_+\tau\Delta_-}(a, b)$

$\Big\} c \qquad \in \underline{\mathrm{Ch}}_\tau(a, b).$

Donc on définit un objet [page 165]

$$(c', w') = \psi(c'', w'') \ \in \mathrm{Ob}\,\mathcal{C}(c; u, v)$$

par

$$c' = c'', \qquad w' = \rho_c w'',$$

et c'est fonctoriel en (c'', w'').

Commentary · Exposition [ms. 164]

The lifting category is contracted relative to its endpoints

The long diagram calculation has a simple purpose: to replace the category of all incoming lifts of (u, v) by a slice with a terminal object. It is a proof of smoothness, and no properness assertion is needed to make it work.

Fix $u : a' \to a$, $v : b' \to b$, and a path $c : a \rightsquigarrow b$. Write $A = \underline{\mathrm{Ch}}(X; a', b')$ and $\widetilde{c} = \mathrm{ch}(u)c\mathrm{ch}(v)^o$. Its slice $A/\widetilde{c}$ has terminal object $1_{\widetilde{c}}$. The functor φ pads an incoming lift $w' : c' \to c$ with a constant edge at each end. Its new map to $\widetilde{c}$ has the components $(1_{a'}, u)$ on the left and $(v, 1_{b'})$ on the right. A morphism $\alpha : c' \to c'_1$ is padded by identities, so the equality $w'_1\alpha = w'$ becomes $\widetilde{w}'_1\widetilde{\alpha} = \widetilde{w}'$. Both functoriality and the slice condition follow from the interchange law for concatenation of natural transformations.

To recover a lift from a slice object, there is an arrow $\rho_c : \widetilde{c} \to c$ over the collapse $\Delta_+\tau\Delta_- \to \tau$, with endpoint components u, v. Define $\psi(c'', w'') = (c'', \rho_c w'')$. The identity which makes the argument relative is

$$\rho_c \widetilde{w}' = w' \rho_{c'}.$$

It holds on the central interval by the definition of $\widetilde{w}'$, and on the two added edges by the two commutative endpoint squares. The maps $\rho_{c'}$ are natural because collapsing constant collars commutes with every endpoint-preserving type map. They give a natural transformation $\psi\varphi \Rightarrow 1$ on the lifting category.

On the other side, both $\varphi\psi$ and the identity map naturally to the constant endofunctor with value $1_{\widetilde{c}}$, because the slice has a terminal object. Thus their nerves are homotopic. The two functors are homotopy inverses, and the lifting category is contractible. This proves smoothness of $\underline{\mathrm{Ch}}(X) \to X \times X$ completely. The wrong primes in the first padding diagram and the wrong final vertex in the diagram of ρ_c are printed errors; the corrected endpoint descriptions above specify the maps without ambiguity.

Le composé $\varphi\psi$ étant un endomorphisme de la catégorie contractile $\underline{\mathrm{Ch}}(X; a', b')/\tilde{c}$, est homotope à l'identité. Il faut vérifier qu'il en est de même de $\psi\varphi$, endomorphisme de $\mathcal{C}(c; u, v)$. Ce foncteur associe à (c', w'), $(\tilde{c}', \overline{w'})$, où $\tilde{c}'$ est défini comme plus haut, $\tilde{c}' = a'_{\Delta_+} \circ c' \circ b'_{\Delta_-}$, et où $\overline{w'}$ est le composé

$$\underbrace{\tilde{c}'}_{=\delta'^{*}_{\tau'}(c')} \quad \underbrace{\xrightarrow{\rho_{c'}}}_{\substack{\text{flèche}\\ \text{canonique}}} \quad c' \xrightarrow{w'} c.$$

On a donc

$$(\psi\varphi)(c', w') = (\tilde{c}', \overline{w'}) \xrightarrow{\rho_{c'}} (c', w'),$$

c'est bien un morphisme dans $\mathcal{C}(c; u, v)$, i.e. on a commutativité dans

$$\begin{array}{ccc} \tilde{c}' & \xrightarrow{\quad\rho_{c'}\quad} & c' \\ & {\scriptstyle \overline{w'}}\searrow \quad \swarrow{\scriptstyle w'} & \\ & c & \end{array} \qquad \text{(flèche de } \underline{\mathrm{Ch}}(X; a', b')\text{)}.$$

Ainsi, le foncteur $\psi\varphi$ est bien homotope au foncteur identique. On a gagné ! p. 104

Passons à 1′, 2′) pour $\mathcal{C}_{\mathbf{N}^o}$. L'assertion 1′) se démontre exactement de la même manière [page 166] que 1) pour $\underline{\mathrm{Ch}}(X)$, en regardant $\mathcal{C}_{\mathbf{N}^o}$ comme fibrée sur $\mathbf{N}^o$ (qui a un objet final 0), et en utilisant le diagramme

$$\begin{array}{ccccc} X = (X_{\mathbf{N}^o})_e & \xrightarrow{\quad i' \quad} & X_{\mathbf{N}^o} = X \times \mathbf{N}^o & \xrightarrow{\qquad j' \qquad} & \mathcal{C}_{\mathbf{N}^o} \\ & & & \searrow \quad \swarrow & \\ & & & \mathbf{N}^o\ , & \end{array}$$

où j' est (cartésien et) une Hot-équivalence sur chaque fibre d'après le lemme, donc une Hot-équivalence globalement, et i' est une Hot-équivalence car $\mathbf{N}^o$ est asphérique (ayant un objet final). Donc $j'i'$ est asphérique, q.e.d.

Il reste à prouver que

$$\mathcal{C}_{\mathbf{N}^o} \longrightarrow X \times X$$

est propre et lisse. Ici encore, c'est exactement le même argument que tantôt, je présume. Il y [page 167] a cependant une complication technique. Nous avions pris, pour définir

$$\underline{t} : \mathbf{N}^o \longrightarrow \underline{\mathrm{Ty}}, \qquad \underline{t} = (t_n)_n,$$

le choix

$$t_n = (\Delta_+\Delta_-)^{2n},$$

ou si on préfère

$$t_n = (\Delta_+\Delta_-)^n,$$

en tous cas les t_n sont à direction initiale $+$, terminale $-$, et ce sont des types réduits. Si on prend $\Delta_+ t_n \Delta_-$, on trouve un type non réduit, qui n'est pas parmi les t_n. Il ne servirait à rien de changer la définition de t_n en $t_n = (\Delta_-\Delta_+)^{\text{quelque chose}}$, car cette fois $\Delta_+ t_n \Delta_-$ sera bien réduit, mais n'aura pas les bons signes initial et terminal. Donc pour définir $\tilde{c}$ en termes de c, comme objet de $\mathcal{C}_{\mathbf{N}^o}$, il faudra, si c est de type $\tau = t_n$, prendre $\tilde{c}$ de type $\Delta_+\Delta_-\tau\Delta_+\Delta_- = t_{n+1}$ (en prenant $t_{n+1} = (\Delta_+\Delta_-)^{2n}$), et de même pour définir $\tilde{c}'$ en termes de c'. Les définitions pertinentes du passage de (c', w') à $(\tilde{c}', \tilde{w}')$ sont décrites dans la figure :

Commentary · Development (commentators') [ms. 166]

Recovering the path-space theorem without properness

The smoothness argument supplies enough control once we also know that transport along an arrow of $X \times X$ is invertible up to homotopy. Full path categories are particularly convenient for this second step, because their concatenation is a genuine functor.

Transport and homotopy fibres for all path types. [ours] Let $E = \underline{\mathrm{Ch}}(X)$ with endpoint functor $p : E \to B = X \times X$. For every (a, b), the natural square with upper left corner $\underline{\mathrm{Ch}}(X; a, b)$ and lower left corner $\{(a, b)\}$ is homotopy Cartesian. In particular,

$$B\underline{\mathrm{Ch}}(X; a, b) \simeq \mathrm{hofib}_{(a,b)}(BX \xrightarrow{\Delta} BX \times BX),$$

where $B(-)$ denotes the classifying space, so the right side is the ordinary path space from a to b up to weak equivalence.

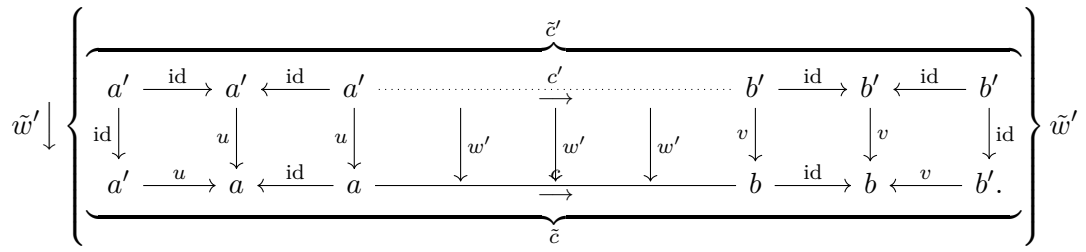
Proof. For $h = (u, v) : (a', b') \to (a, b)$ define

$$S_h : \underline{\mathrm{Ch}}(X; a, b) \longrightarrow \underline{\mathrm{Ch}}(X; a', b'), \qquad c \longmapsto \mathrm{ch}(u)c\mathrm{ch}(v)^o.$$

The opposite paths define a candidate inverse. Its composites insert the two backtracking paths associated to u and v. For an arrow $u : x \to y$, cancellation is provided by the explicit diagrams

$$\mathrm{empty}_x \longleftarrow x_{\Delta_+\Delta_-} \longrightarrow (x \xrightarrow{u} y \xleftarrow{u} x),$$

$$(y \xleftarrow{u} x \xrightarrow{u} y) \longrightarrow y_{\Delta_-\Delta_+} \longrightarrow \mathrm{empty}_y.$$



The first rightward arrow has components $(1_x, u, 1_x)$; the second display's first arrow has components $(1_y, u, 1_y)$. The remaining arrows collapse constant intervals. They are morphisms with fixed endpoints. Whiskering with an arbitrary path makes these diagrams natural in that path. Cancelling each of the two inserted backtracks consequently gives homotopies from both composites to the identity. Hence S_h is a homotopy equivalence.

Smoothness identifies the inclusion $i_z : E_z \to z\backslash E$ as a weak equivalence for every $z \in B$. The arrows $\rho_c : S_h(c) \to c$ over h give a natural transformation

$$i_{(a',b')} S_h \implies h^* i_{(a,b)}$$

in $(a', b')\backslash E$. The three known weak equivalences in this square force $h^* : (a, b)\backslash E \to (a', b')\backslash E$ to be a weak equivalence. Quillen's Theorem B now identifies E_z with the homotopy fibre of p. Finally the constant-path section $X \to E$ is a weak equivalence over $X \times X$, so it identifies that homotopy fibre with the homotopy fibre of the diagonal. The latter is equivalent to the space of paths from a to b: in the standard homotopy-fibre model, join the two paths from the chosen intermediate point, reversing the first. □

The use of Quillen B is classical (Quillen, 1973, §1); the explicit application above repairs the proof in these pages. We have checked the categorical cocylinder treatments of Evrard (1975) and Shoikhet (2016), but did not locate this precise correction of Grothendieck's total path category there. No claim of priority is attached to the argument.

Ainsi

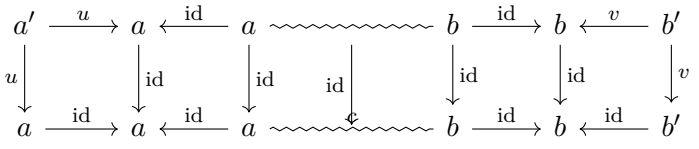
$$\begin{cases} \tilde{c} &= \xi_u \circ c \circ \eta_v & \text{où} & \left\{ \begin{array}{lccccc} \xi_u : & a' & \xrightarrow{u} & a & \xleftarrow{\mathrm{id}} & a \\ \eta_v : & b & \xrightarrow{\mathrm{id}} & b & \xleftarrow{v} & b' \end{array} \right\} \text{ type } \Delta_+\Delta_- \\ \tilde{c}' &= a'_{\Delta_+\Delta_-} \circ c' \circ b'_{\Delta_+\Delta_-} & & & & \\ \tilde{w}' &= \lambda(u) * w * \mu(v) & \text{avec} & \left\{ \begin{array}{lccc} \lambda(u) : & a'_{\Delta_+\Delta_-} & \longrightarrow & \xi_u \\ \lambda(v) : & b'_{\Delta_+\Delta_-} & \longrightarrow & \eta_v \end{array} \right\} & \text{comme dans } \texttt{[la]} \text{ figure.} \end{cases}$$

On trouve ainsi, mutatis mutandis,

$$\mathcal{C}_{\mathbf{N}^o}(c; u, v) \xrightarrow{\varphi} \mathcal{C}_{\mathbf{N}^o}(a', b')/\tilde{c}, \qquad \varphi(c', w') = (\tilde{c}', \tilde{w}'),$$

et on définit le foncteur

$$\mathcal{C}_{\mathbf{N}^o}(c; u, v) \xleftarrow{\psi} \mathcal{C}_{\mathbf{N}^o}(a', b')/\tilde{c}$$



ainsi : à (c'', w'') dans $\mathcal{C}_{\mathbf{N}^o}(a', b')/\tilde{c}$, donc un chemin c'' de type $t_n = (\Delta_+\Delta_-)^{2n}$ de a' à b' et un homomorphisme $w'' : c'' \longrightarrow \tilde{c}$ à extrémités fixes, on associe (c', w') dans $\mathcal{C}_{\mathbf{N}^o}(c; u, v)$, avec

$$c' = c'', \qquad w' = \rho_c w'',$$

où

$$\rho_c : \tilde{c} \longrightarrow c$$

est défini de façon similaire que tantôt, par

$\tilde{c}$, type t_{n+1}.

$\varphi^*_{n,n+1}(c)$.

[page 169]

On doit seulement vérifier que l'endofoncteur $\psi\varphi$ de $\mathcal{C}_{\mathbf{N}^o}(c; u, v)$ est homotope à l'identité. Mais ce foncteur transforme (c', w') en $(\tilde{c}' = a'_{\Delta_+\Delta_-} c' b'_{\Delta_+\Delta_-}, \overline{w'})$, où $\overline{w'}$ est encore le composé

$$\tilde{c}' \xrightarrow{\text{can.}} c' \xrightarrow{w'} c.$$

p. 106

On a donc

$$\psi\varphi \longrightarrow \mathrm{id},$$

$\psi\varphi$ est homotope au foncteur identique.

Cela prouve la lissité de $\mathcal{C}_{\mathbf{N}^o} \longrightarrow X \times X$. Pour la propreté, il faut prouver la lissité de le cas de X^o, et du système projectif $\underline{t}^{\mathrm{opp}} \simeq (t_n^{\mathrm{opp}})_n$. Mais on a $\underline{t}^{\mathrm{opp}} = \underline{t}$, et il suffit d'appliquer ce qu'on a déjà prouvé au cas de X^o, pour voir que $\mathcal{C}_{\mathbf{N}^o} \longrightarrow X \times X$ est propre.

Il ne reste plus que le lemme à prouver. Ça doit être essentiellement trivial, et je renonce à rédiger une démonstration.

[page 170]

Commentary · Development (commentators') [ms. 169]

The sequential intermediary and the repaired comparison

Grothendieck's intermediary remembers a finite stage as part of an object. That memory explains both its value for comparison and the limitation of the padding argument just attempted. Put $D = \Delta_+\Delta_-$, $t_n = D^{2n}$, and denote the specified symmetric-collapse transition by $\delta_{m,n} : t_m \to t_n$. An arrow of $\mathcal{C}_{\mathbf{N}^o}$ over $m \to n$ has exactly this underlying type map. Padding both ends of an arbitrary such arrow produces

$$1_D * \delta_{m,n} * 1_D : t_{m+1} \longrightarrow t_{n+1},$$

which is generally different from $\delta_{m+1,n+1}$. The former retains the outermost blocks and collapses blocks immediately inside them; the latter collapses the outermost blocks. Thus the formula on p. 168 need not even define the promised object of the slice of $\mathcal{C}_{\mathbf{N}^o}$. This is a restriction of the chosen indexing arrows, independent of the corrected exponents and primes.

Smoothness of the sequential intermediary. [ours] Nevertheless $\mathcal{C}_{\mathbf{N}^o} \to X \times X$ is smooth.

Proof. Fix a target path c of stage n and an incoming base arrow $h : (a', b') \to (a, b)$. Its lift category is fibred over the tail $\{m \geq n\}^o$. The fibre at m is the incoming-lift category of h into $\delta^*_{m,n}c$ for the fixed-type endpoint functor

$$\mathrm{Fun}(t_m, X) \longrightarrow X \times X.$$

For $m > 0$ this functor is a Grothendieck fibration: both endpoints of t_m are sources, and a Cartesian lift is obtained by changing their objects and composing the first and last arrows with the specified endpoint maps. The corresponding lift category has that Cartesian lift as a terminal object. The only exception is $m = 0$, possible when $n = 0$. Its fibre is empty unless $a' = b'$ and the two components of h coincide; when these equalities hold it is a singleton. If it is empty, omit stage 0; otherwise retain it. In either case every fibre over the remaining tail is contractible, and that tail has a terminal object. The fibrewise comparison theorem for Grothendieck fibrations, applied to the projection to this tail, shows that the total lift category is weakly contractible. This is the smoothness criterion. □

This argument proves only smoothness. Properness is excluded by the empty-path example above. Likewise the word "asphérique" at the end of the proof of (1′) on p. 166 is stronger than what was proved: for a positive-stage object c, the comma category of $X \to \mathcal{C}_{\mathbf{N}^o}$ over c is empty, since there is no base arrow $0 \to n$ for $n > 0$. The section is a weak equivalence, as required.

Comparison on every fixed-endpoint fibre. [ours] The canonical span

$$\underline{\mathrm{Ch}}(X; a, b) \longleftarrow \mathcal{C}_{\mathbf{N}^o}(a, b) \longrightarrow \underline{\mathrm{Ch}}_\infty(X; a, b)$$

consists of weak equivalences.

Proof. Write $E_1 = \underline{\mathrm{Ch}}(X)$, $E_0 = \mathcal{C}_{\mathbf{N}^o}$, $E_2 = \underline{\mathrm{Ch}}_\infty(X)$, all over $B = X \times X$, and $\pi_i : E_0 \to E_i$. The constant-path lemma proves both π_i are weak equivalences on total categories. The filtered Grothendieck-to-colimit comparison, established in the commentary at manuscript pages 108–109, proves $\pi_2 : E_{0,z} \to E_{2,z}$ is a weak equivalence on each strict fibre: apply that comparison to the sequence of fixed-endpoint categories itself.

By the endpoint theorem for E_2, its strict fibre is its homotopy fibre over z. The natural diagram

$$\begin{array}{ccc} E_{0,z} & \xrightarrow{\quad\pi_2\quad} & E_{2,z} \\ \downarrow & & \downarrow\sim \\ \mathrm{hofib}_z(BE_0 \to BB) & \xrightarrow{\sim} & \mathrm{hofib}_z(BE_2 \to BB) \end{array}$$

is understood after applying B to the top row. Its lower arrow is a weak equivalence because the maps on total spaces are weak equivalences over the same base. The left vertical map is therefore a weak equivalence. The preceding block proves the same homotopy-fibre description for E_1. Repeating the square with π_1 shows that $E_{0,z} \to E_{1,z}$ is a weak equivalence. □

The conclusion of the section is thus recovered, although its claimed properness and its particular sequential padding construction cannot be retained. The repair uses based homotopy fibres, never a conservativity assertion about unbased finite tests. The literature check is the one stated in the preceding development block; these are proofs supplied here for the specified models.

Commentary · Development (commentators') [ms. 169]

Even translation acts trivially after localization

The comparison now also settles the question about T^2 left on pp. 149–150. Its resolution uses a visible change of finite support, rather than equality after restriction to finite test objects.

Translation invariance. [ours] The even translation of an eventually constant alternating path induces the identity in Hot, both on $\underline{\mathrm{Ch}}_\infty(X)$ and on each fixed-endpoint category.

Proof. Keep $D = \Delta_+\Delta_-$ and $t_n = D^{2n}$. Define R on the sequential Grothendieck category by sending a path of stage n to stage $n+1$, adding two constant D-blocks at its right end. The asymmetric collapse $q_n : t_{n+1} \to t_n$ defining this operation commutes with the symmetric transitions:

$$q_n \delta_{m+1,n+1} = \delta_{m,n} q_m \qquad (m \geq n).$$

Both sides collapse the same number of left and right blocks. Hence R is a functor. On the eventual bi-infinite realization, with the centred indexing of these pages this operation is $U = T^{-2}$, and $\pi_2 R = U\pi_2$.

The maps q_n are permitted in $\underline{\mathrm{Ty}}$. They give a natural transformation $\pi_1 R \Rightarrow \pi_1$ into the full path category, whose component is the Cartesian arrow from the padded path to the original path. By the comparison just proved, $k = \pi_1\pi_2^{-1}$ is an isomorphism in Hot. Therefore

$$kU\pi_2 = \pi_1 R = \pi_1 = k\pi_2,$$

and cancellation gives $U = 1$. The same construction fixes the endpoints, so the argument applies to every fibre. Taking inverses gives $T^2 = 1$ as well. □

We did not find this finite-support proof in the checked literature. It is a consequence of the repaired comparison, with no additional general theorem about the restricted Yoneda functor.

Commentary · Development (commentators') [ms. 169]

Why the comparison preserves composition

Grothendieck's original reason for retaining all finite path types was their strictly associative concatenation. The comparison of endpoint fibres should therefore identify that operation with ordinary path concatenation, not merely identify the underlying homotopy types. The constant-path sections determine this compatibility once composable pairs are treated as carefully as individual paths.

Compatibility with path concatenation. [ours] Put $E = \underline{\mathrm{Ch}}(X)$ and $K = BX$. The equivalences

$$u_{a,b} : B\underline{\mathrm{Ch}}(X; a, b) \longrightarrow P_{a,b}K \quad \text{in Hot},$$

obtained from the constant-path diagonal factorization, can be chosen canonically in the localized slice category and satisfy

$$u_{a,c}\, B(*) = *_{\mathrm{top}}(u_{a,b} \times u_{b,c}) \quad \text{in Hot}.$$

Here $P_{a,b}K$ is the ordinary space of paths from a to b, and the products have the indicated endpoint fibres as their domain. In particular the equivalence on loops respects the usual multiplication in the homotopy category.

Proof. Let $D = E \times_X E$, using the target of the first path and the source of the second. Its projection to $\underline{\mathrm{Ty}} \times \underline{\mathrm{Ty}}$ is the fibred Grothendieck construction with fibre $\mathrm{Fun}(\tau * \upsilon, X)$ at (τ, υ): matching the two endpoint values is exactly the condition for gluing the diagrams on the two intervals. The constant-diagram functor from X to this fibre is a categorical homotopy equivalence, by the truncation homotopies proved at manuscript page 160. These functors commute with the type maps. The same fibrewise comparison used there, and the terminal object (e, e) of $\underline{\mathrm{Ty}} \times \underline{\mathrm{Ty}}$, show that the constant-pair section $j : X \to D$ is a weak equivalence.

We also need the relative assertion for D. Its three-endpoint functor $r : D \to X^3$ factors as

$$D \longrightarrow E \times X \longrightarrow X^3, \qquad (c, d) \longmapsto (c, \beta d) \longmapsto (\sigma c, \beta c, \beta d).$$

The first functor is the base change of $E \to X^2$ along $(c, z) \mapsto (\beta c, z)$; the second is its product with 1_X. Thus r is smooth, by stability under base change and composition (Maltsiniotis, 2005, Proposition 4.7). For a base arrow $(u, v, w) : (a', b', c') \to (a, b, c)$ the functor on strict fibres is

$$S_{(u,v)} \times S_{(v,w)}.$$

Both factors are homotopy equivalences by the explicit backtrack cancellations at page 166. The two collapse arrows ρ agree on their common middle endpoint, with component v, so together give a natural arrow over (u, v, w). Smoothness identifies each strict fibre with its under-comma category. The natural arrow then shows that every transition between those comma categories is a weak equivalence, exactly as in the proof for E. Quillen's Theorem B applies. Consequently

$$B\big(\underline{\mathrm{Ch}}(X; a, b) \times \underline{\mathrm{Ch}}(X; b, c)\big) \longrightarrow \mathrm{hofib}_{(a,b,c)}(BD \to K^3)$$

is a weak equivalence.

Now use ordinary spaces, with compactly generated mapping spaces. Put $P = K^{[0,1]}$ and $Q = P \times_K P$, and let $s : K \to P$ and $t : K \to Q$ be their constant-path sections. Both are weak equivalences: P and Q are the spaces of maps from the intervals $[0, 1]$ and $[0, 2]$, respectively, and evaluation at the initial point is a deformation retraction onto constants. Their endpoint maps, to K^2 and K^3, are fibrations. Write $i : K \to BE$ for the constant-path section and still write $j : K \to BD$ for its two-path version. In the homotopy categories of spaces over these endpoint bases, define

$$u = s\, i^{-1} : BE \longrightarrow P, \qquad v = t\, j^{-1} : BD \longrightarrow Q.$$

These are the unique comparison isomorphisms whose composites with the constant sections are s and t.

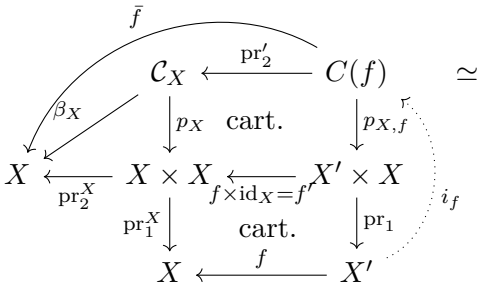
All maps in the remaining argument can be regarded over K^3. For concatenation the target is the pullback of $P \to K^2$ along $(x, y, z) \mapsto (x, z)$; for either projection it is the corresponding pullback along $(x, y, z) \mapsto (x, y)$ or (y, z). These pullbacks are just products with the unused copy of K, so they preserve weak equivalences and the displayed localized comparisons. Both composites comparing categorical concatenation with topological concatenation send j to the same constant path. Since j is invertible in this slice homotopy category, cancellation gives

$$u\, B(*) = *_{\mathrm{top}}\, v.$$

The identical argument with either path projection shows that v commutes with both projections under u.

Take the derived fibre over (a, b, c). The relative assertion for D, the endpoint theorem for E, and the ordinary path fibrations identify these derived fibres with the stated strict path spaces and their products. The two projection identities imply that the induced map of the product fibres is $u_{a,b} \times u_{b,c}$, since a map to a product in Hot is determined by its two projections. The concatenation identity is therefore the required formula. Constants give the corresponding unit identity. □

This argument supplies the compatibility omitted by a bare comparison of homotopy types. It uses Quillen's relative fibre theorem and localization at weak equivalences, not a conservativity or faithfulness assertion about finite tests. We checked the path constructions in Evrard (1975, Section I.1) and the diagonal and cocylinder comparisons in Shoikhet (2016, Sections 1.5 and 2.1, Theorem 2.8); we did not find this particular comparison through the category of composable pairs there. The ingredients are classical, and no priority is claimed.



Je vais maintenant montrer 'formellement' que la factorisation 'canonique' d'une flèche de Cat $f : X' \longrightarrow X$ en

$$X' \xrightarrow{i_f} \overline{X'} \xrightarrow{\bar{f}} X, \qquad i_f \text{ Hot-équivalence},$$

avec (on l'espérait) $\bar{f}$ propre et lisse, à partir d'une factorisation similaire pour la flèche diagonale $X \xrightarrow{\mathrm{diag}_X} X \times X$ en

$$\begin{array}{ccc} & X & \\ & \big\downarrow{\scriptstyle i_X} & \text{Hot-équivalence} \\ \mathcal{C}_X & \text{'chemins'} & \\ & \big\downarrow{\scriptstyle p_X} & \\ & X \times X & \end{array}$$

est chose formelle. (Cf. page 139 pour les notations et [la] problématique.) On regarde le diagramme

([40]). Comme p_X est propre et lisse, i.e. 'parfait', son image inverse sur $X' \times X$, savoir $p_{X,f}$, l'est aussi; d'autre part $\mathrm{pr}_2^X \circ f'$ est la projection pr_2 de $X' \times X$ sur X, donc c'est aussi un morphisme parfait (puisque $X' \longrightarrow e$ est parfait, donc il en est de même du composé p. 107 [page 171]

$$(\mathrm{pr}_2^X \underbrace{f'}) \circ \underbrace{p_{X,f}} = \underbrace{\mathrm{pr}_2^X(p_X} \mathrm{pr}_2') = \beta_X \mathrm{pr}_2' \overset{\text{déf}}{=} \bar f \quad).$$

Commentary · Exposition [ms. 170]

The formal diagonal factorization, with its hypothesis retained

The closing argument extracts the reusable part of the path construction. Suppose a category C_X is given with a factorization

$$X \xrightarrow{i_X} C_X \xrightarrow{p_X} X \times X, \qquad p_X i_X = \Delta_X,$$

where i_X is a weak equivalence and p_X is smooth and proper. Put $\sigma_X = \mathrm{pr}_1 p_X$ and $\beta_X = \mathrm{pr}_2 p_X$. Both are smooth and proper, because these classes are closed under composition and base change; a projection is a base change of a map to the terminal category. The identity $\sigma_X i_X = 1_X$ implies that σ_X is a weak equivalence. Its strict fibres are homotopy fibres by the endpoint argument, hence weakly contractible. The lift-category criterion and Quillen A then show that every base change of σ_X is a weak equivalence.

For $f : X' \to X$, form the ordinary pullback $C(f) = X' \times_{X,\sigma_X} C_X$. Its projection $r : C(f) \to X'$ is a weak equivalence. The section i_f induced by i_X satisfies $r i_f = 1_{X'}$, so i_f is a weak equivalence. The map to the other endpoint factors as

$$C(f) \longrightarrow X' \times X \longrightarrow X.$$

The first arrow is the base change of p_X, and the second is a projection. Their composite $\bar f$ is therefore smooth and proper. The equation $\bar f i_f = f$ proves the requested factorization. This is exactly the formal argument of the manuscript, with the universal weak-equivalence step justified.

It applies to $C_X = \underline{\mathrm{Ch}}_\infty(X)$, whose two lifting properties were proved using the two cofinal parity systems. It cannot be applied with the asserted hypothesis to $C_X = \underline{\mathrm{Ch}}(X)$ or $\mathcal{C}_{\mathbf{N}^\circ}$: those endpoint maps fail properness. Their weak equivalence over $X \times X$ does not transfer a strict comma-category lifting condition. The formal result and the comparison theorem therefore coexist without identifying their hypotheses.

Je rappelle que la section i_f de $C(f)$ sur X' est définie à partir de la section i_X de $(\mathcal{C}_X, \sigma_X)$ sur X. C'est une Hot-équivalence, car $\sigma_X = \mathrm{pr}_1^X p_X$ est parfait à fibres asphériques, donc universellement une Hot-équivalence, donc $\mathrm{pr}_1 p_{X,f} : C(f) \longrightarrow X'$ est aussi une Hot-équivalence, et toute section en est donc une aussi.

40. NB $C(f)$ est défini comme l'image inverse sur X' du fibré C_X sur X (par $\sigma_X = \mathrm{pr}_1^X \circ p_X$) par $f : X' \longrightarrow X$.

Commentary · Examples [ms. 171]

A mapping-path fibre for a homomorphism of groups

The factorization records more than the kernel of a functor on components. For a homomorphism $\phi : H \to G$, write $\mathbf{B}H$ and $\mathbf{B}G$ for their one-object groupoids and consider the functor $\mathbf{B}\phi$ between them. The homotopy fibre has a particularly small categorical model, the action groupoid F_ϕ with objects $g \in G$ and arrows

$$h : g \longrightarrow g' \quad \Longleftrightarrow \quad g'\phi(h) = g.$$

If $h : g \to g'$ and $k : g' \to g''$, their composite is kh, since $g''\phi(kh) = g$. All arrows are invertible. This is the over-comma category $(\mathbf{B}\phi)/{*}$, where $*$ is the unique object of $\mathbf{B}G$. Every arrow in the base groupoid acts on it by an isomorphism, so Quillen B identifies BF_ϕ with the homotopy fibre.

Two objects lie in the same component precisely when they are in the same coset $g \operatorname{im}\phi$. An automorphism of any g is an h with $\phi(h) = 1$, hence the isotropy group is $\ker\phi$. Choosing one representative in each coset gives an equivalence of groupoids

$$F_\phi \simeq \coprod_{G/\operatorname{im}\phi} \mathbf{B}(\ker\phi).$$

Thus π_0 detects the failure of surjectivity and the fundamental group of each component detects the failure of injectivity. For multiplication by a nonzero integer m on $\mathbf{Z}$, the fibre has $|m|$ contractible components. For the map $\mathbf{Z} \to 1$, it is a circle up to homotopy. The corresponding fibre of Grothendieck's mapping-path factorization has exactly these homotopy types. In particular it is weakly contractible precisely when ϕ is an isomorphism, which illustrates the triviality criterion at p. 156 without computing any individual categorical path.

Overview · VII-c

Paths, comparison, and the information carried by a model.

These pages bring the long construction of categorical paths to its decisive test. A path should do more than give a word in arrows and their inverses. Its category should have the homotopy type of a space of paths, should vary with both endpoints, and should turn an arbitrary functor into a map whose strict fibres compute homotopy fibres. Grothendieck wants these properties before making any fibrant replacement of the category in which the paths lie. The problem is therefore one of comparison between concrete models, with their actual arrows and their actual endpoint maps (Grothendieck, 1990–1991o, ms. 108–171).

There are three models in play. The category $\underline{\mathrm{Ch}}(X)$ retains a finite interval type as part of a path, and permits changes of type. Concatenation is strictly associative there. A chosen sequence of longer alternating intervals gives categories C_n and a filtered colimit C_∞; identity arrows added at the ends become identifications in this colimit. Between them stands the Grothendieck construction $C_{\mathbf{N}^o}$, which retains the stage and the transition morphisms. Passing the diagram (C_n) through homotopy first gives yet another object, the ind-object H_T. None of these operations should be silently substituted for another. The opening pages, from manuscript page 108, are largely an investigation of what is lost by doing so.

For a filtered diagram the comparison from its Grothendieck construction to its ordinary colimit is a weak equivalence. Nerves commute with filtered colimits, and filtered homotopy colimits of simplicial sets map by weak equivalences to ordinary colimits. This explains one side of the comparison span on manuscript page 108. The other side depends on the indexing category and on the diagram. Grothendieck correctly observes that cofinality in the preorder of objects does not make the original indexing category contractible: a one-object group already distinguishes the two statements. The appropriate general machinery is the homotopy-colimit theorem for the Grothendieck construction and the comma-category criteria for homotopy cofinality (Thomason, 1979; Quillen, 1973).

The proposed independence of the chosen sequence is more delicate than the text acknowledges. An isomorphism of ind-objects in the ordinary homotopy category does not control the compatibility of the homotopies used at successive stages. Our finite-injection example makes this precise within the general hypotheses of manuscript pages 99–101. To a finite set we associate the one-object category of its permutation group. Injections act by extending permutations by the identity. Parallel injections induce naturally isomorphic functors, yet a morphism between two cofinal sequences induces, on the colimit, the non-surjective shift of the finitary permutation group. Thus the general comparison assertion on pages 117–121 is false. This does not invalidate the geometric path comparison proved later by a different argument.

The same distinction clarifies the questions about $\mathrm{Hot} \longrightarrow \mathrm{Hot}_0^\wedge$. In this notation the subscript 0 refers to a chosen category of finite tests; it is not a truncation to homotopy 0-types. Restricting unbased representable functors to finite tests is neither generally faithful nor generally conservative. The locally inner permutation-group example in the commentary on Chapter V, manuscript page 52, already treats conservativity. Here a telescope of degree-two maps of circles supplies an explicit failure of faithfulness: an essential map to $K(\mathbf{Z}, 2)$ is invisible on every finite stage. Its obstruction is calculated in the commentary, rather than attributed vaguely to a failure of coherence. The cellular and representability tools are classical (Hatcher, 2002, §3F and Theorem 4.57). In addition, a category with finitely many arrows need not have a homotopy-finite nerve. Compactness of a test in the homotopy category requires its own hypothesis. These qualifications matter whenever a displayed bijection is used to infer an isomorphism or an equality of maps.

External Hom and the role of the parameter category.

Section 11 returns to the reason that paths entered the theory of derivators. For a relative

category $(\mathcal{M}, \Sigma)$ one can always form the prederivator

$$A \longmapsto \mathcal{M}^A[\Sigma_A^{-1}],$$

where Σ_A is defined objectwise. Grothendieck asks when the morphisms between constant diagrams are represented by a homotopy type, with the expected dependence on the homotopy type of A. This is a substantive condition on a relative category. It does not follow merely from the existence of an ordinary localization, and the existence of a prederivator is not the existence of all the Kan extensions required of a derivator.

The discussion of a categorical two-sphere on pages 132–135 identifies a real problem but gives an incorrect explanation. A fixed finite circle-shaped parameter can already support arbitrarily high degrees when the length of the target path is allowed to increase: concatenate the same family of loops repeatedly. We work this out for the six-object suspension of the four-object circle poset. The same example gives a genuine failure of homotopy invariance by comparing that circle poset with the one-object category $B\mathbf{Z}$. Every functor from a group to a poset is constant; the resulting localization has lost the family that the circle-shaped parameter sees. The example separates the valid concern about parameter categories from the proposed bound on degrees.

There is a second distinction at page 135. The total arrow category $\mathrm{Fun}([1], C)$ has the homotopy type of C, for every C. Evaluation and the constant-diagram functor give the needed adjunction and natural transformation. What fails for an arbitrary category is the claim that its strict fixed-endpoint arrow sets are derived path spaces. Likewise, Thomason fibrancy of the target alone does not turn every ordinary functor category into a derived internal Hom. The commentary supplies a fibrant-poset counterexample and distinguishes a derived mapping-space construction from this incorrect assertion. The separate claim that ordinary functor categories preserve Thomason fibrancy is also false. An explicit equivariant horn-cell construction gives a fibrant category E for which $\mathrm{Fun}(B(\mathbf{Z}/2), E)$ has a nonfibrant retract; the proof uses the fixed-point pushout formulas of May et al. (2017, Lemmas 4.7–4.8). Simplicial localization provides a systematic external Hom for a relative category, while additional model-theoretic hypotheses justify comparisons with categories of ordinary diagrams (Dwyer and Kan, 1980c,a; Groth, 2013; Cisinski, 2009; Lurie, 2009).

What the path comparison establishes.

Sections 12 and 13 concern $\Sigma = \mathrm{Mor}(X)$. Alternating paths of unbounded length are the essential construction. By choosing the parity of their end arrows one obtains finite-stage Grothendieck fibrations or opfibrations over the endpoint category. The categories of lifts pass to filtered unions. This proves smoothness and properness of $\underline{\mathrm{Ch}}_\infty(X) \to X \times X$, although the union need not itself be a Grothendieck fibration or opfibration. The lift-category argument, not the existence of compatible Cartesian arrows at all stages, is what survives the passage to the union. The terminology comes from base-change phenomena: modern asphericity theory makes the categorical tests precise (Maltsiniotis, 2005).

For the category of all finite paths the source proves smoothness by a useful explicit construction. Given endpoint arrows and a path c, insert those arrows at the two ends to form $\widetilde{c}$. The category of lifts is compared with the slice over $\widetilde{c}$, which has a terminal object. Padding, retraction, and their naturality give the contraction. This is a sound argument once the notation in the diagrams is read correctly. Its claimed dual, however, does not prove properness. An empty path admits no outgoing change to a nonempty interval type. Over $X = [1]$, changing only one endpoint therefore gives an empty category of outgoing lifts. The same obstruction applies to $C_{\mathbf{N}^o}$. The assertion that both these endpoint projections are proper must remain false in the audit.

The desired comparison nevertheless survives. For $\underline{\mathrm{Ch}}(X)$, concatenating an endpoint arrow, or its reversed path, defines transport between fibres. The two composites are connected to the identity by the explicit backtracking-cancellation zigzags. Combining these equivalences

with the proved smoothness gives the hypotheses of the dual of Quillen's Theorem B. Hence strict endpoint fibres compute homotopy fibres. The known total and fibrewise equivalences $C_{\mathbf{N}^o} \to \underline{\mathrm{Ch}}_\infty(X)$ transfer the same property to the middle model. Finally the total equivalence $C_{\mathbf{N}^o} \to \underline{\mathrm{Ch}}(X)$ becomes a fibrewise equivalence by comparison of homotopy fibres. This repairs the concluding argument without assigning a false properness property to either total category.

It follows that the two geometric path models have equivalent endpoint fibres. Strict concatenation in the category of finite paths then furnishes the expected composition in Hot, including the loop-space multiplication. The diagonal factorization and the mapping-path construction on pages 170–171 work with the perfect model $\underline{\mathrm{Ch}}_\infty(X)$; their formal proof is expanded in the commentary. Evrard's earlier categorical cocylinder and Shoikhet's refinement give closely related factorization theorems, with precisely stated homotopy-fibration conclusions. They should not be cited as asserting that Grothendieck's particular maps are Thomason fibrations or that the inclusion of constant paths is a Thomason cofibration (Evrard, 1975; Shoikhet, 2016).

The larger programme is continuous with *Pursuing Stacks*, §69: homotopy theory is to retain the diagram categories needed to form and compare fibres, cofibres, and their operations. The letter to Thomason of 2 April 1991 explicitly returns to unbounded categorical paths and to constructions that avoid a preliminary Kan replacement (Grothendieck, 1983, 1991a). Here the useful boundary is precise. The geometric comparison and mapping-path factorization can be proved; the general finite-test and ordinary-internal-Hom assertions require correction. The developments marked [ours] give the explicit counterexamples and repairs used in the commentary. They record arguments given here, with the literature checks stated in their blocks, and make no claim of priority.

1 Intégration des 1-types d'homotopie relatifs sur une catégorie.

p. 1
[page 1]

Les types d'homotopie relatifs sur une (petite) catégorie S sont définis par les *champs* (en catégories) sur $S^\wedge$, qui correspondent essentiellement aux contrafoncteurs $S^o \longrightarrow (\mathrm{Cat})$, ou encore aux catégories X sur S qui sont Cat-fibrées sur S. (Dans $(\mathrm{Cat}/S)_{\mathrm{fib}}$, on inverse les flèches qui sont des Hot-équivalences sur les fibres.) D'autre part, les 1-types d'homotopie relatifs sur S doivent se décrire par des *champs en groupoïdes* sur S. Si on a un type d'homotopie relatif, défini par

$$X \longrightarrow S, \qquad \text{catégorie Cat-fibrée sur } S,$$

ou par

$$\begin{array}{ccc} S^o & \longrightarrow & \mathrm{Cat} \\ s & \longmapsto & X_s\ , \end{array}$$

le 1-type d'homotopie associé est défini par

$$s \longmapsto \Pi(X_s), \qquad S^o \longrightarrow (\mathrm{Grp}), \qquad \text{catégorie des groupoïdes,}$$

où $\Pi(X_s)$ est le groupoïde fondamental de X_s. On note la catégorie fibrée correspondante sur S par $\boxed{\Pi(X/S)}$. Il est vrai que si

$$X \longrightarrow X'$$

est un homomorphisme de catégories fibrées sur S qui induise une Hot-équivalence sur les fibres, elle induit une équivalence fibrée

$$\Pi(X/S) \longrightarrow \Pi(X'/S),$$

mais non un isomorphisme. Il y aurait donc du travail à faire pour définir un foncteur

$$\underbrace{\mathrm{Hot}(S)}_{\substack{\text{catégorie des}\\ \text{types d'homotopie}\\ \text{relatifs sur } S}} \xrightarrow{\xi \longmapsto \Pi(\xi/S)} \underbrace{\mathrm{Grp}(S)}_{\substack{\text{catégorie des}\\ \text{groupoïdes}\\ \text{fibrés sur } S\\ \text{(ou catégories}\\ \text{des champs en}\\ \text{groupoïdes}\\ \text{sur } S^\wedge)}} .$$

Mais ce n'est pas pour l'instant mon propos. Plutôt, de donner une formule de transitivité en homologie non commutative, analogue à $R(gf)_* \simeq Rg_*Rf_*$ en cohomologie.

Commentary · Exposition [ms. 1]

Why the target is a 2-category

Grothendieck wants integration to retain the automorphisms of a homotopy type, and not merely its connected components. A groupoid is exactly the amount of structure needed for a homotopy 1-type. Its objects represent points, its arrows represent homotopy classes of paths, and the nerve has no homotopy groups above degree one. For a category C, the groupoid ΠC is its localization at *all* arrows. In particular, it is generally very different from the maximal subgroupoid of C.

The relative version must remember transport as well. We write $\mathsf{Gpd}(S)$ for the 2-category of categories fibred in groupoids over S, functors over S, and natural transformations over S. Every arrow of a category fibred in groupoids is cartesian; consequently every functor over the base between such categories preserves cartesian arrows, and every 2-arrow is invertible. A choice of cleavage gives a pseudofunctor $S^{\mathrm{op}} \to \mathsf{Gpd}$, including the isomorphisms comparing successive inverse images. This is the language of Grothendieck (1971b, Exposé VI, §§6–8). No topology imposing additional descent

has been specified here: “champs” is being used through the equivalence with fibred categories on the presheaf topos.

Taking fundamental groupoids fibre by fibre is compatible with these comparison isomorphisms. It therefore gives a relative truncation, rather than a mere collection of unrelated groupoids. A weak equivalence of fibres becomes an equivalence of groupoids, which explains Grothendieck’s hesitation about a functor to an ordinary category of actual groupoids: localization requires its inverted arrows to become *isomorphisms*. One can either pass to the homotopy category of $\mathsf{Gpd}(S)$, whose morphisms are isomorphism classes of cartesian functors, or retain the entire 2-category. In modern language the underlying operation is the pointwise truncation

$$\mathrm{Fun}(NS^{\mathrm{op}}, \mathcal{S}) \longrightarrow \mathrm{Fun}(NS^{\mathrm{op}}, \mathcal{S}_{\leq 1}).$$

Here $\mathcal{S}$ denotes spaces and $\mathcal{S}_{\leq 1}$ their full subcategory of 1-types. The composition law for integration will be an equivalence with coherent comparison isomorphisms, precisely the form in which it can be useful again under a further change of base.

The terminology continues the programme of Grothendieck (1983, §69, especially printed pp. 3–5): integration is the left adjoint to change of the indexing category. The present calculation isolates a particularly concrete part of that programme, where ordinary categories and their groupoid completions suffice to construct the adjoint.

p. 2
[page 2]

Si

$$f : S \longrightarrow T$$

est un foncteur, on va définir un foncteur

$$f_! : \underline{\mathrm{Grp}}(S) \longrightarrow \underline{\mathrm{Grp}}(T)$$

(image directe de 1-types d'homotopie relatifs). Mais notons d'abord que si

$$p : X \longrightarrow S$$

est une S-catégorie *quelconque* (pas nécessairement Cat-fibrée), on lui associe néanmoins un type d'homotopie relatif, via la catégorie fibrée $\tilde{X}^{(S)}$, ou $\tilde{X}$, ayant comme fibres les $s\backslash X$ (en notant que $s' \longrightarrow s$ dans S définit bien $s\backslash X \longrightarrow s'\backslash X$) ([1]). On a un S-foncteur canonique

$$X \xrightarrow{i} \tilde{X}, \qquad x \longmapsto (x, p(x), \underbrace{p(x)}_{=\,`s'} \xrightarrow{\mathrm{id}} p(x)).$$

C'est une S-Hot-équivalence si X était déjà fibrée. En fait, sur chaque fibre c'est un homotopisme car on définit alors $\tilde{X}_{s_0} \xrightarrow{j} X_{s_0}$ de façon évidente, de façon que

$$X_{s_0} \underset{j}{\overset{i}{\rightleftarrows}} \tilde{X}_{s_0}, \qquad ji \simeq \mathrm{id}, \qquad ij \underbrace{\xrightarrow{\text{homotopie simple}}}_{\substack{\text{NB cette flèche}\\ \text{n'est pas [un]}\\ \text{isomorphisme}\\ \text{en général.}}} \mathrm{id}.$$

Revenons alors à $f : S \longrightarrow T$, et considérons un groupoïde fibré sur S,

$$G \longrightarrow S,$$

ce n'est pas une catégorie fibrée sur T, mais on peut lui associer

$$t \longmapsto t\backslash G, \qquad T^o \longrightarrow (\mathrm{Cat}),$$

d'où une catégorie fibrée sur T, dont on prend le Π relatif. Mais il est plus simple de prendre directement

$$t \longmapsto \Pi(t\backslash G),$$

qui définit une catégorie fibrée en groupoïdes sur T.

Commentary · Exposition [ms. 2]

The comma category computes integration

The comma construction makes the variance visible. For $p : X \to S$, an object of $s\backslash_S X$ is a pair $(x, \alpha : s \to p(x))$; an arrow to (x', α') is an arrow $v : x \to x'$ with $p(v)\alpha = \alpha'$. Precomposing α gives the contravariant dependence on s. Thus the displayed formula is meaningful even when p has no cartesian lifts.

When p is fibred, those lifts explain the comparison with the actual fibre. Choose a normalized cleavage and send (x, α) to $\alpha^* x \in X_s$. If v is a comma arrow, its composite with the chosen cartesian arrow $\alpha^* x \to x$ factors uniquely through $\alpha'^* x' \to x'$. This defines a functor $j_s : s\backslash_S X \to X_s$. Its composite with the inclusion i_s is the identity, and the cartesian arrows give $i_s j_s \Rightarrow \mathrm{id}$. Applying the nerve yields a homotopy equivalence. The last natural transformation need not be an isomorphism, exactly as the manuscript warns; after applying Π, it becomes one. This also proves the asserted equivalence $H \simeq \Pi(H/S)$ when H is fibred in groupoids.

1. Ayant $\tilde{X}$, on définit $\Pi(X/S) \overset{\text{déf}}{=} \Pi(\tilde{X}/S)$.

For $f : S \to T$ and $G \to S$, the same construction gives

$$(f_!G)_t = \Pi(t\backslash_T G).$$

The subscript on the comma is essential: its objects use arrows $t \to f(s)$ in T. Equivalently, if $F : S^{\mathrm{op}} \to \mathsf{Gpd}$ describes G, then

$$(f_!F)(t) \simeq \tau_{\leq 1} \operatorname*{colim}_{(s,\alpha)\in(t\backslash f)^{\mathrm{op}}} F(s),$$

where the colimit on the right is the homotopy colimit in spaces. The total category is the concrete way to form this colimit before truncation. In particular, the $s\backslash G$ printed in the unit on manuscript page 4 must be read as $f(s)\backslash_T G$; this is a notational slip in the edition, not an error introduced by the transcription.

For orientation, let $S = [0 \to 1]$, and let F be the diagram $F(1) \to F(0)$. Integration over S gives $F(0)$ up to equivalence, whereas its groupoid of sections is $F(1)$. Indeed, the construction above sends an object over 1 to its inverse image over 0, and its cartesian arrow becomes invertible in ΠG. Sections are instead determined by their value over 1. The two endpoints already separate homology from cohomology.

Ainsi on trouve bien un foncteur (en fait, même un 2-foncteur de 2-catégories) p. 3 [page 3]

$$f_! : \underline{\mathrm{Grp}}(S) \longrightarrow \underline{\mathrm{Grp}}(T).$$

Si

$$u : G \longrightarrow G'$$

est un homomorphisme de groupoïdes fibrés sur S, qui induise des Cat-équivalences sur les fibres, alors

$$f_!(u) : f_!(G) \longrightarrow f_!(G')$$

est aussi une Cat-équivalence sur les fibres. (Cela est formel, à partir du fait que $f_!$ est un 2-foncteur, compte tenu que si on a une équivalence sur les fibres, alors il y a un quasi-inverse – c'est une histoire générale de catégories fibrées …)

Soit maintenant

$$p : X \longrightarrow S,$$

et prenons le cas $G = \Pi(X/S)$. Je dis qu'on a alors une T-équivalence

$$(*) \qquad \boxed{f_!(\Pi(X/S)) \simeq \Pi(X/T),}$$

en d'autres termes, pour connaître $\Pi(X/T)$ (à T-équivalence près), il suffit de connaître $\Pi(X/S)$, et de lui appliquer le foncteur $f_!$ d'intégration des 1-types d'homotopie relatifs, pour $f : S \longrightarrow T$.

Notons que l'on a trivialement

$$\Pi(X/S) = p_!(e_X),$$

où e_X désigne le X-groupoïde fibré trivial (toutes les fibres ponctuelles). Donc la formule précédente s'écrit comme une formule de transitivité

$$f_!(p_!(\Gamma)) \simeq (fp)_!(\Gamma),$$

où Γ est le groupoïde fibré trivial sur X. Cela suggère de généraliser la formule $(*)$ en [page 4]

$$\boxed{(fp)_!(\Gamma) \simeq f_!(p_!(\Gamma))}$$

pour *tout* groupoïde fibré sur X, dans une situation

$$X \xrightarrow{p} S \xrightarrow{f} T.$$

Ce sera formel, si on établit une propriété de 2-adjonction pour le foncteur $f_!$:

Théorème. *Soit $f : S \longrightarrow T$ une flèche dans* (Cat)*, G un champ en groupoïdes sur S, H un champ en groupoïdes sur T. On a alors une équivalence de catégories canonique* p. 4

$$\boxed{\underline{\mathrm{Hom}}_{\underline{\mathrm{Grp}}(S)}(G, f^*H) \simeq \underline{\mathrm{Hom}}_{\underline{\mathrm{Grp}}(T)}(f_!G, H).}$$

Les flèches d'adjonction

$$\begin{cases} f_!f^*H \longrightarrow H & H \in \mathrm{Ob}\,\underline{\mathrm{Grp}}(T) \\ f^*f_!G \longleftarrow G & G \in \mathrm{Ob}\,\underline{\mathrm{Grp}}(S) \end{cases}$$

devraient se définir sans problème. Pour la deuxième, il faut définir pour $s \in S$

$$G_s \longrightarrow (f^*(f_!(G)))_s = (f_!(G))_{f(s)} \overset{\text{déf}}{=} \Pi(s\backslash G),$$

or on a

$$G_s \longrightarrow s\backslash G,$$

d'où

$$\underbrace{\Pi(G_s)}_{\substack{= G_s \\ \text{car } G_s \\ \text{est un} \\ \text{groupoïde}}} \longrightarrow \Pi(s\backslash G),$$

O.K. C'est fonctoriel en s …

Pour la flèche $f_! f^* H \longrightarrow H$ sur T, il faut trouver pour tout $t \in \mathrm{Ob}\, T$, et fonctoriellement en t, [page 5]

$$\underbrace{(f_! f^* H)_t}_{\overset{\text{déf}}{=} \Pi(t\backslash f^*(H))} \longrightarrow \underbrace{H_t}_{= \Pi(H_t)},$$

il suffirait donc de définir

$$t\backslash f^*(H) \longrightarrow H_t,$$

mais on a le diagramme cartésien

$$\begin{array}{ccc} f^*H = H \times_S T & \longrightarrow & H \\ \downarrow & & \downarrow \\ S & \xrightarrow{\quad f \quad} & T \ni t \end{array}$$

`[plutôt` $H \times_T S$`]` induisant

$$f^* H \longrightarrow H,$$

d'où p. 5

$$t\backslash f^* H \longrightarrow t\backslash H \qquad \text{(au lieu de s'envoyer dans } H_t),$$

mais d'autre part, comme H est fibrée sur T, donc lisse sur T, l'inclusion

$$H_t \longrightarrow t\backslash H$$

est une Hot-équivalence. Ou disons plutôt : $f^* H \longrightarrow H$ est un morphisme de catégories sur T, induisant

$$\underbrace{\Pi(f^* H/T)}_{\overset{\text{déf}}{=} f_!(f^* H)} \longrightarrow \Pi(H/T),$$

or le T-foncteur canonique [page 6]

$$H \longrightarrow \Pi(H/T) \qquad (= \text{catégorie sur } T \text{ définie par } t \longmapsto \Pi(t\backslash H))$$

est une équivalence, parce que H est un fibré en groupoïdes sur T. Donc on peut trouver un T-quasi-inverse

$$\Pi(H/T) \longrightarrow H$$

et en composant on trouve

$$f_!(f^* H) \longrightarrow \Pi(H/T) \longrightarrow H$$

la flèche cherchée.

Ayant les 2-flèches d'adjonction, je m'arrête là dans les vérifications !

Commentary · Exposition [ms. 6]

Completing the adjunction and its transitivity

The proposed unit and counit are the right ones. To finish their verification without making incompatible choices of quasi-inverses, it is useful to prove a slightly more general universal property. For any category $X \to T$, put $R_T X = \Pi(X/T)$. If $H \to T$ is fibred in groupoids, restriction along $X \to R_T X$ induces an equivalence

$$\mathrm{Hom}_T(R_T X, H) \simeq \mathrm{Fun}_T(X, H). \tag{VIII.1}$$

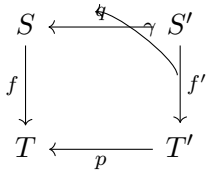
Both sides are groupoids of functors and transformations over T.

Here is a direct construction of the inverse. Given $A : X \to H$ over T, choose cartesian lifts in H and send $(x, \alpha : t \to p(x))$ to $\alpha^* A(x)$. For a comma arrow v, the cartesian factorization of $A(v)$ gives an arrow between these two objects in H_t. All such arrows are invertible, so the functor extends uniquely across the localization $t\backslash_T X \to \Pi(t\backslash_T X)$. The comparison isomorphisms of the cleavage supply its dependence on t; their cocycle equation follows from the uniqueness of cartesian factorization. A transformation $A \Rightarrow B$ extends by applying α^* to its component at x. Thus this construction is a functor on the Hom-groupoids, not just a bijection between classes of objects.

Restricting the extension to $(x, \mathrm{id}_{p(x)})$ recovers A. Conversely, an over-T functor $B : R_T X \to H$ sends the cartesian arrow from (x, α) to $(x, \mathrm{id}_{p(x)})$ to a cartesian arrow in H. Cartesian factorization therefore gives a natural isomorphism between $B(x, \alpha)$ and $\alpha^* B(x, \mathrm{id})$. This identifies B with the extension of its restriction, naturally also in transformations. It proves (VIII.1), including all the coherence needed for an adjunction.

Apply (VIII.1) to the total category of G viewed over T. An over-T functor $G \to H$ is exactly an over-S functor $G \to f^* H$. We obtain the claimed equivalence of Hom-groupoids. The unit sends $g \in G_s$ to the class of $(g, \mathrm{id}_{f(s)})$. The counit sends the class of $((s, h), \alpha : t \to f(s))$ to $\alpha^* h$. The first triangle evaluates the latter formula at an identity arrow. The second uses the canonical cartesian arrow just described, so is the natural isomorphism between extension after restriction and the original functor. Their compatibility is the uniqueness assertion in the same cartesian factorization. Choosing different cleavages changes these formulas by a unique compatible comparison; it does not change the biadjunction.

Transitivity now follows at the same level of precision. For $X \xrightarrow{p} S \xrightarrow{f} T$,



$$\begin{aligned} \mathrm{Hom}_T(f_! p_! \Gamma, H) &\simeq \mathrm{Hom}_S(p_! \Gamma, f^* H) \\ &\simeq \mathrm{Hom}_X(\Gamma, p^* f^* H) \\ &\simeq \mathrm{Hom}_T((fp)_! \Gamma, H). \end{aligned}$$

The bicategorical Yoneda argument identifies the two representing objects. For three composable maps, both parenthesizations represent the same composite restriction; the representing equivalences consequently satisfy the associativity constraint. Taking $\Gamma = e_X$ gives $p_! e_X = \Pi(X/S)$ and the first boxed transitivity formula. What the source leaves unchecked is therefore a coherence verification, not a missing hypothesis in the theorem.

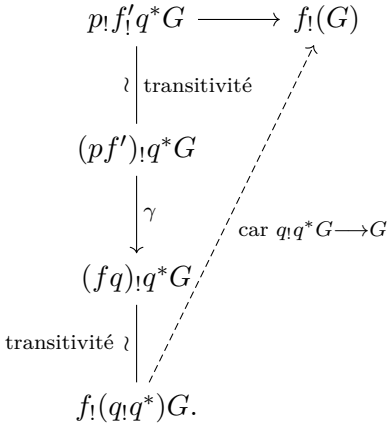
2 Questions de changement de base



(∗)

$$p^* f_!(G) \longleftarrow f'_! q^*(G)$$

La flèche est définie, pourvu qu'on ait commutativité ou une flèche de commutativité $\gamma : pf' \longrightarrow fq$ (pas nécessairement [un] isomorphisme). Par adjonction, il revient au même

de donner

On se demande quand la flèche est [un] isomorphisme.

Le théorème suivant doit être vrai, et résulte de mes fourbis généraux. [page 7]

Théorème. *Si le carré* $(*)$ *est* cartésien *dans* (Cat)*,* γ *un isomorphisme, et si on suppose que* f *soit* 1*-lisse, ou* p 1*-propre, alors le* T'*-foncteur de changement de base est une équivalence de* T'*-catégories.*

Les 'fourbis' généraux seraient en termes d'un dérivateur **D** ad hoc, celui des 1-types d'homotopie relatifs. J'y reviendrai par la suite.

Commentary · Later developments [ms. 7]

Base change for truncated homotopy types

Grothendieck's next step asks whether integration can be performed after restricting the base. The natural transformation $\gamma : pf' \Rightarrow fq$ fixes the direction of the comparison: contravariance gives $q^* f^* \Rightarrow f'^* p^*$, whose mate is $f'_! q^* \Rightarrow p^* f_!$. At t', its effect before groupoid completion is the evident functor sending a lift $\delta : t' \to f'(s')$ to the composite $p(t') \xrightarrow{p\delta} pf'(s') \xrightarrow{\gamma_{s'}} fq(s')$.

The theorem is valid for the derivator of 1-types. More generally, set

$$\mathbb{D}_n(I) = h\,\mathrm{Fun}(NI^{\mathrm{op}}, \mathcal{S}_{\leq n}), \qquad n \geq -1.$$

Its left Kan extensions are homotopy left Kan extensions followed by n-truncation; its right Kan extensions are homotopy limits. The truncation is an accessible reflector, and the truncated category remains presentable (Lurie, 2009, Proposition 5.5.6.18 and Remark 5.5.6.21), so these Kan extensions exist for every small indexing category. An n-aspherical category is one whose n-truncation is a point, with the case $n = -1$ meaning nonemptiness. Smoothness and properness must be taken relative to this theory. They are conditions on the relevant comma categories and their changes of base, not merely on the homotopy types of the strict fibres.

A precise later formulation is Maltsiniotis (2005, Theorem 1.2, Corollary 4.16, Example 4.17, and §5). Theorem 1.2 identifies smoothness with the asphericity of the fibre-to-comma inclusions; §5 treats the corresponding base-change morphism. With his covariant convention replaced by the contravariant convention here, its two alternatives are exactly that the integrating map f is smooth or that the restricting map p is proper. Applying the statement to the localizer detected by fundamental groupoids gives equivalences of groupoids at every t', hence an equivalence of fibred groupoids. No information above the first homotopy group is needed for this particular comparison.

This distinction between a correct integration theorem and an insufficient local-constancy criterion will matter on manuscript page 9. Truncating the *values* of a diagram does not truncate all the coherence by which the values are assembled over its base.

On se pose la question quand le 2-foncteur associé à $f : S \longrightarrow T$

$$f^* : \underline{\underline{\mathrm{Grp}}}(T) \longrightarrow \underline{\underline{\mathrm{Grp}}}(S)$$

est 0-fidèle, 1-fidèle, 2-fidèle ([2]). Si G, H sont des fibrés en groupoïdes sur T, on considère p. 7

$$\underline{\underline{\mathrm{Hom}}}_{\mathrm{Grp}(T)}(G,H) \longrightarrow \underline{\underline{\mathrm{Hom}}}_{\mathrm{Grp}(S)}(f^*G, f^*H),$$

et suivant que ce foncteur est toujours fidèle, ou pleinement fidèle, ou une équivalence de catégories, on dit que f^* est 0-, 1-, ou 2-fidèle. Dans le cas 2-fidèle, cela implique que si K est un fibré en groupoïdes sur S, s'il est équivalent à un f^*G, alors G est déterminé à T-équivalence près, elle même déterminée à isomorphisme unique près.

Commentary · Examples [ms. 7]

Sections alone do not test full faithfulness

The three faithfulness conditions distinguish the lifting of transformations, of functors, and of their isomorphisms. The footnote proposes testing them using section groupoids alone. As an assertion for an arbitrary f, that reduction is false.

Let $T = [0 \to 1]$, $S = \{1\}$, and let f be the inclusion. For every contravariant groupoid diagram $H = (H_1 \to H_0)$, evaluation at 1 is an equivalence $\Gamma(T,H) \simeq H_1$: a section consists of h_1, h_0, and an isomorphism $h_0 \simeq u^*h_1$, and the choices of the latter pair form a contractible groupoid. Thus

$$\Gamma(T,H) \longrightarrow \Gamma(S, f^*H)$$

is an equivalence for every H.

Nevertheless, take $G_1 = H_1 = \varnothing$, $G_0 = *$, and $H_0 = B(\mathbf{Z}/2)$. The only structure maps from the empty groupoid exist uniquely. A functor $G \to H$ is now just a functor $* \to B(\mathbf{Z}/2)$, and its natural automorphism group is $\mathbf{Z}/2$. Consequently

$$\mathrm{Hom}_T(G,H) \simeq B(\mathbf{Z}/2) \longrightarrow \mathrm{Hom}_S(f^*G, f^*H) \simeq *$$

is not faithful. The proposed section test therefore fails even for 0-faithfulness, despite satisfying the strongest of its own three tests.

There is a useful exact replacement. If $\pi_G : G \to T$ denotes the *total category* of the first coefficient, then

$$\mathrm{Hom}_T(G,H) \simeq \Gamma(G, \pi_G^*H).$$

Indeed, a section of $G \times_T H \to G$ is precisely a functor $G \to H$ over T, and the same identification holds for transformations. After restriction, the base becomes $S \times_T G$. Testing sections on these changed bases, with the pulled-back coefficients, is equivalent to testing the required Hom-groupoids. The missing base change cannot in general be suppressed by invoking an internal Hom: arbitrary restriction of presheaves does not preserve that internal Hom.

Commentary · Development (commentators') [ms. 7]

Factorizations detect all three levels

Grothendieck's faithfulness question can be answered without imposing smoothness or properness. The appropriate test keeps both endpoints of an arrow of T, as did the factorization categories discussed in the commentary on Chapter II, manuscript page 53. In the untruncated setting, Groth and Ŝtovíček (2016, arXiv version, Definition 6.9 and Theorem 6.10) give the corresponding criterion for homotopical epimorphisms. We spell out its elementary three-level refinement for groupoids. We did not find this combined formulation in the sources checked; the argument uses standard density and adjunction, and carries no claim of priority.

For an arrow $\beta : t \to t'$ of T, let $\mathcal{F}_f(\beta)$ have objects

$$(s, a : t \to f(s), b : f(s) \to t'), \qquad ba = \beta,$$

and arrows $v : s \to s'$ satisfying $f(v)a = a'$ and $b'f(v) = b$.

2. La i-fidélité de f^* ($i \in \{0,1,2\}$) équivaut à celle des foncteurs (obtenus en prenant $G = e_T$)

$$\underline{\Gamma}(H/T) \longrightarrow \underline{\Gamma}(f^*H/S).$$

Proposition (the three tests). [ours] For $i \in \{0,1,2\}$, restriction $f^* : \mathsf{Gpd}(T) \to \mathsf{Gpd}(S)$ is i-faithful if and only if every $\mathcal{F}_f(\beta)$ is $(i-1)$-connected. Explicitly, these conditions are nonemptiness for $i=0$, nonempty connectedness for $i=1$, and $\Pi\mathcal{F}_f(\beta) \simeq *$ for $i=2$.

Proof. The counit makes the factorization categories appear. Write $h_{t'} = \mathrm{Hom}_T(-,t')$, viewed as a discrete groupoid-valued presheaf. The comma formula gives, at t,

$$(f_! f^* h_{t'})_t \simeq \coprod_{\beta : t \to t'} \Pi\mathcal{F}_f(\beta) \longrightarrow \mathrm{Hom}_T(t,t'). \tag{VIII.3}$$

The counit maps every summand to its indexing arrow. The biadjunction identifies restriction on $\mathrm{Hom}_T(G,H)$ with precomposition by $\varepsilon_G : f_! f^* G \to G$.

To prove necessity at a fixed t, use a coefficient $H = t_* K$, where t_* is the right biadjoint to evaluation at t and K is an arbitrary groupoid. The adjunction reduces the test for $G = h_{t'}$ to precomposition along (VIII.3), with values in K. If a summand is empty, take $K = B(\mathbf{Z}/2)$: an automorphism at that index is invisible after restriction, so faithfulness fails. If a summand has two connected components, the same K allows different automorphisms on those components, which cannot descend from the single index; full faithfulness fails. If a summand is connected but has nontrivial fundamental group, take K to be that summand's groupoid. Its identity functor, extended by constant functors on the other summands, is not isomorphic to a functor factoring through the discrete target. Essential surjectivity fails. These observations give precisely the three necessary conditions.

For sufficiency, first keep $G = h_{t'}$ and allow arbitrary H. Under the nonemptiness condition, a modification between two maps $h_{t'} \to H$ is determined by its pullback along $\varepsilon_{h_{t'}}$: at every t and every β, there is an object over β on which to evaluate it. Under connectedness, a modification between the pulled-back maps has equal components on all objects over a fixed β, since the two maps send every arrow of that groupoid to an identity. It therefore defines a unique component at β. These components are natural in t: reindex an object lying over β, and use naturality of the given modification. Thus the modification descends uniquely, proving full faithfulness. In the third case, (VIII.3) is itself an equivalence at every t, so precomposition is an equivalence of Hom-groupoids.

To pass from representables to an arbitrary G, one needs their coherent density, not just generation of connected components. Index the representables by the total category of G, sending (t', g) to $h_{t'}$. Their homotopy colimit in groupoid-valued presheaves, evaluated at t, is $\Pi(t\backslash_T G)$, hence is equivalent to G_t by the cartesian-lift argument already proved. Thus G is this homotopy colimit. Restriction preserves it, because such colimits are computed pointwise. Taking maps into H, respectively into f^*H, changes these colimits into homotopy limits of the corresponding Hom-groupoids. Faithful functors remain faithful under these limits, because a modification is determined by its components. Fully faithful functors remain fully faithful, because the components lift uniquely and their compatibility follows by faithfulness. Equivalences remain equivalences by the universal property of a homotopy limit. Equivalently, the homotopy fibres of faithful and fully faithful functors of groupoids are, respectively, 0-truncated and (-1)-truncated spaces; these conditions are preserved by limits. The representable tests therefore imply the required assertion for every G, H. This completes the proof.

At level zero the condition has a particularly concrete form: every t is a retract of some $f(s)$. Indeed, apply nonemptiness to id_t; conversely such a retraction supplies a factorization of every arrow with target t. For $f : Z \to e$, the sole factorization category is Z. The three tests become, respectively, that Z is nonempty, connected, or 1-connected. Even the strongest condition concerns maps between constant coefficients; it leaves room for the nonconstant diagram over S^2 constructed below.

[page 8]

Soit $i \in \mathbf{N}$. On dit que f est i-asphérique si $\forall t \in T$, $Z = S/t$ est i-asphérique, i.e.

$$(*) \qquad \pi_0(Z),\ \ldots,\ \pi_i(Z) \qquad \text{triviaux.}$$

On définit aussi (-1)-asphérique : les S/t sont non-vides. De même pour la notion de i-coasphérique.

Commentary · Exposition [ms. 8]

The valid descent assertions in Theorem 3

Theorem 3 contains a useful distinction: full faithfulness of restriction describes how a coefficient already on T is recovered, whereas its essential image describes which coefficients on S descend. The hypotheses in parts 1 and 2 do give these conclusions. The assertion in part 3 needs an additional degree of connectivity.

We give the argument for the valid assertions. Put $n = i - 1$. Under hypothesis a, the inclusions $S_t \to S/t$ are n-coaspherical; under hypothesis b, the inclusions $S_t \to t\backslash S$ are n-aspherical. This is the fibre-to-comma criterion for properness or smoothness, respectively. Combining it with the stated asphericity or coasphericity shows that every strict fibre S_t is n-connected. The same criterion says that the categories of lifts of an arrow of T, with its source fixed in the proper case or its target fixed in the smooth case, are n-connected.

For $i = 0$, every fibre is nonempty. A natural transformation between two functors $G \to H$ over T is determined by its components over each object of T; choosing one object of S_t detects each component. Restriction is therefore faithful on every Hom-groupoid.

For $i = 1$, every fibre is connected. Suppose a transformation between the restrictions of two functors $G \to H$ has been given. At $g \in G_t$, its component calculated using $s \in S_t$ is independent of s, because naturality along the vertical arrows of S_t, and then along zigzags of such arrows, identifies the components. These components are natural within G_t. To verify naturality across an arrow $a : t \to t'$, choose a lift of a with one endpoint fixed; its existence follows from the lift-category criterion. Naturality upstairs is the required naturality downstairs. The descended transformation is unique because every fibre is nonempty. This proves full faithfulness on Hom-groupoids.

For $i = 2$, base change computes the relevant adjunction on each strict fibre. Under hypothesis b, if H is on T, the counit has the fibrewise form

$$(f_! f^* H)_t \simeq \Pi(S_t) \times H_t \longrightarrow H_t.$$

Under hypothesis a, use the right biadjoint f_* instead: its unit is

$$H_t \longrightarrow (f_* f^* H)_t \simeq \mathrm{Fun}(\Pi(S_t), H_t).$$

The right biadjoint is the groupoid of cartesian sections over the comma category S/t; the proper base-change formula replaces that comma category by S_t. Since $\Pi(S_t) \simeq *$, the displayed arrows are equivalences. The adjunction equivalences on Hom-groupoids now prove that f^* is 2-faithful. Notice that this argument uses constant coefficients *on each fibre*; it does not assert that every locally constant coefficient there is constant.

The essential-image statement follows by applying the other adjunction arrow. Under hypothesis b, its restriction to a fibre is the unit

$$G|_{S_t} \longrightarrow \mathrm{const}_{S_t}\left(\Pi \int_{S_t} G\right).$$

If $G|_{S_t}$ is equivalent to a constant groupoid K, integration gives $\Pi(S_t) \times K \simeq K$, so this unit is an equivalence. Thus $G \to f^* f_! G$ is fibrewise an equivalence, and G descends. Under hypothesis a, use $f^* f_* G \to G$ and the same argument with sections: $\mathrm{Fun}(\Pi(S_t), K) \simeq K$. Necessity is immediate, because a coefficient pulled back from T restricts to a constant coefficient on each strict fibre. This proves part 2 with precisely its printed fibrewise-*constant* condition. Its replacement by equivalence of transport functors requires a separate argument and is where the next difficulty lies.

En fait, pour $i \in [-1, +\infty[\subseteq \mathbf{Z}$, on définit un dérivateur $\mathbf{D}_i$ des i-types d'homotopie relatifs (cf. plus bas). D'où les notions d'objet $\mathbf{D}_i$-asphérique (= i-asphérique), de $\mathbf{D}_i$-équivalence, de foncteur $\mathbf{D}_i$-asphérique et $\mathbf{D}_i$-coasphérique, de foncteur $\mathbf{D}_i$-lisse et $\mathbf{D}_i$-propre, de $\mathbf{D}_i$-fibration et de $\mathbf{D}_i$-fibration *triviale* (i.e. à fibres $\mathbf{D}_i$-asphériques). On doit avoir le

Théorème 3. *Soit $f : S \longrightarrow T$ dans* (Cat)*, $i \in \{0, 1, 2\}$. Supposons l'une des conditions suivantes satisfaite :*

a) f est $(i-1)$-propre, et $(i-1)$-asphérique (s'exprime par la condition que certaines catégories, telles les S/t, soient $(i-1)$-asphériques).

b) f est $(i-1)$-lisse, et $(i-1)$-coasphérique.

Alors :

1°) Le foncteur f^* image inverse

$$f^* : \underline{\mathrm{Grp}}(T) \longrightarrow \underline{\mathrm{Grp}}(S)$$

est i-fidèle.

*2°) Dans le cas $i = 2$ (f pleinement fidèle), on a de plus ceci : si $G \in \mathrm{Ob}\,\underline{\mathrm{Grp}}(S)$ est un fibré en groupoïdes sur S, alors G est équivalent à un fibré en groupoïdes de la forme $f^*(H)$ si et seulement si pour tout $t \in T$, la restriction G_t de G à S_t est équivalente à un fibré en groupoïdes constant sur S_t. (**NB** La condition a) ou b) implique déjà que S_t est 1-connexe, i.e. que son groupoïde fondamental est équivalent à e.)* p. 8 [page 9]

3°) Soit Z un objet 1-connexe dans (Cat)*, G un fibré en groupoïdes sur Z. Pour que G soit Z-équivalent à un groupoïde constant sur Z, il faut et il suffit que pour toute flèche u dans Z, le morphisme de groupoïdes u^* induit sur les fibres de G soit une Z-équivalence* ([3]).

Corollaire. *La condition nécessaire et suffisante de 2°) s'écrit aussi ainsi : pour toute flèche u de S 'verticale' sur T, i.e. telle que $f(u)$ soit une flèche identique, le foncteur u^* induit par u sur les fibres de G soit une équivalence de groupoïdes.*

Commentary · Examples [ms. 9]

A finite obstruction in degree two

Grothendieck wants a practical descent test that can be checked on the arrows of the fibres. The obstruction to this last simplification already appears over a finite poset, with every fibre the same two-element automorphism group. It makes the distinction from the preceding valid argument quite explicit. The general coherence issue was isolated in the commentary on Chapter VI, manuscript pages 7 and 74; here it produces a counterexample to a stated theorem.

Let Z be the poset of nonempty proper subsets of $\{0,1,2,3\}$, ordered by inclusion. It has fourteen objects. Its nerve is the barycentric subdivision of the boundary of a tetrahedron, so $|NZ| \cong S^2$ and $\Pi Z \simeq *$. Write $A = \mathbf{F}_2$. On the strictly increasing triples in Z, define

$$c(\sigma,\tau,\upsilon) = \begin{cases} 1, & (\sigma,\tau,\upsilon) = (\{0\},\{0,1\},\{0,1,2\}), \\ 0, & \text{otherwise.} \end{cases}$$

Extend c by zero to triples with a repeated object. There is no strictly increasing chain of four objects, so this normalized 2-cochain is a cocycle.

It is useful to verify directly that it is not a coboundary. Let z be the sum, with coefficients in $\mathbf{F}_2$, of the twenty-four flags vertex $\subset$ edge $\subset$ face of the tetrahedral boundary. Every edge of this order complex occurs in exactly two such flags: a vertex–edge pair extends to two faces, a vertex–face pair has two intervening edges, and an edge–face pair has two possible vertices. Hence $\partial z = 0$, whereas $\langle c, z\rangle = 1$. If $c = \delta b$, this pairing would equal $\langle b, \partial z\rangle = 0$, a contradiction.

Now define a category E_c over Z. There is one object over each σ, and for $\sigma \subseteq \tau$ the arrows over that inclusion are labelled by A; there are no other arrows. The identity has label zero, and composition is

$$(\tau \subseteq \upsilon, b) \circ (\sigma \subseteq \tau, a) = \big(\sigma \subseteq \upsilon, a + b + c(\sigma,\tau,\upsilon)\big). \tag{VIII.2}$$

The cocycle equation is exactly associativity; normalization gives the unit equations. Each fibre is BA. Every arrow is cartesian: composition with a fixed arrow carries the set of lifts of any preceding inclusion bijectively onto the set of lifts of its composite, since in (VIII.2) it adds a fixed element of A. Thus $E_c \to Z$ is a category fibred in groupoids. Choosing the lift labelled zero for each inclusion makes every inverse-image functor $BA \to BA$ the identity. Only the comparison isomorphisms for successive inverse images are nontrivial, and they are encoded by c. Passing to an equivalent split

3. On dit alors que G est *essentiellement localement constant* sur Z.

fibration gives the same counterexample in terms of a strict groupoid-valued functor; the obstruction does not arise from a choice of presentation.

Suppose that E_c were equivalent over Z to a constant fibred groupoid. Its fibre would have to be equivalent to BA, so the constant fibred groupoid would admit a section. An equivalence over Z and its quasi-inverse transport that section to a section of E_c. Such a section chooses a label $b(\sigma,\tau)$ on each inclusion; its functoriality says

$$b(\sigma,\upsilon) = b(\sigma,\tau) + b(\tau,\upsilon) + c(\sigma,\tau,\upsilon).$$

This is precisely $\delta b = c$, which has just been excluded. Therefore E_c is not constant, although Z is 1-connected and every transport functor is an equivalence. This disproves part 3.

It also disproves the corollary under its own hypotheses. Take $f : Z \to e$. A functor to e is both a Grothendieck fibration and an opfibration, hence smooth and proper for the localizer of 1-types. Its sole fibre is the 1-connected category Z, so hypotheses a and b for $i = 2$ both hold. Every arrow is vertical and satisfies the proposed transport test, but E_c is not in the image of f^*. Part 2 itself remains valid: its actual condition demands that $E_c|_Z$ be constant, which it is not.

Commentary · Present state [ms. 9]

The corrected local-constancy criterion

The missing datum is classical 2-monodromy. A locally constant diagram with fibre a groupoid K determines a classifying map

$$|NZ| \longrightarrow B\,\mathrm{Aut}(K),$$

where $\mathrm{Aut}(K)$ is the groupoid of self-equivalences of K and natural isomorphisms. The target is a 2-type: its first homotopy group records equivalence classes of self-equivalences, and its second is $\mathrm{Aut}(\mathrm{id}_K)$. A simply connected base removes the first kind of monodromy but can still support the second. In the finite example it is the nonzero class in $H^2(S^2;\mathbf{F}_2)$.

A precise classification is given by Polesello and Waschkies (2005, arXiv version, Theorem 2.2.5 and §2.3); their Corollary 2.2.4 gives constancy over a 2-connected base. Applied to the CW complex $|NZ|$, it proves the corrected statement: if Z is 2-connected, a groupoid diagram is equivalent to a constant one if and only if all its transport functors are equivalences. Alternatively, over a 1-connected base one must require its remaining 2-monodromy to vanish. This is a known obstruction, not a new conjecture or a priority claim. Strengthening the corollary by requiring 2-connected strict fibres, while retaining the hypotheses of part 2, makes the vertical-arrow criterion sufficient by applying this corrected statement separately to every fibre.

G. Maltsiniotis

1 Fonctorialité de $\mathrm{Ch}_\infty^\Sigma(a,b)$ en a, b dans $\mathcal{M}\Sigma^{-1}$

p. 1
[page 1]

On se donne une catégorie $\mathcal{M}$ avec [un] ensemble admissible de flèches $\Sigma \subseteq \mathrm{Fl}(\mathcal{M})$, d'où (en prenant p. ex. $\underline{t} = (t_n)$, avec $t_n = (\underbrace{\Delta_+\Delta_-}_{\tau_0})^{2n}$, et $\underbrace{t_{n+1}}_{=\tau_0^{2n+2}} \longrightarrow \underbrace{t_n}_{=\tau_0^{2n}}$ défini comme $p * \mathrm{id}_{\tau_0^{2n}} * p$, où $p : \tau_0 \longrightarrow 1$ la dégénérescence.) On a alors une théorie des $\underline{\mathrm{Ch}}_{\Sigma,\infty}(\mathcal{M},a,b)$, que je note simplement $\mathrm{Ch}_\infty(a,b)$ en tant qu'objet de Hot. Des accouplements

$$\mathrm{Ch}_\infty(a,b) \times \mathrm{Ch}_\infty(b,c) \longrightarrow \mathrm{Ch}_\infty(a,c) \qquad \text{dans Hot}$$

avec (nous allons l'admettre) *associativité* dans Hot. Cela définit donc des accouplements sur les $\pi_0(\mathrm{Ch}_\infty(a,b)) \overset{\text{déf}}{=} \pi_0(a,b)$, qui n'est autre que la composition des flèches dans $\mathcal{M}\Sigma^{-1}$. D'autre part, on a pour $a,b \in \mathrm{Ob}\,\mathcal{M}$

$$\mathrm{Hom}_{\mathcal{M}}(a,b) \longrightarrow \pi_0(\mathrm{Ch}_\infty(a,b)) = \pi_0(a,b),$$

compatible avec les compositions. Mais on peut l'ignorer pour l'instant, et regarder $\mathrm{Ob}\,\mathcal{M}$, ou simplement $\mathcal{M}_0$, avec la seule structure

$$\begin{cases} \mathcal{M}_0 \times \mathcal{M}_0 & \longrightarrow & \mathrm{Hot} & (a,b) & \longmapsto & \mathrm{Ch}_\infty(a,b) \\ \mathcal{M}_0 \times \mathcal{M}_0 \times \mathcal{M}_0 & \longrightarrow & \mathrm{Fl}\,\mathrm{Hot} & (a,b,c) & \longmapsto & (\mathrm{Ch}_\infty(a,b) \times \mathrm{Ch}_\infty(b,c) \underbrace{\longrightarrow}_{\substack{\text{flèche} \\ \text{dans Hot}}} \mathrm{Ch}_\infty(a,c)) \end{cases}$$

avec condition [d']associativité, et aussi une condition d'unités :

$$\mathrm{Ch}_\infty(a,a) \text{ est muni d'un } 1_a \in \pi_0\mathrm{Ch}_\infty(a,a) = \pi_0(a,a),$$

jouant le rôle d'une 'identité bilatère', dans le sens suivant. Notons que les accouplements

$$\begin{array}{ccccc} \mathrm{Ch}_\infty(a,b) & \times & \mathrm{Ch}_\infty(b,c) & \longrightarrow & \mathrm{Ch}_\infty(a,c) \\ P & \times & Q & \longrightarrow & R \end{array}$$

définissent [page 2]

$$\begin{array}{ccc} P & \longrightarrow & \underline{\mathrm{Hom}}_{\mathrm{Hot}}(Q,R) \\ Q & \longrightarrow & \underline{\mathrm{Hom}}_{\mathrm{Hot}}(P,R), \end{array}$$

d'où en passant aux π_0

$$\begin{array}{ccc} \pi_0(P) & \longrightarrow & \mathrm{Hom}_{\mathrm{Hot}}(Q,R) \\ \pi_0(Q) & \longrightarrow & \mathrm{Hom}_{\mathrm{Hot}}(P,R), \end{array}$$

en d'autres termes, p. 2

$$\begin{array}{ccc} \pi_0(a,b) & \longrightarrow & \mathrm{Hom}_{\mathrm{Hot}}(\mathrm{Ch}_\infty(b,c),\mathrm{Ch}_\infty(a,c)) \\ \pi_0(b,c) & \longrightarrow & \mathrm{Hom}_{\mathrm{Hot}}(\mathrm{Ch}_\infty(a,b),\mathrm{Ch}_\infty(a,c)). \end{array}$$

Commentary · Exposition [ms. 1]

Composition before functoriality

Grothendieck wants a morphism in the localized category to act on an entire space of paths, not merely on its set of components. This is why he temporarily forgets how the path categories were constructed. Once composition and its units are available, change of either endpoint is a formal operation. The hypothesis being made is substantial: associativity is assumed for the particular spaces $\mathrm{Ch}_\infty(a,b)$. The abstract argument that follows does not establish that hypothesis.

Here is the argument with all its variance visible. Write $C(a,b)$ for the proposed Hom object in a monoidal category $(\mathcal{H},\otimes,I)$, and suppose that

$$m_{abc} : C(a,b)\otimes C(b,c) \longrightarrow C(a,c), \qquad j_a : I \longrightarrow C(a,a)$$

satisfy associativity and the two unit equations, with the associator and unitors of $\mathcal{H}$ understood. This is enrichment, with the factors ordered in the direction in which a path is traversed; reversing the tensor convention gives the usual notation of Kelly (1982, §§1.1–1.3). Symmetry is not required. In particular, the Cartesian signs in the general displays on manuscript page 7 should be read as the specified monoidal product $*$.

The ordinary category C_0 has

$$C_0(a,b) = \mathrm{Hom}_{\mathcal{H}}(I, C(a,b)).$$

For $u : I \to C(a,b)$ and $v : I \to C(b,c)$ its composition is

$$I \xrightarrow{\sim} I\otimes I \xrightarrow{u\otimes v} C(a,b)\otimes C(b,c) \xrightarrow{m_{abc}} C(a,c).$$

The enriched associativity and unit equations give the ordinary ones after precomposition with I. Thus the j_a become the identities of C_0. Their uniqueness follows already in the endomorphism monoid: if j and j' are both two-sided units, then $j = j\circ j' = j'$. Existence as units on the Hom objects is a separate assumption; an element that is a unit only after applying $\mathrm{Hom}(I,-)$ need not satisfy the stronger enriched equations.

To change endpoints, let $u : a' \to a$ and $v : b \to b'$ belong to C_0. Insert the corresponding maps out of I on the two sides of $C(a,b)$ and compose twice. This gives

$$C(u,v) : C(a,b) \longrightarrow C(a',b').$$

For composable $u' : a'' \to a'$ and $v' : b' \to b''$, the two composites $C(u',v')C(u,v)$ and $C(uu',v'v)$ are the two parenthesizations of the same fivefold composition, with u', u on the left and v, v' on the right. Associativity identifies them. The unit equations identify $C(1_a,1_b)$ with the identity. Inserting only the left or only the right element also shows that the two actions commute. We have therefore obtained an ordinary bifunctor

$$C_0^{\mathrm{op}} \times C_0 \longrightarrow \mathcal{H}.$$

Applying $\mathrm{Hom}_{\mathcal{H}}(I,-)$ gives the ordinary Hom bifunctor, including its action on morphisms, rather than only objectwise bijections.

For $\mathcal{H} = \mathrm{Hot}$, I is a point and $\mathrm{Hom}(I,-)$ is π_0. One can obtain the two endpoint actions by currying in the Cartesian closed homotopy category, as Grothendieck does on page 2, but the insertion argument shows that closedness is unnecessary. This economy matters when he passes to ind-objects: it is the monoidal structure and its coherence that the construction uses.

On en déduit en particulier pour $a, b \in \mathcal{M}_0$

$$(*) \qquad \begin{cases} 1) & \pi_0(a,a) & \longrightarrow & \mathrm{Hom}_{\mathrm{Hot}}(\mathrm{Ch}_\infty(a,b), \mathrm{Ch}_\infty(a,b)) \\ 2) & \pi_0(a,a) & \longrightarrow & \mathrm{Hom}_{\mathrm{Hot}}(\mathrm{Ch}_\infty(b,a), \mathrm{Ch}_\infty(b,a)), \end{cases}$$

et un objet α_a de $\pi_0(a,a)$ est unité bilatère si ses deux images sont les homomorphismes identiques dans $\mathrm{Ch}_\infty(a,b)$ resp. $\mathrm{Ch}_\infty(b,a)$. Passant aux π_0 de ceux-ci, cela implique que α_a est unité bilatère pour la composition des $\pi_0(x,y)$, relativement à b. Si on veut que ce soit le cas pour *tout* b, cela signifie (prenant $b = a$) que α_a est un objet unité bilatère pour la structure de composition associative (donc de monoïde) dans $\pi_0(a,a)$, donc que $\pi_0(a,a)$ est un monoïde *unitaire,* ayant α_a pour objet unité. L'élément α_a est donc déterminé de façon unique. Et on veut que α_a existe pour tout $a \in \mathcal{M}_0$, donc $\mathcal{M}_0$, muni des $\pi_0(a,b)$ et de leur composition, devient une *catégorie,* soit $\mathcal{M}_\Pi$; et les flèches identiques de celle-ci doivent jouer le rôle d'unité bilatère également pour les 'Hom externes' $\mathrm{Ch}_\infty(a,b)$, à valeurs dans Hot. [page 3]

On peut dire que pour $a = a_0$ fixé, les $\mathrm{Ch}_\infty(a_0, b)$ (b variable) forment les valeurs d'un *foncteur* covariant

$$\mathcal{M}_\Pi \longrightarrow \mathrm{Hot} \qquad b \longmapsto \mathrm{Ch}_\infty(a_0, b),$$

en associant à

$$b \xrightarrow{u} b', \qquad u \in \pi_0(b, b'),$$

la flèche

$$\mathrm{Ch}_\infty(a, b) \longrightarrow \mathrm{Ch}_\infty(b')$$

[plutôt $\mathrm{Ch}_\infty(a_0, b) \longrightarrow \mathrm{Ch}_\infty(a_0, b')$] correspondante $*_1$ [?]. Que ce soit bien là une loi fonctorielle doit résulter formellement de l'associativité des accouplements sur les Ch_∞. De même, on a une loi fonctorielle, pour b fixé,

$$\mathcal{M}_\Pi^o \longrightarrow \mathrm{Hot}, \qquad a \longmapsto \mathrm{Ch}_\infty(a, b),$$

grâce à l'associativité. En fait, l'associativité impliquera aussi qu'on a un *bifoncteur*

$$\begin{array}{ccc} \mathcal{M}_\Pi^o \times \mathcal{M}_\Pi & \longrightarrow & \mathrm{Hot} \\ (a\,,\,b) & \longmapsto & \mathrm{Ch}_\infty(a, b), \end{array}$$

car si

$$a' \xrightarrow{u} a, \qquad b \xrightarrow{v} b',$$

p. 3
[page 4]

on a le diagramme

$$\begin{array}{ccc} \mathrm{Ch}_\infty(a, b) & \xrightarrow[v]{\text{comp. avec}} & \mathrm{Ch}_\infty(a, b') \\ \Big\downarrow{\scriptstyle \text{comp. avec } u} & & \Big\downarrow{\scriptstyle \text{comp. avec } u} \\ \mathrm{Ch}_\infty(a', b) & \xrightarrow[v]{\text{comp. avec}} & \mathrm{Ch}_\infty(a', b'), \end{array}$$

qui est commutatif grâce à l'associativité pour

$$\mathrm{Ch}_\infty(a', a),\ \mathrm{Ch}_\infty(a, b),\ \mathrm{Ch}_\infty(b, b').$$

Corollaire de cette dépendance bifonctorielle : *Si* $u : a' \longrightarrow a$, $v : b \longrightarrow b'$ *sont dans* $\mathcal{M}_\Pi$, *alors la flèche correspondante*

$$\mathrm{Ch}_\infty(a, b) \longrightarrow \mathrm{Ch}_\infty(a', b') \qquad \textit{dans } \mathrm{Hot}$$

est un isomorphisme.

Commentary · Examples [ms. 4]

An invertibility hypothesis already restored on page 8

The intended application is that weakly equivalent endpoints have the same Hom object. For this application u and v are invertible in the localization. The corollary as printed has omitted this condition; manuscript page 8 states the correct version explicitly.

A discrete example detects the omission without any homotopy theory. Enrich the ordered category $0 < 1$ in sets, regarded as discrete spaces, by its usual Hom sets. Change the first variable by the noninvertible map $u : 0 \to 1$ and fix the second variable at 0. The induced map is

$$C(1, 0) = \varnothing \longrightarrow C(0, 0) = \{1_0\}.$$

This is the endpoint action of $u : 0 \to 1$ with the second variable fixed at 0, and is not an isomorphism. If u and v are invertible, functoriality supplies the inverse $C(u^{-1}, v^{-1})$, proving the repaired corollary.

The following display also omits the opposite on the first factor: its domain is $\mathcal{M}_\Pi^{\mathrm{op}} \times \mathcal{M}_\Pi$. Both omissions occur in the edition, so they are retained in the source and entered separately in the audit. They do not invalidate the preceding construction of the bifunctor.

Les mêmes arguments devraient marcher si au lieu des Hom ext à valeurs dans Hot, on les prenait dans Ind Hot, ou dans Cat hot, ou dans Ind Cat hot – je pense bien sûr aux $\mathrm{CH}_\infty(a,b)$ (dans la théorie de la localisation) dans Ind Cat hot, qui peuvent être regardés comme provenant d'un bifoncteur (où $\mathcal{M}_\Pi = \mathcal{M}\Sigma^{-1}$)

$$\mathcal{M}_\Pi \times \mathcal{M}_\Pi \longrightarrow \mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}.$$

[page 5]

Voici l'axiomatisation définitive (?). On remplace Hot par une catégorie

$\mathcal{H}$, catégorie avec produit $*$ associatif, commutatif (?) ([2]), unitaire, et toutes les compatibilités habituelles au besoin,

l'objet unité pour $*$ sera noté 1, et on notera

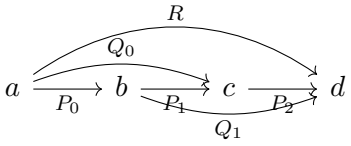
$$\begin{cases} \pi_0(\xi) & \overset{\text{déf}}{=} & \mathrm{Hom}_{\mathcal{H}}(1,\xi) \\ \pi_0 : \mathcal{H} & \longrightarrow & \mathrm{Ens}. \end{cases}$$

Si on a

$$P * Q \xrightarrow{u} R,$$

p. 4

on en déduit



$$\begin{cases} \pi_0(P) & \xrightarrow{c^{\mathrm{l}}_u} & \mathrm{Hom}_{\mathcal{H}}(Q,R) \\ \pi_0(Q) & \xrightarrow{c^{\mathrm{r}}_u} & \mathrm{Hom}_{\mathcal{H}}(P,R) \end{cases}$$

ainsi :

$$\begin{array}{rrcl} \text{Si } \alpha \in \pi_0(P),\ \text{i.e. } 1 \xrightarrow{\alpha} P,\ \text{alors} & \alpha * \mathrm{id}_Q : Q \longrightarrow P * Q & & \\ \text{et} & c^{\mathrm{l}}_u(\alpha) & = & u \circ (\alpha * \mathrm{id}_Q) \\ \text{et dualement} & c^{\mathrm{r}}_u(\beta) & = & u \circ (\mathrm{id}_P * \beta). \end{array}$$

Si on a trois objets P_0, P_1, P_2 dans $\mathcal{H}$, des accouplements

$$\begin{cases} P_0 * P_1 & \xrightarrow{u_1} & Q_0 \\ P_1 * P_2 & \xrightarrow{u_2} & Q_1 \\ P_0 * Q_1 & \xrightarrow{u_3} & R \\ Q_0 * P_2 & \xrightarrow{u_4} & R \end{cases}$$

avec une relation d'associativité, disant que

[page 6]

$$\begin{array}{ccc} P_0 * P_1 * P_2 & \longrightarrow & Q_0 * P_2 \\ \downarrow & & \downarrow \\ P_0 * Q_1 & \longrightarrow & R \end{array}$$

est commutatif, alors on en déduit deux relations de transitivité et une de commutation, pour les opérations associées aux éléments de $\pi_0(P_0)$, $\pi_0(P_1)$, $\pi_0(P_2)$, qu'on n'explicitera pas, sauf l'une :

$$\begin{array}{rrcl} \text{Soit } \beta \in P_1,\ \gamma \in P_2, & & & \\ \text{d'où par } \beta : & c_{u_1}(\beta) : \ P_0 & \longrightarrow & Q_0, \\ \text{et par } \gamma : & c_{u_4}(\gamma) : \ Q_0 & \longrightarrow & R, \\ \text{et par } \beta *_{u_2} \gamma \in \pi_0(Q_1) : & c_{u_3}(\beta \ [*_{u_2}] \gamma) : \ P_0 & \longrightarrow & R, \end{array}$$

p. 5

[plutôt $\beta \in \pi_0(P_1)$, $\gamma \in \pi_0(P_2)$], et bien on a

$$\boxed{c(\beta *_{u_2} \gamma) \;=\; c(\gamma)c(\beta).}$$

Il faut encore définir $\beta *_{u_2} \gamma$, via l'accouplement $P_1 * P_2 \xrightarrow{u_2} Q_1$, on a en effet

$$\begin{array}{ccc} \pi_0(P_1) \times \pi_0(P_2) & \longrightarrow & \pi_0(P_1 * P_2) \\ (\beta\,,\,\gamma) & \longmapsto & \beta * \gamma, \end{array}$$

et on compose avec

$$\pi_0(u_2) : P_1 * P_2 \longrightarrow Q_1$$

[plutôt $\pi_0(u_2) : \pi_0(P_1 * P_2) \longrightarrow \pi_0(Q_1)$].

On se donne un ensemble $\mathcal{M}_0$, et [page 7]

$$\left\{ \begin{array}{rcll} \mathcal{M}_0 \times \mathcal{M}_0 & \xrightarrow{\text{Ch}} & \mathcal{H} \quad \text{noté} & (a,b) \longmapsto \text{Ch}(a,b) \text{ ou } \text{Hom ext}_{\mathcal{H}}(a,b) \\ \mathcal{M}_0 \times \mathcal{M}_0 \times \mathcal{M}_0 & \xrightarrow{\text{comp.}} & \text{Fl}\,\mathcal{H} & (a,b,c) \longmapsto (\text{Ch}(a,b) \times \text{Ch}(b,c) \longrightarrow \text{Ch}(a,c)) \end{array} \right.$$

avec deux axiomes

a) Associativité pour les compositions, pour $(a,b,c,d) \in \mathcal{M}_0^4$

$$\begin{array}{ccc} \text{Ch}(a,b) \times \text{Ch}(b,c) \times \text{Ch}(c,d) & \longrightarrow & \text{Ch}(a,c) \times \text{Ch}(c,d) \\ \downarrow & & \downarrow \\ \text{Ch}(a,b) \times \text{Ch}(b,d) & \longrightarrow & \text{Ch}(a,d). \end{array}$$

b) Existence d'objets unité bilatères

$$1_a \in \pi_0(\text{Ch}(a,a)) \qquad \text{pour tout } a \in \mathcal{M}_0$$

Alors les $\pi_0(\text{Ch}(a,b))$ et leur composition définissent sur $\mathcal{M}_0$ comme ensemble d'objets une structure de *catégorie* $\mathcal{M}_{0\,\Pi}$, ayant les 1_a comme identités, et on trouve que

$$(a,b) \longmapsto \text{Ch}(a,b)$$

peut s'interpréter à partir d'un *bifoncteur* canonique

$$\mathcal{M}_{0\,\Pi}^o \times \mathcal{M}_{0\,\Pi} \longrightarrow \mathcal{H},$$

dont le composé avec

$$\mathcal{H} \xrightarrow{\pi_0} \text{Ens}$$

n'est autre que le bifoncteur $(a,b) \longrightarrow \text{Hom}_{\mathcal{M}_{0\,\Pi}}(a,b)$,

$$\text{Hom}_{\mathcal{M}_{0\,\Pi}}(a,b) \;\simeq\; \pi_0(\text{Ch}(a,b)). \qquad \begin{array}{r}\text{p. 6}\\ \text{[page 8]}\end{array}$$

Cette relation est la *définition* de $\underline{\text{Hom}}_{\mathcal{M}_{0\,\Pi}}$, mais ici la relation est entendue comme une bijection *fonctorielle* en a, b.

On trouve notamment que si

$$u : a' \longrightarrow a, \qquad v : b \longrightarrow b'$$

sont des flèches *inversibles* dans $\mathcal{M}_{0\,\Pi}$, alors

$$\text{Ch}(a,b) \longrightarrow \text{Ch}(a',b')$$

2. On ne doit pas avoir besoin de la commutativité.

correspondant dans $\mathcal{H}$ est [un] *isomorphisme.*

On appliquera tout ceci surtout aux deux situations déduites d'une situation $(\mathcal{M}, \Sigma)$, avec

$$\begin{array}{llllll} 1^o) & \mathcal{H} & = & \mathrm{Hot}, & \mathrm{Ch}(a,b) & = & \mathrm{Ch}^{\Sigma}_{\infty}(\mathcal{M}; a, b) \\ 2^o) & \mathcal{H} & = & \mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}, & \mathrm{Ch}(a,b) & = & \mathrm{CH}^{\Sigma}_{\infty}(\mathcal{M}; a, b)\ ([2]). \end{array}$$

Dans les deux cas, on a donc un foncteur sur $(\mathcal{M}\Sigma^{-1})^o \times (\mathcal{M}\Sigma^{-1})$, à valeurs soit dans Hot, soit dans $\mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}$. (**NB** Les deux structures de catégorie sur $\mathcal{M}_0$ déduites des ces deux foncteurs sont canoniquement isomorphes.)

$$\begin{array}{ccc} & \nearrow\ \mathrm{Hot} & (a,b) \longmapsto \mathrm{Ch}^{\Sigma}_{\infty}(a,b) \\ (\mathcal{M}\Sigma^{-1})^o \times (\mathcal{M}\Sigma^{-1}) & & \\ & \searrow\ \mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot} & (a,b) \longmapsto \mathrm{CH}^{\Sigma}_{\infty}(a,b) \end{array}$$

Comme les foncteurs canoniques [page 9]

$$\begin{array}{ccccccc} \mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot} & \xrightarrow{\mathrm{Ind}\,\varphi} & \mathrm{Ind}\,\mathrm{Hot} & \xrightarrow{\mathrm{Ind}\,\psi} & \mathrm{Ind}\,\mathrm{Hot}^{\wedge}_0 & \xrightarrow{\varinjlim} & \mathrm{Hot}^{\wedge}_0, \\ \uparrow & & \uparrow & & \uparrow & \nearrow_{\mathrm{id}} & \\ \mathrm{Cat}\,\mathrm{hot} & \xrightarrow{\varphi} & \mathrm{Hot} & \xrightarrow{\psi} & \mathrm{Hot}^{\wedge}_0 & & \end{array}$$

commutant aux produits finis, toute théorie de 'Hom externes' à valeurs dans une de ces catégories, en définit une à valeurs dans chacune de celles dans laquelle elle s'envoie. D'ailleurs, ces foncteurs ne sont pas tous pleinement fidèles (c'est en tous cas faux pour φ et $\mathrm{Ind}\,\varphi$, et j'ignore ce qui en est de ψ et $\mathrm{Ind}\,\psi$ – les flèches verticales par contre sont pleinement fidèles ([3]).) Mais ils induisent des bijections pour les π_0. Donc la catégorie $\mathcal{M}_{0\,\Pi}$ déduite d'une théorie de Hom externes à valeurs dans une de ces catégoires, et celle déduite dans une autre où elle s'envoie, est la même à isomorphisme canonique près. Pour ce qui est de cette définition de $\mathcal{M}_{0\,\Pi}$, rien n'est changé donc quand on regarde les CH_{∞} comme des objets de $\mathrm{Ind}\,\mathrm{Hot}$, ou seulement de $\mathrm{Ind}\,\mathrm{Hot}^{\wedge}_0$, ou même seulement de $\mathrm{Hot}^{\wedge}_0$, ou quand on regarde les Ch_{∞} comme des objets dans $\mathrm{Hot}^{\wedge}_0$. Mais bien sûr, la donnée des accouplements de composition perd chaque fois en précision (sauf peut-être en passant de Hot à $\mathrm{Hot}^{\wedge}_0$, si ψ est pleinement fidèle …). Quand on prend les images des $\mathrm{CH}^{\Sigma}_{\infty}(a,b)$ et $\mathrm{Ch}^{\Sigma}_{\infty}(a,b)$ dans $\mathrm{Hot}^{\wedge}_0$ (la dernière catégorie du diagramme), on trouve des objets canoniquement isomorphes (fonctoriellement en a, b dans $\mathcal{M}_{0\,\Pi} \simeq \mathcal{M}\Sigma^{-1}$). Quand on les regarde comme étant respectivement dans Ind Hot et dans $\mathrm{Hot} \hookrightarrow \mathrm{Ind}\,\mathrm{Hot}$, on trouve un homomorphisme fonctoriel

p. 7

[page 10]

$$(*) \qquad \mathrm{CH}^{\Sigma}_{\infty}(a,b) \longrightarrow \mathrm{Ch}^{\Sigma}_{\infty}(a,b) \qquad \text{dans } \mathrm{Ind}\,\mathrm{Hot} \text{ ou dans } \mathrm{Ind}\,\mathrm{Hot}^{\wedge}_0 \text{ au choix.}$$

La $\varinjlim$ de $\mathrm{CH}^{\Sigma}_{\infty}(a,b)$ dans Hot n'existe pas en général (sauf si l'ind-objet est essentiellement constant), mais elle existe dans $\mathrm{Hot}^{\wedge}_0$, et l'isomorphisme canonique

$$(**) \qquad \varinjlim_{\mathrm{Hot}^{\wedge}_0} \mathrm{CH}^{\Sigma}_{\infty}(a,b) \xrightarrow{\sim} \mathrm{Ch}^{\Sigma}_{\infty}(a,b) \qquad \text{dans } \mathrm{Hot}^{\wedge}_0$$

est la flèche déduite de $(*)$ dans $\mathrm{Ind}\,\mathrm{Hot}^{\wedge}_0$.

2. $*$ dans Hot et $\mathrm{Ind}\,\mathrm{Cat}\,\mathrm{hot}$ est le produit cartésien sans plus.

3. et également, $\mathrm{Ind}\,\mathrm{Hot}^{\wedge}_0 \xrightarrow{\varinjlim} \mathrm{Hot}^{\wedge}_0$ n'est *pas* pleinement fidèle.

Commentary · Present state [ms. 9]

What the finite tests forget

Grothendieck is trying to recover a space of morphisms from its values on a manageable collection of diagram shapes. The attraction is clear: if those values determined both spaces and maps between them, a difficult coherence argument could be replaced by calculations on finite diagrams. The notation needs its earlier definition. In Chapter V, manuscript pages 51–52, Hot_0 is the full subcategory of homotopy types represented by categories with finitely many objects and arrows (Grothendieck, 1990d, Chapter V, printed pp. 31–32). It is not the subcategory of finite CW complexes. For example, the one-object category of a finite nontrivial group is finite, whereas its nerve need not have finite dimension.

Choose a small skeleton $\mathcal{A}$ of Hot_0. The functor in question is

$$\psi(X)(K) = [K, X], \qquad K \in \mathcal{A}.$$

It preserves products, and evaluation at the one-point category recovers $\pi_0 X$. These useful facts survive the negative answer to the full-faithfulness question. The commentary on Chapter V, manuscript p. 52, discusses the obstruction ("Finite unbased tests miss a symmetric-group shift" and "The modern scope of the final obstruction"). The general theorem is that no set of unpointed homotopy types jointly detects isomorphisms in Hot (Arlin and Christensen, 2023, Theorem 2.1). Applied to $\mathcal{A}$, this says that ψ is not even conservative, and hence is not fully faithful.

There is also a separate answer to the faithfulness question, which is what the hoped-for associativity argument actually needs. The presheaf category on $\mathcal{A}$ has a faithful set-valued functor

$$F \longmapsto \coprod_{K \in \mathrm{Ob}\,\mathcal{A}} F(K) :$$

a natural transformation is determined by its components, which this disjoint union retains. If ψ were faithful, the composite would make Hot concrete. Freyd's nonconcreteness theorem rules this out; his argument already applies to a full subcategory of simply connected, finite-dimensional CW complexes, so forgetting basepoints does not evade the obstruction (Freyd, 1970, pp. 1 and 5 of the 2004 reprint). Thus ψ is not faithful either. These are statements with the usual fixed-universe interpretation of small spaces and small sets; restricting the allowed spaces to a particular small category changes the question.

Consequently, agreement after passage to $\mathrm{Hot}_0^{\wedge}$ cannot in general prove equality of the two composites in Hot. It follows as well, by restriction to constant ind-objects, that $\mathrm{Ind}\,\psi$ is not fully faithful. None of this invalidates the underlying category of morphisms obtained by taking π_0; it identifies exactly the additional coherence that manuscript page 13 still has to supply.

Commentary · Examples [ms. 10]

Three meanings of a limiting space

Grothendieck keeps an ind-object because it records the stage at which a family of paths can be represented. Passing to its union, or to a colimit of its homotopy types, asks a different question. The phrase "n'existe pas en général" should be read as the absence of a general existence theorem here. Essential constancy is a sufficient condition, not a necessary condition for an ordinary colimit in Hot.

For a complete elementary example, let $E_n = \{0, \dots, n\}$, with the discrete topology and the evident inclusions, and let $E = \mathbf{N}$. For every space Y there are natural bijections

$$[E, Y] = (\pi_0 Y)^{\mathbf{N}} \simeq \varprojlim_n (\pi_0 Y)^{E_n} = \varprojlim_n [E_n, Y].$$

Hence E is the ordinary colimit in Hot. Nevertheless, the ind-object (E_n) is not essentially constant. If it were isomorphic to a constant object Z, its functor of maps to constant objects would imply $Z \simeq E$. An inverse morphism from the constant E to (E_n) factors through some E_n, by the defining formula for maps in an ind-category. Its composite with the cocone would make the identity of $\mathbf{N}$ factor through a finite set on π_0, which is impossible.

The same example explains the footnote about the colimit functor on presheaves. Let F_n be the constant presheaf with value E_n on $\mathcal{A}$, and F the constant presheaf with value $\mathbf{N}$. Then

$\operatorname{colim} F_n = F$. The identity of F has no lift to a morphism from the constant ind-object F to (F_n): such a lift would factor through one finite F_n, again contradicting evaluation at any object of $\mathcal{A}$. Thus

$$\mathrm{Ind}(\widehat{\mathcal{A}}) \longrightarrow \widehat{\mathcal{A}}, \qquad (F_n) \longmapsto \operatorname{colim} F_n,$$

is not full.

A further qualification is needed for the displayed comparison with Ch_∞. A filtered homotopy colimit $K = \operatorname{hocolim} K_n$ is tested by a *compact* homotopy type A through

$$\operatorname{colim}_n [A, K_n] \simeq [A, K].$$

Finite-category homotopy types are not all compact. Take $A = BC_2 = \mathbf{RP}^\infty$ and $K_n = \mathbf{RP}^n$. Their union is A, but the identity of A cannot factor, even up to homotopy, through any K_n: it would kill the nonzero mod-2 cohomology in degrees above n (Hatcher, 2002, Theorem 3.19). Thus the finite-category definition of Hot_0 alone does not justify the comparison in manuscript page 10. For the particular path system, one must either prove the required factorization on these test categories by its special categorical structure, or impose an appropriate finite-test/compactness hypothesis. We do not replace that missing model-specific argument by a general assertion about filtered homotopy colimits.

Dans les deux cas CH et Ch (qu'on va désigner par le symbole commun $C_\infty(a,b)$), la [page 11]
fonctorialité de cet objet $C_\infty(a,b)$ (même au sens le plus faible, comme objet de $\mathrm{Hot}_0^\wedge$) par rapport à a et b (même au sens le plus faible, comme foncteur $\mathcal{M}^o \times \mathcal{M} \longrightarrow \mathrm{Hot}_0^\wedge$ et pas même $(\mathcal{M}\Sigma^{-1})^o \times (\mathcal{M}\Sigma^{-1}) \longrightarrow \mathrm{Hot}_0^\wedge$) n'est pas évidente du tout sur la définition directe en termes du système inductif explicite dans Cat

$$C_\infty(a,b) \;=\; (\mathrm{Ch}_{\tau_0^{2n}}(a,b))_{n\in\mathbf{N}},$$

car une flèche $a' \longrightarrow a$ ou $b \longrightarrow b'$ dans $\mathcal{M}$, et même qu'elle serait dans Σ, ne définit aucunement une flèche dans Cat

$$\begin{array}{rcl} & C_\infty(a,b) & \longrightarrow \quad C_\infty(a',b) \\ \text{ou} \;\; & C_\infty(a,b) & \longrightarrow \quad C_\infty(a,b'). \end{array}$$

Cette difficulté rappelle celle qu'avait à surmonter Quillen, dans Homotopical Algebra, pour affronter la différence entre 'left homotopies' et 'right homotopies'. Je me rappelle comment on peut néanmoins définir de telles flèches, comme résultant d'une flèche (beaucoup plus riche) de 'composition' de chemins entre a' et a, et a et b, ou entre a et b, et b et b', soit en p. 8
général donc l'accouplement [page 12]

$$C_\infty(a,b) \times C_\infty(b,c) \longrightarrow C_\infty(a,c),$$

dont la définition directe n'est pas moins problématique, et ne peut en tous cas *pas* se donner comme une flèche dans Cat lui-même, ou dans Ind Cat. Interprétant p. ex. $\mathrm{Ch}_\infty(a,b)$ en termes de chemins *infinis* (des deux cotés) de a à b, en un sens évident (mais 'essentiellement finis' des deux cotés), on peut définir aussi

$$\mathrm{Ch}^-_\infty(a,b), \qquad \mathrm{Ch}^+_\infty(a,b)$$

comme les sous-catégories pleines formées respectivement de chemins qui sont totalement dégénérés en degrés ≥ 0 (i.e. $a_0 \longleftarrow a_1 \longrightarrow a_2 \longleftarrow a_3 \cdots$ sont tous des identités), ce qui revient aux chemins infinis seulement à gauche, i.e. s'arrêtant à a_0, et symétriquement pour $\mathrm{Ch}^+_\infty(a,b)$. Même tabac pour les CH^+, CH^-.

Ceci dit, on a ceci (revenant à la notion C_∞ ambivalente) :

a) les inclusions pleinement fidèles [page 13]

$$C^-_\infty(a,b) \hookrightarrow C_\infty(a,b) \hookleftarrow C^+_\infty(a,b)$$

sont des isomorphismes dans Ind Cat hot resp. dans Hot, et

b) On a bel et bien une composition des chemins

$$C_\infty^-(a,b) \times C_\infty^+(b,c) \longrightarrow C_\infty(a,c).$$

L'*associativité* dans le cas du CH n'offre d'ailleurs pas de difficulté, à cause de la possibilité de se ramener aux

$$C_m(a,b) \times C_n(b,c) \times C_p(c,d) \rightrightarrows C_N(a,d)$$

pour N grand, et prouver l'egalité comme flèches dans Cat hot – ce qui résultera du lemme d'homotopie sur les intervalles dans Cat. Dans le cas du Ch_∞ par contre je n'ai pas trouvé de démonstration. (Faute seulement d'avoir essayé sérieusement de m'y mettre? Je n'ai pas trop envie, vu qu'il se pourrait que Hot $\longrightarrow \mathrm{Hot}_0^\wedge$ soit pleinement fidèle, auquel cas le travail devient inutile …)

Commentary · Later developments [ms. 13]

The path model and the localization it is meant to represent

Grothendieck is trying to make concatenation independent of an arbitrary placement of the middle endpoint. Moving one path to the left and the other to the right produces an actual functor; the homotopy equivalences from these one-sided path categories then give composition in Hot. For the ind-object CH_∞, every finite collection of paths and reparametrizations can be handled at one larger stage. His interval homotopies therefore give the asserted associativity in Ind Cat hot. For the realized Ch_∞, the text explicitly leaves the associativity proof unfinished. An eventual equality at every finite stage is not, by itself, a specified compatible homotopy on the whole realization.

The commentary on Chapter V, manuscript p. 12 ("What composition in an ind-category actually asserts") explains the relevant ind-Hom formula. Here it gives the exact associativity argument. Put $\mathcal{A} = \mathrm{Cat\,hot}$ and write $C_m(a,b)$ for the finite stages. Morphisms from the triple product into $\mathrm{CH}_\infty(a,d)$ are computed by

$$\varprojlim_{m,n,p} \varinjlim_{N} \mathrm{Hom}_{\mathcal{A}}\big(C_m(a,b) \times C_n(b,c) \times C_p(c,d), C_N(a,d)\big).$$

For each fixed (m,n,p), concatenate the three finite words before returning to the chosen standard shape. Parenthesization does not change this concatenated word; it changes only the finite reparametrization and the inserted identity padding. At a common larger stage the interval-homotopy lemma identifies those reparametrizations; its relative endpoint condition is the one explained in "Even indices and reparametrization relative to the ends" and "Sliding an even block gives a natural transformation" in the commentary on Chapter V, manuscript pp. 14 and 21. Hence the two representatives have the same class in the displayed filtered colimit for every (m,n,p), which proves equality in the inverse limit. No choice of these finite homotopies compatible as (m,n,p) varies is required for this equality of ind-morphisms. Concatenating an identity path similarly adds only identity padding, so the same argument proves the strong unit equations for CH_∞. This is the precise advantage of the ind-object in the present argument.

The general target of this construction was already available in a different model. The hammock localization of Dwyer and Kan (1980a, §2; Propositions 2.2 and 3.1) is a simplicial category whose composition concatenates and reduces hammocks; its category of components is $\mathcal{M}[W^{-1}]$. Thus it supplies coherent mapping spaces, with strictly associative composition at that model level, for a relative category. These statements concern the hammock construction. They do not identify its simplicial sets with Grothendieck's fixed-type path categories, whose transformations and stabilization conventions must be compared separately.

This distinction continues the commentary on Chapter V, manuscript p. 27 ("From components of path categories to mapping spaces"). Equality of π_0, agreement on finite tests, and a weak equivalence of the mapping spaces are three different assertions. We have not located in the sources checked a comparison theorem stated for exactly the bilateral stabilization and unrestricted natural transformations used here. The model-specific comparison, including compatibility with concatenation, is consequently left identified as an unfinished verification in these pages, not advertised as a new open problem in homotopy theory. The abstract bifunctor construction above is complete once its stated associativity and unit hypotheses hold.

2 Comparaison avec Quillen

Il se pose un certain nombre de questions sur ce foncteur $(\mathcal{M}\Sigma^{-1})^o \times (\mathcal{M}\Sigma^{-1}) \longrightarrow \mathrm{Hot}$, et sa relation aux constructions classiques, notamment à la théorie de Quillen. Je vais maintenant noter

$$\mathrm{Ch}^{\Sigma}_{\infty}(a,b) \;=\; \mathrm{Hom}\,\mathrm{ext}_{\mathrm{Hot}}(a,b) \quad \text{ou simplement}$$
$$\mathrm{Hom}\,\mathrm{ext}(a,b).$$

1°). Soient $f, g : a \rightrightarrows b$ dans $\mathcal{M}$, alors (si $\mathcal{M}$ est une 'model category') Quilllen définit un ensemble

$$\pi_1(a,b;f,g) \qquad \text{ou} \qquad \pi_1(f,g)$$

des classes d'homotopie de f à g, de telle façon que $\mathrm{Hom}_{\mathcal{M}}(a,b)$ devient l'ensemble des objets d'un groupoïde, dont les flèches sont les éléments de $\pi_1(f,g)$, pour une notion de composition naturelle. Je suspecte que l'on a

$$\pi_1(f,g) \;=\; \mathrm{Hom}_{\underbrace{\Pi(\underline{\mathrm{Ch}}^{\Sigma}_{\infty}(a,b))}_{\substack{\text{groupoïde}\\ \text{fodamental}\\ \text{de } \underline{\mathrm{Ch}}^{\Sigma}_{\infty}(a,b)}}}(f,g),$$

quand f et g sont considérés comme des 'chemins infinis' (en insérant chaque $f : a \longrightarrow b$ dans

$$\cdots \underbrace{a_{-2}}_{=a} \xleftarrow{\mathrm{id}} \underbrace{a_{-1}}_{=a} \xrightarrow{f} \underbrace{a_0}_{=b} \xleftarrow{\mathrm{id}} \underbrace{a_1}_{=b} \longrightarrow \cdots \;)$$

Commentary · Exposition [ms. 14]

Homotopies as arrows in a mapping groupoid

Grothendieck's question asks for the first layer of the mapping space, where homotopies themselves become morphisms. Its modern formulation begins with a derived mapping space $\mathrm{Map}^h(a,b)$, and takes its fundamental groupoid. The objects corresponding to actual maps $a \to b$ form a full subgroupoid. They need not meet every component until the usual cofibrancy and fibrancy hypotheses, or replacements, have been imposed.

For a cofibrant object a and a fibrant object b in a simplicial model category, $\mathrm{Map}(a,b)$ is a Kan complex. A simplicial path from f to g represents a homotopy; two such paths give the same arrow of its fundamental groupoid precisely when they are homotopic relative to their endpoints. Concatenation in the groupoid is defined by filling an inner two-dimensional horn. Different fillers give the same class because the Kan conditions provide the requisite relative homotopy. Constant paths give identities and reversed paths give inverses. Consequently

$$\mathrm{Hom}_{\Pi\,\mathrm{Map}(a,b)}(f,g)$$

is the exact object Grothendieck wants, not the set of equivalence classes of maps $a \to b$.

Quillen's original construction has precisely the cofibrant-source and fibrant-target qualifications: see Chapter I, §2, Proposition 1.2.1 in the checked retypesetting; Chapter II, §2 identifies this groupoid with the fundamental groupoid of the simplicial mapping complex (Quillen, 1967). For a general model category, Dwyer and Kan (1980b, Propositions 4.4–4.5 and 4.8) compare resolutions with the hammock mapping spaces and with the simplicial enrichment when it exists. These results justify the same description using Map^h after replacements. The identification with $\Pi\mathrm{Ch}^W_{\infty}(a,b)$ still requires the particular path-model comparison just discussed. The source's conjectural equality should therefore be stated as a natural equivalence of groupoids after that comparison, not as a literal equality of two chosen constructions.

[page 15]

Donc la définition des $\pi_1(f,g)$ (si c'est bien ça) se prolonge de façon naturelle aux chemins infinis (essentiellement finis) arbitraires.

2°) Supposons que $\mathcal{M}$ admette un objet à la fois initial et final $0_{\mathcal{M}}$ ($\mathcal{M}$ 'ponctuée'). Je dis qu'alors toutes les catégories $\underline{\mathrm{Ch}}^{\Sigma}_{\infty}(a,b)$ sont ponctuées de façon naturelle : à savoir, par le chemin infini de a à b défini (comme plus haut) à partir de $f = 0_{a,b} : a \longrightarrow b$, l'application nulle de a à b. On a envie alors de regarder les $\underline{\mathrm{Ch}}^{\Sigma}_{\infty}(a,b)$ comme définissant des éléments dans le $\mathrm{Hot}_\bullet$ ('Hot ponctué'). C'est plus fin que de dire qu'on se donne une classe neutre

$$e \longrightarrow \mathrm{Ch}(a,b) \qquad \text{dans Hot},$$

car le foncteur de $\mathrm{Hot}_\bullet$ dans Hot (ou dans $e\backslash\mathrm{Hot}$) n'est pas fidèle. Le problème, c'est de définir les flèches

$$\mathrm{Ch}(a,b) \times \mathrm{Ch}(b,c) \longrightarrow \mathrm{Ch}(a,c)$$

dans $\mathrm{Hot}_\bullet$, et pas seulement dans Hot, et avec associativité (et les unités) dans $\mathrm{Hot}_\bullet$ également. Si on applique la définition avec $\mathrm{Ch}^-(a,b)$ et $\mathrm{Ch}^+(b,c)$, le composé des éléments nuls $a \xrightarrow{0} b$ de $\mathrm{Ch}^-(a,b)$ et $b \xleftarrow{\mathrm{id}} b \xrightarrow{0} c$ de $\mathrm{Ch}^+(b,c)$ est l'élément de $\mathrm{Ch}_\infty(a,c)$ que voici p. 10 [page 16]

$$\begin{array}{ccccccccccccccc}
 & & a_{-2} & \longleftarrow & a_{-1} & \longrightarrow & a_0 & \longleftarrow & a_1 & \longrightarrow & a_2 & & \cdots & & \\
 & & & & & & \| & & & & & & & & \\
\mathrm{id} & \cdots & a & \xleftarrow{\mathrm{id}} & a & \xrightarrow[0]{} & b & \xleftarrow{\mathrm{id}} & b & \xrightarrow[0]{} & c & \xleftarrow{\mathrm{id}} & \cdots & \mathrm{id} &
\end{array}$$

ce n'est *pas* l'élément nul de $\mathrm{Ch}_\infty(a,c)$! Mais on a des flèches canoniques

$$e^-_{a,b} \circ e^+_{b,c} \rightleftarrows e_{a,c} \qquad \text{dans } \mathrm{Ch}_\infty(a,c)$$

qui sont l'identité sur tous les sommets sauf celui d'indice 0. Il y a un sorite à développer, comme quoi une paire

$$(f : K_\bullet \longrightarrow L_\bullet, c)$$

d'un foncteur entre catégories ponctuées, et d'un chemin $c : f(e_{K_\bullet}) \longrightarrow e_{L_\bullet}$, définit dans Hot une flèche canonique

$$\mathrm{hot}_\bullet(K_\bullet) \longrightarrow \mathrm{hot}_\bullet(L_\bullet)$$

avec transitivité si on a

$$(f' : L_\bullet \longrightarrow M_\bullet, c' : f'(e_{L_\bullet}) \longrightarrow e_{M_\bullet}),$$

Commentary · Exposition [ms. 16]

The path needed to preserve a basepoint

Grothendieck wants the zero map to remain a specified point throughout composition, because its loop group will define suspension and loops. A point chosen in the unpointed homotopy category does not contain the required information. For example, based maps $S^1 \to BG$ are classified by elements of a group G, whereas free homotopy identifies conjugate elements. For $G = S_3$, the two distinct transpositions (12) and (13) give different based classes and the same free class. This proves the asserted failure of faithfulness of the forgetful functor.

The proposed extra datum is exactly the right one at the level of spaces. For pointed CW spaces (K,k) and (L,l), a map $f : K \to L$ together with a path c from $f(k)$ to l defines a morphism in the pointed homotopy category. To see this without suppressing the path, attach an interval to K at k and point the resulting space K^+ at its free endpoint. Define $F : K^+ \to L$ by f on K and by c on the interval. The collapse $r : K^+ \to K$ is a pointed homotopy equivalence. The required morphism is $[F][r]^{-1}$. The same construction applies to nerves of pointed categories after geometric realization, because a vertex inclusion is a cofibration.

For a second pair (g,d), the composite is represented by $(gf, (gc) * d)$. Indeed, the space obtained by attaching two successive intervals to K maps to the target by f, then the first path followed

under g, then d. Collapsing the subdivision of the two intervals identifies this representative with the single attached interval carrying $(gc) * d$. Repeating this argument gives associativity: the increasing piecewise-linear reparametrizations of a concatenated interval are homotopic relative to the two endpoints. Homotopic choices of c relative endpoints give the same pointed morphism. Arbitrary paths with the same endpoints need not do so; their difference can act through the fundamental group.

The specific claim immediately before this construction is stronger and is false as written, but it has a simple canonical repair. Denote the displayed concatenation by P and the standard zero path from a to c by Q. Then P has b at vertices $0, 1$, while Q has c at both. A transformation cannot be the identity at every vertex except 0: the backward identity edge between 1 and 0 forces its components at those two vertices to agree. Instead define $\alpha : P \to Q$ by

$$\alpha_0 = \alpha_1 = 0_{b,c}, \qquad \alpha_i = \mathrm{id} \quad (i \neq 0, 1).$$

The square at $-1 \to 0$ commutes because a composite with a zero map is zero; the square at $1 \to 0$ compares two identity edges; and the square at $1 \to 2$ says $\mathrm{id}_c \, 0_{b,c} = 0_{b,c}$. Every other square is an identity square. Since transformations of paths are unrestricted, this is an admissible canonical comparison for every W containing identities. It supplies the needed basepoint path without a reparametrization or an additional choice. A reverse arrow with zero components would force $\mathrm{id}_c = 0_{c,c}$ at the last square and is not available in general. This repairs the single basepoint comparison; associativity and the other coherence conditions for the particular pointed composition still require verification.

[page 17]

d'où

$$f'' = f' \circ f : K_\bullet \longrightarrow M_\bullet, \qquad \text{et} \quad c'' : f''(e_{K_\bullet}) \longrightarrow e_{M_\bullet}),$$

définit ainsi

$$f'(f(e_{K_\bullet})) \xrightarrow{f'(c)} f'(e_{L_\bullet}) \xrightarrow{c'} e_{M_\bullet}$$
$$\underbrace{\qquad\qquad\qquad\qquad}_{c'' \text{ par définition}}$$

? Cela nous donne donc bel et bien des accouplements dans $\mathrm{Hot}_\bullet$ (et aussi dans $\mathrm{Cat}\,\mathrm{hot}_\bullet$?). Il est difficile de croire qu'ils pourraient ne pas être associatifs! D'ailleurs $\mathrm{Hot}_\bullet$, avec le produit cartésien ordinaire ([4]), satisfait à l'axiomatique de tantôt pour $\mathcal{H}$, et $\mathrm{Hot}_\bullet \longrightarrow \mathrm{Hot}$ est compatible avec ce produit ([5]), et avec π_0.

Commentary · Exposition [ms. 17]

Why the monoidal unit changes in the pointed theory

The two footnotes identify a genuine change of monoidal structure. In pointed spaces the Cartesian unit is the one-point space, and

$$\mathrm{Hom}_{\mathrm{Hot}_\bullet}(*, X) = \{*\}.$$

It cannot recover the components of X, so the Cartesian structure does not instantiate the earlier convention $\pi_0(X) = \mathrm{Hom}(I, X)$. With the smash product, the unit is S^0, and

$$\mathrm{Hom}_{\mathrm{Hot}_\bullet}(S^0, X) = \pi_0(X).$$

Thus the corrected enrichment uses smash composition

$$C(a, b) \wedge C(b, c) \longrightarrow C(a, c).$$

The identity is the pointed map $S^0 \to C(a, a)$ carrying the nonbasepoint to 1_a and the basepoint to zero. Composition must kill either zero input, not merely the pair of zero inputs. That is the additional requirement hidden by a single basepoint comparison for a Cartesian product. The standard pointed simplicial model of derived mapping spaces has this absorbing-zero property, hence

4. Non, il faut prendre le produit $\xi_\bullet \divideontimes \eta_\bullet$ ($\xi_\bullet \times \eta_\bullet$, avec $\xi_\bullet \vee \eta_\bullet$ contracté en e).
5. Non, mais on s'en tire quand même …

its composition factors through the smash product. This is the familiar monoidal example in Kelly (1982, §1.1).

Forgetting basepoints is not strong monoidal for smash and Cartesian products. Nevertheless there is a natural quotient map

$$U(X) \times U(Y) \longrightarrow U(X \wedge Y)$$

and a unit map $* \to U(S^0)$ selecting its nonbasepoint. These make U lax monoidal: both associativity composites collapse exactly those tuples with a zero coordinate, and both unit composites leave the other coordinate unchanged. Composing these maps with smash composition recovers associative unpointed composition. The footnote "on s'en tire quand même" can therefore be made precise without asserting preservation of products. The symbol in the edition is the crossed product ⁂, explained there as collapsing the wedge, and is faithfully transcribed; its meaning here is the smash product.

Si tout ceci marche, on aurait donc une théorie des $\operatorname{Hom}\operatorname{ext}_\bullet$ à valeurs dans $\operatorname{Hot}_\bullet$; et sans doute aussi pour les CH_∞ comme objets de $\operatorname{Ind}\operatorname{Hot}_\bullet$, et non seulement de $\operatorname{Ind}\operatorname{Hot}$. Mais de p. 11
toutes façons on ne peut en général laisser tomber Cat hot, qui reste importante – donc il faudrait avoir des objets $\mathrm{CH}_\infty(a,b)$ dans $\operatorname{Ind}\operatorname{Cat}\operatorname{hot}_\bullet$, pour avoir une côte bien taillée.

Les $\pi_0(C(a,b))$ seront à présent des ensembles ponctués, et ce sera par l'image de l'application nulle $a \xrightarrow{0} b$, i.e. le composé

$$a \longrightarrow 0 \longrightarrow b$$

[page 18]

qu'il faut composer avec l'elément déduit du chemin tronqué

$$a \longrightarrow \underbrace{0}_{=a_0} \longleftarrow b \qquad \dots$$

Il faudrait montrer que 0 est aussi un objet neutre de $\mathcal{M}\Sigma^{-1}$, i.e. que

$$\pi_0(a,0) = \pi_0(0,a) = \{0\} \qquad \text{pour tout } a \in \operatorname{Ob}\mathcal{M}$$

et interpréter l'élément nul dans $\pi_0(a,b)$ comme l'application nulle dans $\mathcal{M}\Sigma^{-1}$. De façon générale, il faut des conditions qui assurent (sans que $\mathcal{M}$ soit forcément ponctuée) que

$$\mathcal{M} \xrightarrow{\gamma} \mathcal{M}\Sigma^{-1}$$

commute aux sommes finies, aux produits finis (donc $\gamma(\varphi_{\mathcal{M}}) = \varphi_{\mathcal{M}\Sigma^{-1}}$, resp. $\gamma(e_{\mathcal{M}}) = e_{\mathcal{M}\Sigma^{-1}}$) ([6]).

Commentary · Exposition [ms. 18]

Zero objects and finite sums after localization

Grothendieck needs the distinguished component to be an actual zero morphism of the localized category. At the level of ordinary localization this requires no additional compatibility condition on W. If z is initial in $\mathcal{M}$, write $i_x : z \to x$ for its unique maps. For every ordinary arrow $u : x \to y$ we have $ui_x = i_y$. If u is inverted, the same equality gives $u^{-1}i_y = i_x$ in the localization. An induction along any finite zigzag starting at z therefore identifies it with i_x. Thus z remains initial. The reversed argument preserves terminal objects. In particular a zero object remains zero, and $a \to 0 \to b$ is the zero morphism in $\mathcal{M}[W^{-1}]$. This is also the nullary case of descent of adjunctions through localization (Krause, 2021, Lemma 1.1.6).

The displayed path $a \to 0 \leftarrow b$ needs a different caution: its backward edge belongs to W only when $b \to 0$ does. The two forward zero maps $a \to 0 \to b$ always give the required ordinary zero morphism; inserting backward identity edges puts this composite into the permitted zigzag shapes.

6. à faire.

The preservation of the zero object therefore does not depend on the inadmissible shortened path or on the unresolved pointed composition.

For binary products there is a useful sufficient condition. Suppose $\mathcal{M}$ has finite products and W contains identities and is closed under their finite products. The product functor and the diagonal then descend to the localizations, as do the unit and counit of $\Delta \dashv \prod$. Naturality for inverse generators follows by multiplying the original naturality squares by the inverses of their W-edges; the triangle identities remain equalities after localization. Finally

$$(\mathcal{M}^n)[(W^n)^{-1}] \simeq (\mathcal{M}[W^{-1}])^n \qquad (n < \infty) :$$

a tuple of finite zigzags is represented by one tuple-shaped zigzag after padding the finitely many words by identities, and the relations are coordinatewise. Consequently the descended diagonal still has the descended product as right adjoint. This proves that localization preserves finite products. Reversing arrows gives the corresponding statement for finite coproducts. One can weaken closure by requiring only that the relevant products or coproducts of W-arrows become invertible.

For an additive category, closure of W under finite direct sums is already enough for the ordinary localized category to be additive; a five-lemma hypothesis is unnecessary for this conclusion (Krause, 2021, Lemma 2.2.1). Indeed, products and coproducts survive and the original canonical comparison from their sum to their product remains an isomorphism, giving biproducts. Addition is therefore defined by the usual diagonal–biproduct–codiagonal formula. The morphism -1_x remains an inverse for the addition on x, and its naturality extends over inverted arrows, so every Hom monoid is a group. A central k-action similarly extends. These conclusions concern ordinary Hom groups; constructing the proposed complexes of higher Hom information is the further problem on the next page.

Supposons enfin que $\mathcal{M}$ soit *additive,* et même k-linéaire (k un anneau fixé), i.e. on a de plus un homomorphisme d'anneaux

$$k \longrightarrow \mathrm{End}(\mathrm{id}_{\mathcal{M}}).$$

On doit supposer quelque compatibilité de Σ à la structure additive, p. ex. que la somme directe de deux flèches dans Σ est dans Σ, et sans doute quelque chose de plus fort, du genre 'lemme des cinq' pour Σ. (Mais on ne suppose pas forcément $\mathcal{M}$ abélienne, donc on aurait dû mal à formuler un lemme des cinq?)

Mais peut-être ici faut-il un axiome plus subtil, p.ex. (si $\underbrace{\Sigma}_{\text{suspension}}$ et Ω existent ([7])) que [page 19] l'ensemble des morphismes d'adjonction $\Sigma\Omega \longrightarrow \mathrm{id}$, $\mathrm{id} \longrightarrow \Omega\Sigma$ soit `[formé d']`isomorphismes, ce qui implique que Ω resp. Σ est pleinement fidèle. En tous cas, l'attente naturelle ici, c'est que $\mathrm{Ch}^{\Sigma}_{\infty}(a,b)$ soit non seulement dans $\mathrm{Hot}_\bullet$, mais même dans la catégorie $D^{\leq 0}(k\text{-Mod})$, sous-catégorie pleine de la catégorie dérivée $D^{-}(k\text{-Mod})$ formée des K tels que $H^i(K) = 0$ si $i > 0$. On peut aussi la noter $D_{\geq 0}(k\text{-Mod})$, l'interprétant en termes de complexes de 'chaînes' p. 12 plutôt que de cochaînes. Ici les accouplements doivent correspondre à l'opération $* = \overset{\mathbf{L}}{\otimes}_k$ dans $D_{\geq 0}(k\text{-Mod})$, admettant k comme objet unité, et

$$\pi_0(K_\bullet) \;\simeq\; H_0(K_\bullet).$$

Donc on doit avoir

$$\mathrm{Hom\,ext}(a,b) \overset{\mathbf{L}}{\otimes}_k \mathrm{Hom\,ext}(b,c) \longrightarrow \mathrm{Hom\,ext}(a,c),$$

où cette fois Hom ext désigne l'objet de $D_{\geq 0}(k\text{-Mod})$, au lieu d'un objet de Hot seulement, ou de $\mathrm{Hot}_\bullet$. On utilise les foncteurs

$$D_{\geq 0}(k\text{-Mod}) \longrightarrow \mathrm{Hot}_\bullet \longrightarrow \mathrm{Hot}$$

pour faire le lien avec la théorie ponctuée dans $\mathrm{Hot}_\bullet$, ou `[la]` théorie générale dans Hot. Si

7. cf. plus bas ce que ça signifie. [page 20]

on désigne par

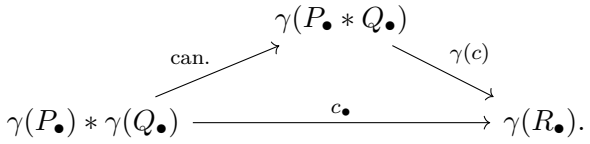
$$\gamma : \ D_{\geq 0}(k\text{-Mod}) \ \longrightarrow \ \mathrm{Hot}_\bullet$$

le premier de ces foncteurs, il ne commute pas aux produits $*$ ($\overset{\mathbf{L}}{\otimes}_k$ et $\times$ respectivement), mais on a, pour $P_\bullet$, $Q_\bullet$ variable dans $D_{\geq 0}(k\text{-Mod})$, une flèche fonctorielle canonique

$$\gamma(P_\bullet \overset{\mathbf{L}}{\otimes}_k Q_\bullet) \xleftarrow{can.} \gamma(P_\bullet) \times \gamma(Q_\bullet)$$

'k-bilinéaire', ce qui montre que de donner des accouplements

$$P_\bullet * Q_\bullet \xrightarrow{c_k} R_\bullet,$$



d'où

$$(*) \qquad \gamma(P_\bullet * Q_\bullet) \xrightarrow{\gamma(c_k)} \gamma(R_\bullet),$$

est l'un et l'autre plus fin que de se donner seulement

$$(*') \qquad \gamma(P_\bullet) * \gamma(Q_\bullet) \xrightarrow{c_\bullet} \gamma(R_\bullet),$$

vu qu'une donnée $(*)$ impliquera une donne $(*')$ par

Ceci vu, on s'attend bien à avoir une théorie *forte* des accouplements p. 13 [page 21]

$$\mathrm{Hom}\,\mathrm{ext}_k(a,b) \overset{\mathbf{L}}{\otimes}_k \mathrm{Hom}\,\mathrm{ext}_k(b,c) \ \longrightarrow \ \mathrm{Hom}\,\mathrm{ext}_k(a,c),$$

d'où on déduira les accouplements plus faibles dans $\mathrm{Hot}_\bullet$ (au lieu de $D_{\geq 0}(k\text{-Mod})$)

$$\mathrm{Hom}\,\mathrm{ext}_{\mathrm{Hot}_\bullet}(a,b) \times \mathrm{Hom}\,\mathrm{ext}_{\mathrm{Hot}_\bullet}(b,c) \ \longrightarrow \ \mathrm{Hom}\,\mathrm{ext}_{\mathrm{Hot}_\bullet}(a,c).$$

Commentary · Later developments [ms. 19]

A sufficient differential graded setting

Grothendieck now asks for more than additive Hom groups: he wants composition on their derived complexes before taking H_0. A precise sufficient setting is a differential graded model, for example complexes of modules with quasi-isomorphisms. Choose one cofibrant replacement $Qa \to a$ for each object, in the projective model structure; all complexes are fibrant. The complexes $\mathrm{Hom}^\bullet(Qa, Qb)$ then compose literally by differential graded composition, since the middle representative is the same in the two factors. This is the enhancement described in Keller (2006, §§2.2 and 3.2). The claim here is about this specified setting. The text does not state a set of hypotheses on an arbitrary additive relative category that would construct such an enhancement, and the existence of an adjoint equivalence $\Sigma \dashv \Omega$ alone does not give that construction.

For a commutative ring k, put

$$C(a,b) = \tau_{\leq 0}\,\mathrm{Hom}^\bullet_k(Qa, Qb) \simeq \tau_{\leq 0}\mathbf{R}\,\mathrm{Hom}_k(a,b).$$

The good truncation retains the negative degrees and the cycles in degree zero. It belongs to $D^{\leq 0}(k)$, or equivalently to $D_{\geq 0}(k)$ after reversing degrees. Differential graded composition gives

$$C(a,b) \overset{\mathbf{L}}{\otimes}_k C(b,c) \longrightarrow C(a,c),$$

using the Koszul interchange to put the factors into the usual composition order. Composing two cycles of degree zero gives a cycle, and the sum of two nonpositive degrees is nonpositive, so composition restricts to the good truncations. Replacing the two input complexes by projective resolutions provides the indicated derived tensor map. Its associativity is inherited from differential graded composition and the coherent tensor comparison; its unit is $k \to C(a,a)$ carrying 1 to the identity. Since k is projective over itself,

$$\mathrm{Hom}_{D(k)}(k, C(a,b)) = H^0 C(a,b) = \mathrm{Hom}_{D(k)}(a,b).$$

The unqualified "ring" in the source needs attention at exactly this tensor product. Two left modules over a noncommutative ring do not have the displayed tensor product with values in left modules. One may assume k commutative, as above, or use the appropriate bimodule category. Moreover, the image of $k \to \mathrm{End}(\mathrm{id}_{\mathcal{M}})$ is central: any two natural endomorphisms commute by applying the naturality of one to a component of the other. Thus the scalar action already factors through a commutative image.

The connective complex produces a pointed space by Dold–Kan and forgetting the simplicial module structure. The convention is

$$\pi_n \mathrm{Map}^h(a,b) = H^{-n}\mathbf{R}\,\mathrm{Hom}_k(a,b) = \mathrm{Hom}_{D(k)}(a[n], b), \qquad n \geq 0,$$

with the first equality at the zero basepoint for $n > 0$. The higher positive Ext groups of two degree-zero modules are not positive homotopy groups of this mapping space. This is the grading distinction explained in the commentary on Chapter III, manuscript p. 12 ("Keeping all degrees of the mapping complex").

For a concrete calculation, take $a = k[0]$ and $b = k[1]$, with cohomological convention $K[1]^i = K^{i+1}$. The source is projective, so the ordinary Hom complex already computes derived Hom and is $k[1]$, concentrated in degree -1. Dold–Kan gives $K(k,1)$; there is one component, its fundamental group is the additive group of k, and every higher homotopy group vanishes. On the other hand $\mathrm{Hom}_{D(k)}(k[1], k[1]) = k$, exactly the group predicted by suspension representability. This example makes visible the information that would disappear if one kept only the ordinary zero map $k \to k[1]$.

Commentary · Exposition [ms. 20]

The bilinear comparison is lax monoidal

Grothendieck correctly asks for a comparison map in the direction needed to transport composition. It need not be an isomorphism. Let P and Q be nonnegative chain complexes and choose nonnegative projective resolutions $P' \to P$ and $Q' \to Q$. Their Dold–Kan simplicial modules $A = \Gamma P'$ and $B = \Gamma Q'$ have a degreewise map of pointed sets

$$U(A) \times U(B) \longrightarrow U(A \otimes_k B), \qquad (a,b) \longmapsto a \otimes b.$$

The shuffle equivalence identifies the normalized complex of $A \otimes_k B$ with $P' \otimes_k Q'$, which computes $P \otimes_k^{\mathbf{L}} Q$. This yields the source's comparison in $\mathrm{Hot}_\bullet$. It factors through the smash product because either zero input is sent to zero. For coherence, use the unital associative Alexander–Whitney comparison $\Gamma P' \otimes_k \Gamma Q' \to \Gamma(P' \otimes_k Q')$; its normalized map is inverse to shuffle up to chain homotopy. The derived construction is independent of the chosen projective replacements. Dold–Kan itself is Theorem 14.24.3 of The Stacks Project Authors (2026c); the tensor comparisons, their identities, and the induced monoidal structure on Γ are checked in Schwede and Shipley (2003, §2.3, especially equation (2.8)).

Already with $P = Q = k[0]$, the map on components is

$$k \times k \longrightarrow k, \qquad (x,y) \longmapsto xy,$$

which is not injective for any nonzero ring, since $(0,0)$ and $(0,1)$ have the same image. It nonetheless carries a tensor pairing to a pointed or unpointed pairing by composition. Thus "more information" means that the bilinear factorization is specified, not that the forgetful functor is fully faithful or that its monoidal comparison is invertible. The displayed Cartesian product is legitimate for this weaker pairing; to apply the enriched unit convention in pointed spaces one uses its smash factorization, as explained above.

3°) Revenant au cas $\mathcal{M}$ ponctuée sans plus, Quillen définit, pour a, b dans $\mathcal{M}$,

$$\pi_1(a,b) \;=\; \pi_1(a,b\,;0_a,0_b)$$

comme bifoncteur sur $(\mathcal{M}\Sigma^{-1})^o \times (\mathcal{M}\Sigma^{-1})$ (avec les notations de 1°)). Si ce que j'avance sans preuve dans 1°) est vrai, il doit s'ensuivre qu'on a un isomorphisme canonique

$$\pi_1(a,b) \;\simeq\; \pi_1(\mathrm{Ch}_\infty^\Sigma(a,b)),$$

où $\mathrm{Ch}_\infty^\Sigma(a,b)$ est vu comme objet de $\mathrm{Hot}_\bullet$, donc son π_1 est défini. On a en tous cas, sans aucune référence à des cofibrations et des fibrations, un bifoncteur à valeurs dans Groupes, composé dans

$$(\mathcal{M}\Sigma^{-1})^o \times (\mathcal{M}\Sigma^{-1}) \xrightarrow{(a,b)\longmapsto \mathrm{Ch}_\infty^\Sigma(a,b)} \mathrm{Hot}_\bullet \xrightarrow{\pi_1} (\text{Groupes}).$$

Si pour a fixé, b variable,

$$b \;\longmapsto\; \pi_1(a,b)$$

est représentable, on note l'objet qui le représente par $\Sigma(a)$ (*suspension* – ne pas confondre ce Σ avec $\Sigma \subseteq \mathrm{Fl}(\mathcal{M})$, qu'il vaut mieux maintenant noter W, comme 'weak equivalence'). Donc

[page 22]

$$\mathrm{Hom}(\Sigma a,b) \;\simeq\; \pi_1(a,b),$$

et Σa dépend fonctoriellement de a, sous réserve d'existence. S'il existe toujours, on a

$$\Sigma : \; \mathcal{M}W^{-1} \;\longrightarrow\; \mathcal{M}W^{-1}.$$

On définit de même, sous réserve d'existence,

$$\Omega : \; \mathcal{M}W^{-1} \;\longrightarrow\; \mathcal{M}W^{-1}$$

par

$$\mathrm{Hom}(a,\Omega b) \;\simeq\; \pi_1(a,b),$$

et si tous les deux existent, on a la formule d'adjonction

$$\mathrm{Hom}(\Sigma a,b) \;\simeq\; \mathrm{Hom}(a,\Omega b) \qquad (\simeq \pi_1 \mathrm{Hom}\,\mathrm{ext}_{\mathrm{Hot}_\bullet}(a,b)).$$

Commentary · Exposition [ms. 22]

Representability and its higher counterpart

The representability argument is complete once the pointed mapping bifunctor has been constructed. Let $\mathcal{C} = \mathcal{M}[W^{-1}]$ and write $F(a,b) = \pi_1 \operatorname{Map}^h(a,b)$ at zero. If $F(a,-)$ is represented by Σa, then a morphism $a \to a'$ induces $F(a',-) \to F(a,-)$; Yoneda gives $\Sigma a \to \Sigma a'$. Uniqueness in Yoneda proves the functor laws. The same argument in the other variable constructs Ω, and the two representing bijections give $\Sigma \dashv \Omega$. The appearance of $0_a, 0_b$ in the source's page-21 expression must be read as two copies of $0_{a,b}$, since both endpoints of a path lie in the same mapping space.

Representability of π_1 alone supplies only a statement on components of loop spaces. To obtain the displayed equivalences of whole mapping spaces one requires homotopy limits and colimits in the enhanced category. In a pointed category with derived mapping spaces and a homotopy pullback defining $\Omega b = 0 \times^h_b 0$, the defining universal property gives

$$\operatorname{Map}^h(a,\Omega b) \simeq * \times^h_{\operatorname{Map}^h(a,b)} * = \Omega \operatorname{Map}^h(a,b).$$

Dually, the homotopy pushout $\Sigma a = 0 \amalg^h_a 0$ gives the other equivalence. Both respect loop multiplication because concatenation is induced by the same pointed path construction. This is the additional structure behind the source's test (c), rather than a consequence of an arbitrary bijection on π_0.

Quillen proves the group-valued bifunctor and its two representabilities for a pointed model category in Chapter I, §2; the checked retypesetting labels the result Theorem 1.2 (Quillen, 1967). The same construction is built into pointed derivators, where the coherent square, rather than a square in the underlying homotopy category, defines suspension and loops (Groth, 2013, Definition 3.16 and Proposition 3.17). The unit being invertible makes Σ fully faithful; the counit being invertible makes Ω fully faithful. If both are invertible, they form an equivalence. Requiring both is the stability condition, not a prerequisite for the existence of the two functors in a pointed model theory.

The following paragraph also uses existence of the appropriate finite products and coproducts. With those in place, a natural multiplication on $\mathrm{Hom}(-, \Omega b)$ is, by Yoneda, a map $\Omega b \times \Omega b \to \Omega b$; the group equations follow by the same argument. Dually Σa is a cogroup. In the enhanced setting, a derived mapping-space functor carries homotopy products in its second variable, and homotopy coproducts in its first, to products of spaces. These are the products and coproducts that justify the source's compatibility with group objects. Existence of ordinary products in the localized category, without a comparison to the enhanced products, would not by itself prove the mapping-space statement. On a pointed derivator Ω is right adjoint to Σ as a morphism of derivators, so it preserves homotopy right Kan extensions, and Σ preserves homotopy left Kan extensions; this supplies the left and right exactness anticipated in footnote 8.

L'existence de p. 14

$$\Omega : \mathcal{M}W^{-1} \longrightarrow \mathcal{M}W^{-1}, \quad \text{ou de}$$
$$\Sigma : \mathcal{M}W^{-1} \longrightarrow \mathcal{M}W^{-1},$$

voire même des deux à la fois, apparaît comme une hypothèse ⓐ extrêmement forte sur $(\mathcal{M}, W)$. Cette condition *plus* celle ⓑ que les $\underline{\mathrm{Ch}}_\infty(a, b)$ soient homotopes à des catégories de Thomason-Kan, ou (ce qui revient au même, à peu de choses près?) que $Y \longmapsto \mathrm{Hom}_{\mathcal{M}(Y)W_Y^{-1}}(a_Y, b_Y)$ transforme Hot-équivalences de Cat en bijections (ne serait-ce que pour Y fixé …), semble le test crucial pour savoir si '$(\mathcal{M}, \Sigma)$ `[plutôt` $(\mathcal{M}, W)$`]` se prête à une théorie homotopique 'dans $\mathcal{M}$' '. Je doute que

ces conditions puissent être satisfaites pour $\mathcal{M}$ finie, sauf dans le cas trivial où $\mathcal{M} = \emptyset$, où $\mathcal{M}\Sigma^{-1}$ `[plutôt` $\mathcal{M}W^{-1}$`]` est équivalente à la catégorie ponctuelle. [page 23]

Commentary · Development (commentators') [ms. 23]

A finite test of the proposed axioms

Grothendieck suspects that his tests already force an infinite supply of objects and operations. This would be natural for a model of a nontrivial stable homotopy theory, but the tests actually written permit a finite pointed category. The following calculation isolates the missing requirement. We checked the cited localization and model-category sources and the commentary on the earlier chapters; we did not find this particular example discussed as a response to this passage. Its role is diagnostic, without a claim of priority.

A finite relative category satisfying tests (a) and (b). [ours] Let $\mathcal{E}$ have objects $0, x$, with 0 a zero object, $\mathrm{End}(x) = \{1_x, z\}$, and z the composite $x \to 0 \to x$, so $z^2 = z \neq 1_x$. All other Hom sets are singletons. This is the full subcategory of pointed sets on a singleton and a two-element pointed set. Take W to consist of identities. Then $\mathcal{E}[W^{-1}] = \mathcal{E}$, which is neither empty nor equivalent to a point.

We first compute the actual path category. With all backward edges identities, a bilateral eventually constant path is an eventually constant forward chain from a to b, with duplicated vertices at the backward steps. Composition of its finite nonidentity part defines a functor

$$q : \mathrm{Ch}^W_\infty(a, b) \longrightarrow \mathrm{Hom}_{\mathcal{E}}(a, b)_{\mathrm{disc}}.$$

Naturality with fixed endpoints makes the composite invariant under morphisms of paths. Choose the section s that inserts a morphism at the forward edge $-1 \to 0$, with identities elsewhere. Define a third functor R by replacing the part strictly before 0 by the constant value a, retaining the part from 0 onward, and using the composite $a \to a_0$ at the joining edge. The eventual identity tails make that composite well-defined. There is a natural transformation $R \to \mathrm{id}$: its early components

are the composites $a \to a_i$, and its later components are identities. There is also $R \to sq$: its early components are identities and its later components are the composites $a_i \to b$. All the squares commute by composition of forward chains; duplicated backward vertices have identical components. Thus

$$\mathrm{id} \longleftarrow R \longrightarrow sq, \qquad qs = \mathrm{id}.$$

This proves a categorical homotopy equivalence to the discrete Hom category. In particular every component is contractible, every π_1 is zero, and the path categories are homotopy equivalent to discrete categories, which are Thomason–Kan fibrant. This verifies the first formulation of test (b).

The second formulation is equally direct. Since W_Y contains only identities, no localization changes $\mathcal{E}(Y)$. A natural transformation between the constant diagrams a_Y, b_Y assigns one arrow $a \to b$ to each connected component of Y, because naturality along every arrow forces equality. Hence

$$\mathrm{Hom}_{\mathcal{E}(Y)}(a_Y, b_Y) \cong \mathrm{Hom}_{\mathcal{E}}(a,b)^{\pi_0 Y}.$$

Every Hot-equivalence induces a bijection here. Finally $\Sigma a = 0 = \Omega a$ represents the identically trivial group-valued bifunctor $\pi_1(a,b)$ in both variables. Test (a) holds, as do the mapping-space equivalences of test (c): all their terms are points. The nontrivial endomorphisms of x survive in π_0, so this is not the terminal exception.

The finite-limit hypothesis introduced on the next page would rule this example out for an elementary reason. If a category has finitely many arrows, say N, and all finite powers, then two distinct maps $a \to b$ would give at least 2^n maps $a \to b^n$ for every n, contradicting $2^n > N$. Thus every Hom set has at most one element. If the category is pointed, the zero maps make every Hom set nonempty, so it is equivalent to the terminal category. This is the finite form of the usual small-completeness argument; see Leinster (2014, Exercise 6.3.23(d)). The distinction is therefore exact: the stated tests do not imply the finiteness obstruction, while a finite pointed category with finite products is already trivial before localization.

Un troisième test ⓒ qui me paraît important (mais peut-être ça résulte du reste), c'est les formules dans $\mathrm{Hot}_\bullet$

$$(*) \qquad \begin{cases} \mathrm{Hom\,ext}_\bullet(\Sigma a, b) \simeq \mathrm{Hom\,ext}_\bullet(a, \Omega b) \\ \qquad\qquad\qquad\quad \simeq \Omega \mathrm{Hom\,ext}_\bullet(a,b), \end{cases}$$

où le $\mathrm{Hom\,ext}_\bullet$ désigne le Hom externe à valeurs dans $\mathrm{Hot}_\bullet$. Il faut le voir séparément (sous condition d'existence soit de Ω, soit de Σ) comme deux formules 'duales' l'une de l'autre,

$$(**) \qquad \begin{cases} \mathrm{Hom\,ext}_\bullet(a, \Omega b) \simeq \Omega \mathrm{Hom\,ext}_\bullet(a,b) \\ \mathrm{Hom\,ext}_\bullet(\Sigma a, b) \simeq \Omega \mathrm{Hom\,ext}_\bullet(a,b), \end{cases}$$

isomorphismes de *groupes* dans $\mathrm{Hot}_\bullet$. (**NB** Ωb est un objet groupe de $\mathcal{M}W^{-1}$, car il représente un contrafoncteur à valeurs dans Gr, et de même Σa est un cogroupe de $\mathcal{M}W^{-1}$. Le foncteur $y \longmapsto \mathrm{Hom\,ext}(a,y)$ doit commuter aux produits finis, et donc transformer objets groupes en itou. Et de même $x \longmapsto \mathrm{Hom\,ext}(x,b)$ doit transformer sommes finies en produits finis, donc cogroupes en groupes ([8]).)

Je me suis convaincu que les isomorphismes $(**)$ n'ont de chance d'exister que si on a la condition préalable ⓑ.

8. Le foncteur Ω doit provenir d'un endomorphisme du dérivateur $\mathbf{D} = \mathbf{D}_{\mathcal{M},W}$, et celui-ci doit être exact à gauche, et dualement pour Σ.

3 Essai de construction du foncteur Ω

p. 15
[page 24]

Il n'y a sans doute guère de chance de prouver quelque chose sur le foncteur

$$\Omega : \mathcal{M}W^{-1} \longrightarrow \mathcal{M}W^{-1},$$

sans tenir en mains une *construction* plus ou moins explicite de celui-ci. Je vais essayer, en m'inspirant de Quillen, de dégager des conditions générales sur $(\mathcal{M}, W)$ (plus générales que celles de Quillen) qui assurent l'existence de Ω, et permettent de le construire. L'idée géométrique remonte à Serre-Cartan. Il s'agit, pour un objet S de $\mathcal{M}$, de construire un objet $\mathrm{Ch}(S)$ *dans* $\mathcal{M}$, jouant le rôle d'un 'espace de chemins', et qui doit s'inclure dans un diagramme de factorisation de $\mathrm{diag}_S : S \longrightarrow S \times S$ (on suppose que dans $\mathcal{M}$ les $\varprojlim$ finies, donc les produits finis, existent)

$$\begin{array}{ccc} & & S \\ & & \downarrow{\scriptstyle i_S} \\ \mathrm{diag}_S & \searrow & \mathrm{Ch}(S) \\ & & \downarrow{\scriptstyle p_S} \\ & & S \times S \longleftarrow e. \end{array}$$

La propriété essentielle, c'est que p soit une *'fibration'* (dans un sens convenable, à dégager).

Commentary · Exposition [ms. 24]

Which factorization computes loops

Grothendieck returns to an actual path object because representability must eventually be proved by a construction. In a pointed model category, choose a fibrant replacement of S and a factorization

$$S \xrightarrow{\sim} PS \xrightarrow{(d_0,d_1)} S \times S$$

of its diagonal, with the first map a weak equivalence and the second a fibration. The fibre over $(0,0)$ computes ΩS. Fibrancy is part of the useful hypothesis: it makes the endpoint maps fibrations to a fibrant object, so their pullbacks compute the intended homotopy fibres. The first map may be chosen to be a trivial cofibration, but its weak-equivalence property is essential. At this point the source is still seeking its axioms, so this is a completion of the proposed construction, not a correction of a theorem claimed to have been proved.

Merely asking for the second map to be a fibration, even adding a cofibration for the first, would be insufficient. In pointed simplicial sets take a nontrivial Kan complex $S = K(A,1)$, let $PS = S \times S$, and let the second map be the identity. The diagonal is a monomorphism, hence a cofibration, and S is fibrant. Nevertheless the indicated fibre is a point, whereas the true loop space has components A. What fails is precisely the omitted weak equivalence $S \to PS$.

The representation can be read directly from mapping spaces. In a pointed simplicial model category, let T be cofibrant. Applying $\mathrm{Map}(T,-)$ to the displayed factorization gives a path object for the Kan complex $K = \mathrm{Map}(T,S)$: its endpoint map is a fibration by the simplicial model axiom and its first map is a weak equivalence between fibrant objects. Mapping out of T preserves the pullback that defines the fibre. Therefore

$$\mathrm{Map}(T, \Omega S) \simeq \Omega K, \qquad [T, \Omega S] \cong \pi_1 \,\mathrm{Map}(T,S).$$

The latter bijection is natural in both variables after replacements. It is independent of the chosen path object because all such objects compute the same homotopy pullback $0 \times^h_S 0$. For arbitrary model categories the corresponding statement is Quillen's path-object argument, using homotopy classes of left and right homotopies; the checked version gives it as equation (5) in the proof of Theorem 1.2 (Quillen, 1967, Chapter I, §2).

To replace the mapping space by $\mathrm{Ch}^W_\infty(T,S)$ in the final display of the manuscript requires its comparison with the derived mapping space. A path object in $\mathcal{M}$ and an interval of zigzags in Cat play complementary roles; they are not interchangeable definitions. The audit leaves the specific comparison visibly conditional while giving the completed argument in the model setting.

Commentary · Context [ms. 24]

Path objects before the full model structure

Grothendieck is looking for precisely the axioms needed to construct loops. This route had already been isolated by Brown (1973, §1, pp. 420–421), whose categories of fibrant objects retain weak equivalences, fibrations, and path objects without specifying cofibrations. Brown requires pullbacks of fibrations and of trivial fibrations to exist and remain of the same kind; every object is fibrant. His path-object axiom factors the diagonal by a weak equivalence followed by a fibration. These are sufficient structural data for the factorization lemma proved there, which replaces an arbitrary map by a weak equivalence followed by a fibration.

The comparison clarifies the two tentative choices on the next manuscript page. Fibrancy of S supplies part of the working setting, while the essential property of $S \to \mathrm{Ch}(S)$ is its being a weak equivalence. A cofibration condition on that arrow is not needed for Brown's axioms. We use this established precedent to specify a sufficient framework, without suggesting that the manuscript cites Brown or that these axioms alone identify its particular bilateral path categories with derived mapping spaces.

[page 25]

À titre accessoire il peut être utile (peut-être) que i soit une 'cofibration' ([9]). On définit $\Omega(S)$ comme la fibre de $\mathrm{Ch}(S)$ sur $S \times S$ (par rapport à l'unique morphisme $e = e_{\mathcal{M}} \longrightarrow S \times S$, où $e_{\mathcal{M}}$ est l'objet nul de $\mathcal{M}$).

$$\begin{array}{ccc} \mathrm{Ch}(S) & \longleftarrow & \Omega S \\ \downarrow & & \downarrow \\ S \times S & \longleftarrow & e. \end{array}$$

9. et peut-être que $S \longrightarrow e$ soit également une fibration ?

C'est un objet de $\mathcal{M}$, qu'on regardera surtout comme un objet de $\mathcal{M}W^{-1}$. Il faut s'assurer qu'on a une bijection fonctorielle en T dans $\mathcal{M}W^{-1}$ p. 16

$$\underbrace{\pi_1 \underline{\mathrm{Ch}}^W_\infty(T,S)}_{\overset{\text{déf}}{=}\pi_1(T,S)} \simeq \underbrace{\mathrm{Hom}_{\mathcal{M}W^{-1}}(T,\Omega S)}_{\overset{\text{déf}}{=}\pi_0\underline{\mathrm{Ch}}^W_\infty(T,\Omega S)}.$$

Pour cela, il s'impose de comparer

$$\underline{\mathrm{Ch}}^W_\infty(T,\Omega S) \qquad \text{et} \qquad \underbrace{\Omega_{\mathrm{Hot}_\bullet}(\underline{\mathrm{Ch}}^W_\infty(T,S))}_{\overset{\text{'par définition' pour } \Omega \text{ de Hot}_\bullet}{=} \underline{\mathrm{Ch}}_\infty(\mathrm{Ch}^W_\infty(T,S);0,0)},$$

puisqu'il s'agit de construire une bijection entre leurs π_0.

Commentary · Examples [ms. 25]

The loop object of a complex, with its contraction

For complexes the proposed construction can be written down without any choices, and its fibre displays the sign in the loop shift. Use cochain complexes of k-modules with the model structure whose weak equivalences are quasi-isomorphisms and whose fibrations are degreewise surjections. Every complex is fibrant. For a complex B, define

$$(PB)^n = B^n \oplus B^n \oplus B^{n-1}, \qquad d(x,y,h) = (dx, dy, y - x - dh).$$

The third component of d^2 is $dy - dx - d(y - x - dh) = 0$, so this is a complex. The maps

$$i(b) = (b,b,0), \qquad p(x,y,h) = (x,y), \qquad r(x,y,h) = x$$

are chain maps, pi is the diagonal, and p is a degreewise surjection. To verify the required weak equivalence, define the degree -1 homotopy $H(x,y,h) = (0,h,0)$. Direct calculation gives

$$(dH + Hd)(x,y,h) = (0, y - x, h) = (\mathrm{id} - ir)(x,y,h), \qquad ri = \mathrm{id}.$$

Thus i is a chain homotopy equivalence. Its fibre over zero under p is the complex with terms B^{n-1} and differential $-d$, namely $B[-1]$. We have obtained $\Omega B = B[-1]$ and, dually, $\Sigma B = B[1]$.

For a cofibrant replacement $QT \to T$, the corresponding Hom complex satisfies

$$H^0 \mathrm{Hom}^\bullet(QT, B[-1]) = H^{-1} \mathrm{Hom}^\bullet(QT, B) = \pi_1 \mathrm{Map}^h(T,B),$$

which verifies the source's required bijection in this example. More than the bijection is visible: applying the good nonpositive truncation and Dold–Kan to these Hom complexes identifies the whole mapping space into $B[-1]$ with the loop of the mapping space into B. All maps used above commute with chain maps $B \to B'$, so the construction is functorial before localization. This is exactly the kind of explicit factorization that the closing paragraph asks us to find.

1 Rappel des notions de D-asphéricité, et lien avec le 'localisateur fondamental $W_{\mathbf{D}}$'

p. 1 [page 1]

Pour un dérivateur **D**, il s'agit des notions suivantes (cf. I) :

Commentary · Exposition [ms. 1]

The homotopy shapes seen by a coefficient theory

Grothendieck now returns to the part of a derivator that can be expressed without choosing a particular category of coefficients. The relevant equivalences concern *constant* coefficients. Write $p_A : A \to e$ and $K_A = p_A^* K$. Then $u : A \to B$ belongs to $W_{\mathbf{D}}$ precisely when, for every $K, L \in \mathbf{D}(e)$, restriction gives a bijection

$$\mathrm{Hom}_{\mathbf{D}(B)}(K_B, L_B) \longrightarrow \mathrm{Hom}_{\mathbf{D}(A)}(K_A, L_A).$$

This recalls the distinction explained in the commentary on Chapter I, manuscript p. 61 ("Equivalence measured by constant coefficients"). It is not the assertion that $u^* : \mathbf{D}(B) \to \mathbf{D}(A)$ is an equivalence on arbitrary coherent diagrams. The distinction is what makes $W_{\mathbf{D}}$ a theory of homotopy *shapes*, while **D** still records the coefficients carried by those shapes.

The two comma categories retain different orientations. An object of A/b is an arrow $u(a) \to b$; an object of $b\backslash A$ is an arrow $b \to u(a)$. Accordingly, the fibre of $A/a \to B/u(a)$ over $\beta : b \to u(a)$ consists of factorizations of β by arrows $a' \to a$ lying over it. Its asphericity is the lifting criterion for smoothness, with the opposite criterion for properness. These are the categorical forms of the two base-change conditions, not assertions that the strict fibres A_b alone control base change. The later formulation is Maltsiniotis (2005, Theorem 1.2 and its dual).

(i) *Objet* **D**-*asphérique* de Cat (i.e. $Z \longrightarrow e$ est une **D**-équivalence). NB Je préfère dire '**D**-asphérique' au lieu de '**D**-contractile', qui prête parfois à confusion.

(ii) **D**-équivalence pour une flèche $f : X \longrightarrow Y$ dans Cat.

(iii) *Foncteur* $f : X \longrightarrow Y$ **D**-*asphérique* (i.e. les X/y sont **D**-asphériques) et **D**-*coasphérique* (les $y\backslash X$ sont **D**-asphériques). C'est ce que j'avais appelé '**D**-équivalence stricte' (ou 'costricte'), ou foncteur homologiquement **D**-cofinal (ou cohomologiquement **D**-cofinal), mais la terminologie 'asphérique' me semble la plus simple et la meilleure. (Pêchée dans PS, Pursuing Stacks.)

(iv) *Foncteur* $f : X \longrightarrow Y$ **D**-*lisse,* **D**-*propre* (i.e. tel que les fibres des foncteurs induits $X/x \longrightarrow Y/f(x)$, respectivement $x\backslash X \longrightarrow f(x)\backslash Y$, soient **D**-asphériques).

(v) **D**-*fibration* $f : X \longrightarrow Y$ (notion autoduale), i.e. telle que pour $Y'' \xrightarrow{u} Y'$ au dessus de Y, si Y'', Y' [sont] Hot-asphériques, alors $u_X : X'' \longrightarrow X'$ dans

$$\begin{array}{ccccc} X & \longleftarrow & X' & \longleftarrow & X'' \\ \downarrow & & \downarrow & & \downarrow \\ Y & \longleftarrow & Y' & \longleftarrow & Y'' \end{array}$$

est une **D**-équivalence ([3]). La **D**-*fibration* est dite *triviale* (ou *asphérique*) si et seulement si ses fibres sont asphériques, ou encore si et seulement si f est asphérique, ou si et seulement si f est coaspérique. Cela signifie aussi que f est une **D**-équivalence *universelle,* i.e. que pour tout $Y' \longrightarrow Y$, $X' = X \times_Y Y' \longrightarrow Y'$ est une **D**-équivalence.

(vi) On a aussi des variantes affaiblies de la notion de **D**-fibrations, savoir les '**D**-*fibrations à gauche',* ou les f '*cohomologiquement* **D**-*fibrants',* et de même les '**D**-*fibrations à droite',* i.e. les f '*homologiquement* **D**-*fibrants'* ([4]). La notion 'gauche' ou cohomologique pour [page 2]

p. 2

3. On dira aussi que f est **D**-*fibrant.* (**NB** Il n'y a pas de notion '**D**-cofibrant' à ma connaissance.)

4. Nouvelle terminologie : fibrations cohomologiques (resp. homologiques) *faibles,* cf. I, pages 111-126 pour une révision corrigée des diverses notions de '**D**-fibrations'.

$f : X \longrightarrow Y$ signifie que les foncteurs $X_y \hookrightarrow X/y$ ($y \in \mathrm{Ob}\, Y$) et $X/y \longrightarrow X/y'$ (pour $(u : y \longrightarrow y') \in \mathrm{Fl}\, Y$) sont des **D**-équivalences. Et dualement avec les $X_y \hookrightarrow y\backslash X$, $y'\backslash X \longrightarrow y\backslash X$ pour la notion 'droite' ou 'homologique'. Les **D**-fibrations ne sont autres que les **D**-fibrations gauches (cohomologiques) universelles ou les **D**-fibrations droites (homologiques) universelles.

Commentary · Exposition [ms. 2]

Why triviality is a universal condition

The point of the fibration condition is to make the fibre calculations survive a change of base. The qualifier "universal" in the next sentence therefore carries real mathematical content; the earlier distinctions are reviewed in the commentary on Chapter I, manuscript p. 104 ("The universal criterion, with the quantifiers restored").

Here is a useful direct verification of the asserted triviality criterion. Suppose $f : X \to Y$ is a **D**-fibration and every X_y is $W_{\mathbf{D}}$-aspherical. After any change of base $B \to Y$, the same hypotheses hold. For $b \in B$, apply the definition to $e \to B/b$, selecting its final object. Both bases are ordinarily contractible, so

$$(X \times_Y B)_b \longrightarrow (X \times_Y B)/b$$

lies in $W_{\mathbf{D}}$. Hence every category on the right is $W_{\mathbf{D}}$-aspherical. The asphericity theorem gives $X \times_Y B \to B \in W_{\mathbf{D}}$. Conversely, a universal $W_{\mathbf{D}}$-equivalence has aspherical fibres by base change to points. It is a **D**-fibration: in its defining square the two projections to Y'' and Y' lie in $W_{\mathbf{D}}$, and $Y'' \to Y'$ does also because both bases are ordinarily contractible; two-out-of-three gives the required arrow between pullbacks. Applying the same comparison with Y/y and $y\backslash Y$ proves the two equivalent comma-category criteria. The ordinary contractibility of the test bases, specified in the manuscript, has not been replaced by $W_{\mathbf{D}}$-asphericity.

Finalement, toute cette kyrielle de notions se déduit de la seule notion de **D**-équivalence (ii). Si je désigne par

$$W_{\mathbf{D}} \subseteq \mathrm{Fl}(\mathrm{Cat})$$

l'ensemble de ces **D**-équivalences, on trouve ce que dans Pursuing Stacks j'ai appelé un 'localisateur' (localiseur) dans Cat ([5]). Dans Pursuing Stacks c'était une telle partie

$$W \subseteq \mathrm{Fl}(\mathrm{Cat}),$$

et non la donnée d'un dérivateur, qui était pris comme la donnée de départ fondamental [page 3]
pour faire de l'algèbre homotopique en tous genres. J'avais d'ailleurs développé une kyrielle de notions du même genre (i) à (vi), en partant de cette donnée W. Il se pourrait que les énoncés pour les notions que j'ai développé dans I, en termes d'un dérivateur, soient valables plus généralement en termes d'un localisateur W, dans la mesure du moins où ils gardent un sens. (Donc pour l'instant je mets à part les énoncés proprement cohomologiques ou homologiques, qui font directement appel à **D**.) Encore qu'il se pourrait que moyennant des conditions à expliciter sur W, qui impliquent que (Cat, W) définissent bel et bien un dérivateur $\mathbf{D}_{\mathrm{Cat},W} = \mathbf{D}$, on arrive encore à interpréter W comme un $W_{\mathbf{D}}$, de sorte que les énoncés cohomologiques et homologiques gardent un sens.

Commentary · Later developments [ms. 3]

Realizing a localizer by a derivator

Grothendieck asks for a coefficient theory realizing the proposed weak equivalences. A precise answer is available under an accessibility hypothesis. Fix a universe for small diagram shapes and a larger universe for coefficient categories, and call a fundamental localizer accessible when it is generated by a small set of functors. Cisinski (2006a, Theorem 5.2.15) constructs a cofibrantly

5. Mais attention, je suppose ici que le domaine Diag de **D** est Cat tout entier!

generated, left proper model structure on Cat with weak equivalences W. The model-category construction of derivators then gives

$$\mathbf{D}_W(A) = \mathrm{Cat}^{A^o}\big[(W^{A^o})^{-1}\big]$$

with both homotopy Kan extensions (Cisinski, 2003, Theorem 6.11 and its dual). The comparison with simplicial presheaves and the recovery of W from constant-coefficient tests are supplied by Cisinski (2006a, Lemma 4.2.13, Theorem 4.2.15, and Corollary 4.2.18). Thus $W_{\mathbf{D}_W} = W$. Accessibility is the hypothesis of this realization statement; it is not implicit in the definition of an arbitrary derivator.

Realization does not determine a pre-existing coefficient theory. For a complete and cocomplete category $\mathcal{C}$, the represented derivator satisfies

$$\mathrm{Hom}_{\mathcal{C}^{A^o}}(K_A, L_A) = \mathrm{Map}\big(\pi_0 A, \mathrm{Hom}_{\mathcal{C}}(K, L)\big).$$

Indeed, naturality says exactly that the component of a natural transformation is constant along every zigzag in A. For $\mathcal{C} = \mathrm{Set}$ or Ab, a Hom set with at least two elements detects whether $\pi_0(u)$ is bijective: a missing component prevents injectivity of precomposition, and two identified components prevent surjectivity. Both derivators consequently give the same localizer W_0 of component bijections. Their categories of coefficients are not equivalent, since Ab has a zero object and Set does not. The equality $W_{\mathbf{D}_W} = W$ answers the question on these pages without identifying the original $\mathbf{D}$ with $\mathbf{D}_W$.

J'ai envie d'abord de regarder dans Pursuing Stacks les axiomes que j'ai dégagé pour les localisateurs, et vérifier s'ils sont tous vérifiés pour $W_{\mathbf{D}}$. Ces conditions L 1 à L 5 sont [page 4] énoncées dans Pursuing Stacks, §64 (page 164).

L 1 Saturation de W_D. O.K.

Cela résulte formellement du fait qu'on a un foncteur

$$\mathrm{Cat} \xrightarrow{\varphi} C \qquad (= \mathrm{Cat}^o)$$

tel que pour $u \in \mathrm{Fl}(\mathrm{Cat})$, $u \in W_{\mathbf{D}} \iff \varphi(u)$ isomorphisme. (Prendre pour $\varphi(X)$ la sous-catégorie de $\mathbf{D}(X)$ formée des $\mathbf{D}$-coefficients *constants* sur X).

Commentary · Exposition [ms. 4]

Making the saturation argument literal

Grothendieck's argument is sound once the category of constants is represented with its coefficient labels retained. Define $C_{\mathbf{D}}(A)$ to have objects $K \in \mathbf{D}(e)$ and morphisms

$$C_{\mathbf{D}}(A)(K, L) = \mathrm{Hom}_{\mathbf{D}(A)}(K_A, L_A).$$

Restriction is the identity on these object labels. Thus $u \in W_{\mathbf{D}}$ if and only if $C_{\mathbf{D}}(u)$ is an *isomorphism* of categories, whereas the essentially full subcategory of constant objects gives the equivalent formulation using equivalences of categories. This avoids choosing representatives for coincident or isomorphic constant diagrams.

The construction proves strong saturation. If the image of u becomes invertible in $\mathrm{Cat}[W_{\mathbf{D}}^{-1}]$, the factorization of the contravariant functor $C_{\mathbf{D}}$ through that localization makes $C_{\mathbf{D}}(u)$ invertible; hence $u \in W_{\mathbf{D}}$. In *Pursuing Stacks*, §64, "saturation" is the weaker list of identities, two-out-of-three, and the two-sided-composite condition. The present argument proves more than that list requires (Grothendieck, 1983, §64, manuscript pp. 163–165).

L 2 "$\mathbf{\Delta}^1$ est W-asphérique sur e", i.e. pour tout X dans Cat, $X \times \mathbf{\Delta}^1 \longrightarrow X$ est dans W. Cela signifie aussi que $\mathbf{\Delta}^1 \longrightarrow e$ est une $\mathbf{D}$-fibration triviale, ce qui est bien le cas.

p. 3

L 3 Si $X \in \mathrm{Ob}\,\mathrm{Cat}$ a un objet final, alors $X \longrightarrow e$ est dans W.

En fait, nous exigeons pour les dérivateurs que ceci soit vrai en supposant seulement X asphérique (au sens absolu), et on en conclut même que $X \longrightarrow e$ est W-asphérique, i.e. $X \times Y \xrightarrow{\mathrm{pr}_2} Y$ est dans W pour tout Y dans Cat ([6]).

L 4 Si $f : X \longrightarrow Y$ est tel que $X/y \longrightarrow Y/y$ sont dans W, alors f est dans W.

C'est OK.

[page 5]

L 5 Si X, Y sont Cat-fibrées sur S, et $X \longrightarrow Y$ est un S-morphisme *cartésien,* induisant sur les fibres des $X_s \longrightarrow Y_s$ qui sont dans W, alors f est dans W.

Pour $W_{\mathbf{D}}$, c'est la proposition 6, page 71 de I.

Ces axiomes L 1 à L 5 (équivalent à L 1, L 3′ ($\mathbf{\Delta}^1 \longrightarrow e$ est dans W) et L 5) sont dans la nature d'axiomes de stabilité, assurant que W est assez grand. Il y a une autre condition qui limite W à ne pas être trop grand :

Commentary · Exposition [ms. 5]

Completing the reduction to three axioms

The shortened axiom list expresses a useful economy: integration of families, together with one interval, already forces the basic homotopy calculus. The reduction is sketched in *Pursuing Stacks*, §64. We spell it out, using the twisted-arrow construction of Chapter I rather than its mapping-cone presentation; compare the commentary on Chapter I, manuscript p. 73 ("The twisted-arrow category and its two projections").

Assume L 1, L 3′, and L 5. Applying L 5 to the constant fibrations $A \times [1] \to A$ gives L 2. Their two sections belong to W by two-out-of-three. A natural transformation $F \Rightarrow G$, viewed as a functor $A \times [1] \to B$, therefore shows that $F \in W$ if and only if $G \in W$. A category with a final or initial object retracts to that object, with its other composite naturally homotopic to the identity. Saturation gives L 3 and its opposite.

To pass between the two comma orientations, let $T(A)$ have objects arrows $a \to b$ and morphisms from $h : a \to b$ to $h' : a' \to b'$ pairs

$$r : a \to a', \qquad s : b' \to b, \qquad sh'r = h.$$

Both projections $T(A) \to A$ and $T(A) \to A^o$ are Grothendieck fibrations. Their fibres are $(a\backslash A)^o$ and A/b, respectively, and have final objects. L 5 consequently puts both projections in W. The construction is natural in A, so its two commutative squares and two-out-of-three give

$$u \in W \quad \Longleftrightarrow \quad u^o \in W.$$

This also establishes the final assertion L d).

Next let $u : A \to B$ have W-aspherical categories $b\backslash A$. The Grothendieck construction

$$E = \int_{b \in B} (b\backslash A) \longrightarrow B$$

is a fibration with these fibres, hence lies in W by L 5. Its objects are triples $(b, a, \alpha : b \to u(a))$. The forgetful functor $r : E \to A$ has the section $i(a) = (u(a), a, 1)$, satisfies $ri = 1$, and has a natural transformation $1_E \Rightarrow ir$ with component $(\alpha, 1_a)$. Thus r and i belong to W, and u does also. Opposite invariance proves the analogous assertion for A/b. Under the hypothesis of L 4, the final object of B/b makes every A/b aspherical by two-out-of-three, so L 4 follows. Conversely, L 1–L 5 include L 1 and L 5 and imply L 3′ by L 3. This proves the claimed equivalence of axiom systems. For the modern relative form, suppose $A \to B$ lies over C and every $A/c \to B/c$ is in W. Opposite invariance gives objectwise equivalences $(A/c)^o \to (B/c)^o$. These diagrams define fibrations over C^o, so L 5 applies to their Grothendieck constructions; their forgetful functors are deformation retractions to A^o and B^o. Thus u^o, and hence u, belongs to W. This yields the relative Theorem A axiom of Cisinski (2004, Definition 1.1.3). No model structure is used.

L a) Si $f \in W$, alors $\pi_0(f)$ est bijectif.

6. En fait L 2 $\Longrightarrow$ L 3.

Ceci n'est pas satisfait pour tous les $W_{\mathbf{D}}$ – p. ex. si $\mathbf{D}$ est le dérivateur *nul,* alors $W_{\mathbf{D}} = \mathrm{Fl}\,\mathrm{Cat}$! Mais pour les dérivateurs utiles en pratique, cela semble toujours satisfait.

Commentary · Examples [ms. 5]

A nonzero coefficient theory that forgets components

The additional condition L a) restricts the amount of homotopy theory the coefficients may forget. Even a nonzero derivator need not satisfy it. Take the complete lattice $\mathbf{2} = \{0 < 1\}$ and its represented derivator

$$\mathbf{D_2}(A) = \mathrm{Fun}(A^o, \mathbf{2}).$$

For nonempty A, the Hom sets between the two constant diagrams are the Hom sets of $\mathbf{2}$: all are singletons except $\mathrm{Hom}(1_A, 0_A) = \varnothing$. For $A = \varnothing$ there is one diagram and one morphism. Therefore

$$u : A \to B \in W_{\mathbf{D_2}} \quad \Longleftrightarrow \quad (A = \varnothing \iff B = \varnothing).$$

In particular the fold $e \amalg e \to e$ belongs to this localizer, although its map on components is not injective. This is the usual coarse localizer W_{-1} (Cisinski, 2006a, Examples 3.3.5–3.3.6). The terminal coefficient category gives the still larger localizer of all functors, exactly as Grothendieck observes. By contrast, coefficients with a Hom set of at least two elements detect components in the represented examples calculated above. His remark about useful examples is a comment on the intended coefficients, not an additional derivator axiom.

L b), c) Le foncteur

$$\mathrm{Cat} \longrightarrow \mathrm{Cat}\, W^{-1}$$

commute aux sommes finies et aux produits finis ([7]).

À examiner ce que ça signifie en termes concrets sur W – je n'ai pas vérifié que c'est O.K. pour les $W_{\mathbf{D}}$.

Commentary · Present state [ms. 5]

Finite products and sums already descend

The questions L b) and L c) have a formal answer under the axioms already retained. If $u : A \to B$ is in W, the map of constant fibrations over any C gives

$$u \times 1_C : A \times C \longrightarrow B \times C \quad \in W$$

by L 5. Applying L 5 over a discrete indexing category likewise shows that coproducts of arrows in W belong to W. These closure properties are also Cisinski (2004, Propositions 1.1.5 and 1.1.7).

Closure alone should be connected to the universal properties of the claimed products and sums. Put $H = \mathrm{Cat}[W^{-1}]$. The localization of $\mathrm{Cat} \times \mathrm{Cat}$ at the componentwise weak equivalences is $H \times H$: a pair of zigzags can be interleaved by holding the other coordinate fixed, and the commutation squares between the two coordinates remain valid after inversion. The diagonal and the product functor are homotopical, so their adjunction, including its unit and counit, descends to H. Thus the image of $A \times B$ represents the product of the images of A and B. Descending the adjunction between coproduct and diagonal proves the corresponding coproduct assertion. The nullary adjunctions give the initial and terminal objects as well. Consequently the canonical localization preserves finite sums and finite products. A Quillen structure is unnecessary here; the explicit closure argument supplies the homotopy invariance needed for the *ordinary* products and sums appearing in the question.

L d) Si $f : X \longrightarrow Y$ dans W, alors $f^o : X^o \longrightarrow Y^o$ aussi.
C'est le corollaire 2, page 75 de I.

7. Ça marche si (Cat, W) provient d'un triple de Quillen (avec des Q-fibrations, Q-cofibrations, Q-équivalences faibles).

Overview · VIII-X

Integration, spaces of morphisms, and the choice of weak equivalences.

These three chapters investigate how much of homotopy theory can be reconstructed from operations on ordinary categories, provided that one keeps the right forms of coherence. Chapter VIII isolates integration for relative 1-types. Chapter IX returns to the path categories introduced earlier, first to extract an abstract theory of composition and then to compare it with Quillen's constructions. The opening of Chapter X changes the point of departure: instead of beginning with a derivator and its coefficients, Grothendieck asks whether a class of weak equivalences of categories can itself generate the theory. The movement is from a concrete adjunction, through the structure of its spaces of morphisms, to the axioms that make such constructions possible.

These pages comprise all of Chapters VIII and IX and the opening of Chapter X, twenty-seven pages of the edition. Manuscript references must always include the chapter: they run through VIII.1–9, IX.1–25, and X.1–5. Our audit follows those separate sequences. Original statements, including the edition's retained slips and editorial interventions, remain distinguishable from the commentary. The two doubtful readings are settled against the edition; neither licenses a mathematical change to Grothendieck's text.

Relative groupoids and a genuine biadjunction.

The decisive construction of Chapter VIII is simple enough to write down on an object of the base. For $f : S \to T$ and a category G fibred in groupoids over S, set

$$(f_!G)_t = \Pi(t\backslash_T G).$$

The comma category records a point of G together with an arrow from t to its image in T; groupoid completion turns this record into a homotopy 1-type. Its use is not limited to an already fibred category. For any $X \to T$, the same construction gives a relative groupoid $R_T X$, and extension along $X \to R_T X$ is universal for functors into categories fibred in groupoids. Cartesian lifts construct the extension, while their uniqueness supplies the coherence.

This universal property completes the adjunction verification left unfinished in the manuscript. It proves an equivalence of Hom-groupoids, not only a bijection on isomorphism classes. Both triangle comparisons arise from the same extension-and-restriction construction. Transitivity of integration is then the uniqueness of the left biadjoint to composite restriction. The point of the 2-categorical formulation is thus practical: the automorphisms that would have been discarded by taking components are precisely what make the comparison usable in a further composition. The base-change theorem has the corresponding later expression in the theory of asphericity structures and smooth functors (Maltsiniotis, 2005, §5).

The final descent statements require a more careful separation. The proper or smooth hypotheses of Theorem 3 support its assertions about faithfulness and about the essential image described by coefficients that are *constant on each strict fibre*. They do not justify replacing this condition by the assertion that every vertical transport is an equivalence. A locally constant groupoid family can carry degree-two coherence even when its base is simply connected. We give a finite example over the fourteen-element face poset of the boundary of a tetrahedron. Every fibre is $B(\mathbf{Z}/2)$ and every transport is the identity, but a nonzero normalized 2-cocycle prevents the total category from admitting a section. Consequently it cannot be equivalent to a constant family. This disproves part 3 and the subsequent corollary as printed, while leaving the preceding fibrewise-constant criterion intact.

The repair is expressed by higher monodromy: equivalence classes of locally constant groupoid families with a fixed fibre are controlled by maps to its automorphism 2-type. A 1-connected base removes ordinary monodromy but can retain the degree-two class; 2-connectivity removes both (Polesello and Waschkies, 2005, Corollary 2.2.4 and Theorem 2.2.5, arXiv version). A separate, shorter counterexample shows that section groupoids alone do not

test all the proposed faithfulness conditions. The correct section tests must also be made after passing to the total category of the first coefficient. Both corrections concern the quantifiers and the coherence in descent, rather than the integration construction itself.

The general faithfulness question also admits an exact answer without smoothness or properness. For each arrow of T, form its category of factorizations through objects in the image of f. Restriction is faithful on transformations, fully faithful on Hom-groupoids, or an equivalence on Hom-groupoids precisely when these factorization categories are respectively nonempty, connected, or 1-connected. We prove this three-level criterion by the counit on representables and coherent density, alongside the known untruncated homotopical-epimorphism criterion (Groth and Šťovíček, 2016, Theorem 6.10, arXiv version).

What composition gives, and what it presupposes.

Chapter IX begins with a strong idea: composition of paths should explain endpoint functoriality. In a monoidal category $\mathcal{H}$, Hom objects $C(a, b)$ with associative composition and coherent units determine an ordinary category with morphisms $\mathrm{Hom}_{\mathcal{H}}(I, C(a, b))$. Inserting these elements into composition produces the bifunctor $C_0^{\mathrm{op}} \times C_0 \to \mathcal{H}$. The proof is formal once the hypotheses are in place. Neither symmetry nor an internal Hom is needed. This is the familiar passage from an enriched category to its underlying ordinary category (Kelly, 1982, §§1.1–1.3).

There are two limits to what this argument proves in the passage under review. First, the endpoint maps give isomorphisms only when those endpoint maps are invertible. The early corollary omits that hypothesis, and a discrete two-object example disproves the wording; the manuscript itself restores it on page 8. Second, the abstract argument assumes associative composition on the particular objects $\mathrm{Ch}_\infty(a, b)$. It does not construct that composition. Grothendieck sketches the finite-stage argument for the ind-object CH_∞ and explicitly leaves the corresponding realized-space verification unfinished.

The possible shortcut through finite tests does not solve this difficulty. The earlier definition of Hot_0 uses homotopy types of finite categories, not just finite CW complexes. The resulting restricted Yoneda functor is not conservative, by the general theorem on small families of unpointed tests, and it is not faithful, by nonconcreteness of the homotopy category (Arlin and Christensen, 2023, Theorem 2.1) and Freyd (1970, pp. 1, 5 of the reprint). Thus equality after passing to those presheaves cannot replace a compatible homotopy on the original mapping spaces. The commentary also distinguishes an ind-object, an ordinary colimit in Hot, and a homotopy colimit. An explicit increasing sequence of finite discrete sets has an ordinary colimit without being essentially constant as an ind-object. A finite-category test such as BC_2, on the other hand, is not compact with respect to all filtered homotopy colimits. These examples delimit the arguments that the comparison maps actually require.

Modern localization supplies the intended kind of mapping-space theory. The hammock localization has coherent mapping spaces and a component category equal to the ordinary localization (Dwyer and Kan, 1980a, §2). This identifies the modern object to which Grothendieck's construction should be compared; it does not by itself prove a comparison for his exact bilateral stabilization and transformation conventions. We keep that model-specific verification explicit. It is not described as a new open problem in the general theory of localization.

Pointed and linear refinements.

The later part of Chapter IX asks that the zero map become a specified basepoint in every mapping space. A basepoint in the unpointed homotopy category is insufficient: based homotopies remember data lost under free homotopy. The commentary constructs the pointed morphism associated to a map and a chosen path between basepoints, including its composition law. It also explains the significance of the manuscript's two corrective footnotes. The Cartesian unit in pointed spaces has only one map to every object; the unit that recovers all components is S^0 for the smash product. Composition must therefore annihilate either

zero input. Forgetting basepoints carries this structure to unpointed composition through a lax monoidal comparison.

Some questions at the level of ordinary localization have particularly direct answers. Initial and terminal objects survive localization without extra hypotheses, by naturality of their unique arrows along both ordinary and inverted generators. Suitable closure under finite products or sums lets the corresponding adjunctions descend. For an additive category, stability of the denominator class under finite direct sums already yields an additive ordinary localization (Krause, 2021, Lemma 2.2.1). The stronger request for complexes of morphisms requires an enhanced setting. We treat complexes of modules explicitly, with connective truncations of derived Hom, derived tensor composition, and the Dold–Kan comparison. This makes the grading visible: positive homotopy groups of the mapping space are negative cohomology groups of the Hom complex.

The suspension and loop objects are then representability statements. Representing the fundamental-group bifunctor yields an adjunction; the equivalences of whole mapping spaces arise from homotopy pushouts and pullbacks. An explicit path complex verifies the loop construction with its differential, its contraction, and its fibre. We also develop a finite counterexample to the proposed force of tests (a) and (b): the full category of pointed sets on one and two elements, with only identities inverted, satisfies both tests and even the displayed mapping-space identities. Its loop and suspension functors are zero, while its ordinary category is nontrivial. The missing strength is therefore not finiteness of the category alone. This calculation is marked as the commentators' development, without a priority claim.

Localizers and the information retained by coefficients.

The opening of Chapter X extracts a class $W_{\mathbf{D}}$ by testing maps of indexing categories against constant coefficients. It must be distinguished from the condition that restriction be an equivalence on all coherent diagrams. The localizer axioms express the stability of those constant-coefficient tests under interval homotopy, comma constructions, and integration of fibrations. We complete the reduction from the five displayed axioms to the shorter list, including the role of the twisted-arrow category in proving invariance under opposites. The finite-product and finite-sum questions are then settled by explicit closure arguments and descent of the product and coproduct adjunctions. No model structure is needed for these formal consequences.

Realization is a further theorem. For an accessible fundamental localizer, the later model structures and derivator constructions give a coefficient theory that realizes its weak equivalences (Cisinski, 2006a, Theorems 4.2.15 and 5.2.15); (Cisinski, 2003, Theorem 6.11 and its dual). This does not reconstruct an arbitrary original derivator from $W_{\mathbf{D}}$. The represented derivators of sets and of abelian groups have the same component-detecting localizer, although their coefficient categories are inequivalent. The represented truth-value lattice gives an equally concrete nonzero example whose localizer detects only emptiness, disproving any attempt to impose component detection on all nonzero derivators. These examples show precisely what Chapter X has isolated: the homotopy shapes visible to a theory, while its further algebra of coefficients remains additional structure.

1 Hot-fibrations dans Cat

Théorème 1. *Soit $f : X \longrightarrow Y$ dans* Cat. *Conditions équivalentes :*

Commentary · Exposition [ms. 127]

The universal meaning of a Hot-fibration

Grothendieck wants the ordinary pullback of categories to calculate a homotopy pullback whenever one of its sides belongs to a recognisable class. This is what makes a fibre a homotopically meaningful object, rather than an accident of a presentation. Write $BC = |NC|$, where N is the nerve, and let W_∞ consist of the functors inducing weak homotopy equivalences of classifying spaces. Condition a) says that

$$f^* : \mathrm{Cat}/Y \longrightarrow \mathrm{Cat}/X, \qquad (T \longrightarrow Y) \longmapsto (X \times_Y T \longrightarrow X),$$

preserves W_∞. The quantifier ranges over maps between *arbitrary* objects of Cat/Y, and not only over weak equivalences with target Y. It therefore includes every further change of base.

In the terminology of Rezk (1998, §2, Proposition 2.7), these are precisely the sharp maps in the Thomason model category. The identification uses the definition of sharpness and the right properness of that model category; it does not identify this class with the smaller class of its model fibrations. Every strict pullback square along such a map is homotopy cartesian. This interpretation also explains why composition and arbitrary base change will be available without choosing liftings.

There is a small but decisive quantifier in a') and a"). The point $e \longrightarrow Y'$ is arbitrary; it need not select the final, respectively initial, object whose existence is assumed. Over the interval $0 \longrightarrow 1$, both endpoint inclusions must therefore become weak equivalences after pullback. Asking only for the distinguished final endpoint, for every category having a final object, leads instead to the later notion of preproperness. Asking only over intervals is weaker again. These distinctions become the subject of Chapter XII, and they should not be erased by replacing every occurrence of "fibration" with a single modern definition.

a) Pour tout $Y'' \xrightarrow{p} Y'$ sur Y, d'où $X'' = X \times_Y Y'' \xrightarrow{q} X' = X \times_Y Y'$, si p est une Hot*-équivalence, q l'est aussi.*

a′) Comme a), avec $Y'' = e$, Y' ayant un objet final.

a″) Comme a), avec $Y'' = e$, Y' ayant un objet initial ([1]).

b′) Pour tout $y \in \mathrm{Ob}\, Y$, $X_y \longrightarrow X/y$ est une Hot*-équivalence, pour tout $y \longrightarrow y'$ dans Y, $X/y \longrightarrow X/y'$ est une* Hot*-équivalence; enfin ces conditions sont encore vérifiées pour $f' : X' \longrightarrow Y'$, pour tout changement de base $Y' \longrightarrow Y$ dans* Cat. *(En fait, il suffit de le demander pour la première des deux conditions, concernant $X_y \longrightarrow X/y$.)*

b″) Dual de b′), avec $X_y \longrightarrow y\backslash X$ et $y'\backslash X \longrightarrow y\backslash X$.

c) Pour tout faisceau d'ensembles localement constant F sur X, $f_*(F)$ est localement constant et se calcule 'fibre par fibre', de même pour $R^1 f_*(F)$ si F est un faisceau en groupes, et pour les $R^i f_*(F)$ si F est un faisceau abélien. De plus, on veut que ces conditions restent satisfaites après tout changement de base. ([2])

Démonstration. On a les implications ± tautologiques

$$\mathrm{a} \implies \mathrm{a}' \implies \mathrm{b}' \implies \mathrm{c},$$

cartésien dans Cat, si p est une Hot-équivalence, q aussi. On utilise le critère d'Artin-Mazur. p. 2

Commentary · Exposition [ms. 127]

Comma categories connect the geometric and coefficient tests

The comma categories in b') serve two purposes at once: they express a pointwise right Kan extension, and they supply canonical transition maps. We use $X/y = (f \downarrow y)$, with objects $(x, f(x) \longrightarrow y)$. Its strict fibre X_y is the full subcategory on identity arrows. A morphism $u : y \longrightarrow z$ gives a genuine functor $u_* : X/y \longrightarrow X/z$, so the coherence needed for transport is already present before localization.

Here is the short argument hidden in a') $\Rightarrow$ b'). Apply a') over Y/y, which has final object $(y, 1_y)$. The inclusion of the strict fibre over that object is $X_y \longrightarrow X/y$. Next work over Y/z and select its object (y, u). The resulting weak equivalence $X_y \longrightarrow X/z$ is the composite of $X_y \longrightarrow X/y$ and u_*. Two-out-of-three proves that $u_* \in W_\infty$. The same argument works after every base change.

The parenthesis in b') retains the transition condition on the original base; it says that only the fibre-to-comma condition needs to be imposed universally. Indeed, after $v : Y' \longrightarrow Y$, the comparison

$$X'/y' \longrightarrow X/v(y')$$

is a weak equivalence: both its source and target receive a weak equivalence from the same strict fibre $X_{v(y')}$. Comparing this square for an arrow of Y' with the corresponding arrow of Y then proves the required transition condition on Y'.

For a locally constant coefficient F, the value of the derived direct image at y is computed on X/y. Thus the preceding weak equivalences identify it with the cohomology of X_y, and identify its transition maps with isomorphisms. In degrees zero and one this means sections and torsors; for abelian coefficients it means every derived degree. The use of local coefficients is essential: untwisted integral homology alone cannot recognise the fundamental group or its action on higher information. The homological form of the categorical Whitehead criterion is stated explicitly in Thomason (1980, Proposition 2.4); the cohomological formulation used here is the criterion to which Grothendieck gives the name Artin–Mazur.

1°) Si F est un faisceau d'ensembles localement constant sur X, il faut prouver que $H^0(X, F) \xrightarrow{\sim} H^0(X', q^*F)$.
Mais [page 128]

$$H^0(X, F) \simeq H^0(Y, \underbrace{f_*(F)}_{\substack{\text{localement constant} \\ \text{par hypothèse c)}}}) \quad \underbrace{\xrightarrow{\qquad\sim\qquad}}_{\substack{\text{car } p \\ \text{Hot-équivalence}}} \quad H^0(Y', p^*f_*(F)),$$

mais

$$p^*f_*(F) \xrightarrow{\sim} f'_*(q^*(F)),$$

car $f_*(F)$ et $f'_*(q^*F)$ se calculent 'fibre par fibre' par hypothèse. Donc

$$H^0(X, F) \simeq H^0(Y', f'_*(q^*(F))) \simeq H^0(X', q^*(F)),$$

q.e.d.

2°) Si F est un faiscau en groupes localement constant sur X, il faut prouver

$$H^1(X,F) \xrightarrow{\sim} H^1(X',q^*F).$$

Le fait que c'est injectif résulte déjà de 1°), qui implique que le foncteur

$$\begin{array}{ccc} F\text{-torseurs sur } X & \longrightarrow & q^*(F)\text{-torseurs sur } X' \\ P & \longmapsto & f^*P \end{array}$$

est pleinement fidèle, par l'argument bien connu utilisant les faisceaux $\mathcal{H}om$. Il faut voir que ce foncteur est essentiellement surjectif.
On a un homomorphisme de suites exactes d'ensembles ponctués [page 129]

$$\begin{array}{ccccccccc} H^1(Y,f_*F) & \xrightarrow{u} & H^1(X,F) & \xrightarrow{v} & \overbrace{H^0(Y,R^1f_*(F))}^{\ni\eta} & \xrightarrow{w} & H^2(Y,f_*F) \\ \downarrow{\scriptstyle\alpha} & & \downarrow{\scriptstyle\beta} & & \downarrow{\scriptstyle\gamma} & & \downarrow{\scriptstyle\delta} \\ H^1(Y',f'_*F) & \xrightarrow{u'} & \underbrace{H^1(X',F')}_{\ni\xi'} & \xrightarrow{v'} & \underbrace{H^0(Y',R^1f'_*(F'))}_{\ni\eta'} & \xrightarrow{w'} & H^2(Y',f'_*F') \end{array}$$

([3]), où les faisceaux f_*F, $R^1f_*(F)$ sont localement constants par hypothèse et se calculent fibre par fibre, les faisceaux $f'_*(F')$ et $R^1f'_*(F')$ aussi, qui implique que ces derniers sont canoniquement isomorphes (par les flèches de changement de base) aux images inverses de leurs homologues $f_*(F)$, $R^1f_*(F)$. Comme p est une Hot-équivalence, cela implique que les flèches α, γ sont `[des]` isomorphismes. Donc si $\xi' \in H^1(X',F')$, son image η' dans $H^0(Y',R^1f'_*(F'))$ provient d'un $\eta \in H^0(Y,R^1f_*(F))$ bien déterminé. Il faut voir que cet η provient d'un $\xi \in H^1(X,F)$. Ceci (si je me rappelle bien) est possible si et seulement si une certaine obstruction $w(\eta)$ dans $H^2(Y,f_*(F))$ est dans le sous-ensemble neutre du H^2. **NB** Le champ sur $Y^\wedge$ des F-torseurs sur les $X^\wedge/U$ qui remontent η est une $\mathcal{F} = f_*F$-gerbe $\mathcal{G}_\eta$, et il faut voir qu'elle est neutre. Mais il y a mieux à faire : p. 3

Commentary · Exposition [ms. 129]

Torsor descent and the band of the obstruction

The difficult part of the coefficient argument is essential surjectivity for torsors. Full faithfulness is already secure: if P, Q are F-torsors, the sheaf $\mathcal{I} = \underline{\mathrm{Isom}}_F(P,Q)$ is locally constant, and

$$\mathrm{Hom}_F(P,Q) = H^0(X,\mathcal{I}).$$

An equivariant map between two torsors is invertible, and the degree-zero calculation identifies these Hom sets after pullback.

The displayed obstruction sequence should, however, be read as a provisional sketch. For a general nonabelian F, the gerbe of lifts of a section η of R^1f_*F need not have the fixed band of f_*F. Its band is obtained from automorphisms of local representatives of η, hence involves inner forms of F. For a direct check, take $f : BC_2 \to e$, constant $F = S_3$, and the torsor represented by the inclusion of a transposition subgroup $C_2 \hookrightarrow S_3$. Its automorphism group is $C_{S_3}(C_2) = C_2$, whereas $f_*F = S_3$. The component of this torsor therefore cannot have the fixed band S_3. Nor does nonabelian H^2 behave as a group with a distinguished zero: neutrality is a condition on a gerbe. The notation G in the next paragraph is not defined. These are reasons to replace that portion of the argument, not reasons to reject the theorem. The classical framework is the theory of bands and gerbes in Giraud (1971, Chapter IV); we give a direct repair that avoids choosing an obstruction class.

For each y, let $\mathcal{T}(y)$ be the groupoid of torsors under the restriction of F to X/y. Restriction along $X/y \longrightarrow X/z$ makes $\mathcal{T}$ a groupoid-valued contravariant diagram on Y. We claim that every

3. où on a posé $F' = q^*(F)$.

transition functor is an equivalence. Essential surjectivity follows from the local constancy of $R^1 f_* F$: its value at y is precisely the set of isomorphism classes of $\mathcal{T}(y)$. To prove full faithfulness for a transition $u : y \longrightarrow z$, take $P, Q \in \mathcal{T}(z)$. Their isomorphism sheaf is a locally constant set-valued coefficient on X/z. Apply the universally quantified degree-zero hypothesis to the base change

$$f_z : X/z \longrightarrow Y/z.$$

The values at $(z, 1_z)$ and (y, u) are respectively $\mathrm{Hom}(P, Q)$ and $\mathrm{Hom}(u^* P, u^* Q)$. Local constancy makes the restriction map bijective. This is the place where coefficients on a base-changed total category, rather than only coefficients originally chosen on X, are needed.

The same hypotheses identify $\mathcal{T}(y)$ with the groupoid of $F|_{X_y}$-torsors. On isomorphism classes this is the fibre formula for $R^1 (f_y)_* F$, applied over Y/y. On Hom sets it is the fibre formula for $(f_y)_* \mathcal{I}$, for the isomorphism sheaf just used. Thus the identification is an equivalence of groupoids, not merely a bijection on H^1.

Now let $p : Y' \longrightarrow Y$ be a weak equivalence, and form the cartesian square of the source. The natural comparison from $p^* \mathcal{T}$ to the torsor diagram $\mathcal{T}'$ on Y' is an objectwise equivalence: both values at y' restrict equivalently to the torsors on the same strict fibre $X_{p(y')}$. Finally,

$$\mathrm{Tors}_F(X) \simeq \operatorname*{holim}_{y \in Y^{\mathrm{op}}} \mathcal{T}(y).$$

This is ordinary descent for torsors, expressed on the representable objects Y/y. Explicitly, a compatible family of torsors on these slices determines its torsor over $x \in X$ by evaluation at $(x, 1_{f(x)})$; the comparison maps along $f(a)$, for $a : x \longrightarrow x'$, give its restriction maps. The descent cocycle is exactly their composition law. Pulling a torsor on X to all slices gives the inverse construction.

Homotopy limits of locally constant groupoid diagrams are invariant under a weak equivalence of indexing categories. One can express this as invariance of sections under equivalence of fundamental 2-groupoids, or obtain it by applying the homotopy-invariance theorem for locally constant model-category diagrams to groupoids and their derived right adjoint of constant diagrams; see Cisinski (2009, Theorem 1.3). Consequently

$$\mathrm{Tors}_F(X) \longrightarrow \mathrm{Tors}_{q^* F}(X')$$

is an equivalence. This proves the missing essential surjectivity and the required bijection on H^1. It also supplies the local-constancy argument for the lifting gerbe that the source compresses into a parenthesis.

On note que cette gerbe $\mathcal{G}$ est localement constante (puisqu'elle correspond à un lien $f_*(G)$ localement constant) et que $\mathcal{G}'$ est son image inverse. Mais comme p est une Hot-équivalence, il s'ensuit que le foncteur [page 130]

$$\underline{\Gamma}(Y, \mathcal{G}) \longrightarrow \underline{\Gamma}(Y', \mathcal{G}')$$

est une équivalence de catégories, donc ξ' provient (à isomorphisme près) d'un unique ξ de $\underline{\Gamma}(Y, \mathcal{G})$, q.e.d.

3°) Soit F faisceau abélien localement constant sur X, il faut voir [que]

$$(*) \qquad H^i(X, F) \xrightarrow{\sim} H^i(X', F') \qquad (F' = q^* F),$$

pour tout $i \in \mathbf{N}$. Mais les deux termes sont l'aboutissement des suites spectrales de Leray, de termes initiaux

$$E_2^{pq} \simeq H^p(Y, R^q f_*(F))$$
$$E_2'^{pq} \simeq H^p(Y', R^q f'_*(F')),$$

et $(*)$ est associé à un homomorphisme de suites spectrales, qui pour les termes initiaux est

$$(**) \qquad H^p(Y, R^q f_*(F)) \xrightarrow{\sim} H^p(Y', R^q f'_*(F')),$$

associé à

$$(***) \qquad p^*(R^q f_*(F)) \longrightarrow R^q f'_*(F').$$

Mais par hypothèse les $R^q f_*(F)$, $R^q f'_*(F')$ sont localement constants et se calculent fibre par fibre,
d'où il résulte que les homomorphismes de changement de base $(***)$ sont [des] isomorphismes, [page 131]
et comme il s'agit de faisceaux localement constants et que p est une Hot-équivalence, il s'ensuit que $(**)$ est [un] isomorphisme, donc aussi $(*)$ sur les aboutissements, q.e.d.

Commentary · Exposition [ms. 131]

The Leray comparison has finite diagonals

Grothendieck can now return to abelian coefficients, where the formal argument is both shorter and complete. For each q, the canonical comparison

$$p^* R^q f_* F \longrightarrow R^q f'_* q^* F$$

is an isomorphism because its values are the cohomology groups of identical strict fibres. Both sides are locally constant. Since p is a weak equivalence, it therefore induces an isomorphism on every $E_2^{p,q}$ term of the Leray spectral sequences.

There is no convergence obstruction here. These are first-quadrant cohomological spectral sequences, and in total degree n only the $n+1$ pairs $p+q=n$ occur. Comparison gives isomorphic associated graded groups of finite filtrations of $H^n(X,F)$ and $H^n(X', q^*F)$; induction through those filtrations gives the asserted isomorphism. No boundedness of the cohomological dimension of X or Y is required. The missing prime on F in the printed E_2-comparison is an edition slip, retained in the transcription and recorded separately. Together with the torsor argument, this completes the coefficient criterion.

Définition 1. Sous les conditions équivalentes du théorème 1, on dit que f est une Hot-*fibration.*

Proposition 1. *Cette notion est stable par changement de base (trivial), par composition (formel sur a)). Pour que f soit une* Hot*-fibration, il faut et il suffit que f* [plutôt f^o] *le soit.* p. 4

Commentary · Later developments [ms. 131]

From strict fibres to homotopy fibres

The stability assertions now have a geometric interpretation. For composable maps $X \longrightarrow Y \longrightarrow Z$, pulling a weak equivalence back along the composite is the succession of the two pullbacks. Opposite categories preserve strict pullbacks, and reversing a nerve simplex identifies the classifying spaces of C and C^{op}. Thus both composition and self-duality follow directly from a), without another coefficient argument.

The strict fibre also calculates the homotopy fibre. By b'), the categories X/y vary by weak equivalences along all arrows of Y, and $X_y \longrightarrow X/y$ is a weak equivalence. The dual form of Quillen's Theorem B therefore identifies

$$BX_y \simeq \mathrm{hofib}_y(BX \longrightarrow BY).$$

The exact citation is Quillen (1973, §1, Theorem B and its corollary); its hypotheses concern the comma-category transition functors. Merely knowing the homotopy types of the strict fibres, without the comparison to comma categories, would not suffice.

This perspective explains the force of the theorem while leaving room for Grothendieck's chosen constructions. Cisinski (2009, Proposition 4.4) later proves that weak equivalences of nerves together with the maps that are both smooth and proper form a category of fibrant objects, with functorial factorization. These smooth-and-proper maps are a particularly useful subclass of the present Hot-fibrations. The statement does not say that all Hot-fibrations are smooth and proper. Their advantages are the explicit categories of lifts and the simultaneous control of left and right homotopy Kan extensions.

Proposition 2. *Soit $f : X \longrightarrow S$ une* Hot*-fibration. Alors $s \longmapsto \mathrm{hot}(X_s)$ est un système local sur S, à valeurs dans* Hot*. Donc les X_s pour s dans une même composante connexe*

de S sont Hot*-isomorphes entre eux (mais pas canoniquement, si cette composante n'est pas* 1*-connexe).*

Commentary · Examples [ms. 131]

A group extension and its monodromy

The local system of fibre homotopy types already contains nontrivial information in a finite group example. Regard a group as its one-object category. If

$$1 \longrightarrow K \longrightarrow G \xrightarrow{\varphi} Q \longrightarrow 1$$

is exact, the functor from the one-object groupoid of G to that of Q is an isofibration. Its nerve is a Kan fibration. Pullbacks of weak equivalences along Kan fibrations are weak equivalences, and the nerve preserves pullbacks, so this functor is a Hot-fibration. Its strict fibre is the one-object groupoid K.

The comma category over the unique object of Q has objects $q \in Q$. A morphism from q to q' is an element $g \in G$ satisfying $q = q'\varphi(g)$, with a harmless reversal if the other convention for composition is chosen. Surjectivity of φ makes this a connected groupoid; the automorphism group of any object is K. Thus the inclusion of the strict fibre is an equivalence of categories. If φ is not surjective, its connected components are the corresponding cosets of $\varphi(G)$, and that inclusion is not a weak equivalence. This computes precisely why an arbitrary homomorphism of groups need not be a Hot-fibration.

For the nontrivial monodromy, take $G = \mathfrak{S}_3$, $K = \mathfrak{A}_3 = C_3$, and $Q = C_2$, with φ the sign. A lift of the nonidentity element of C_2 is a transposition. Conjugation by it sends a three-cycle to its inverse. A different lift changes this automorphism by an inner automorphism of K; inner automorphisms induce naturally isomorphic functors on the one-object groupoid and hence the same map in Hot. The action on the fibre is consequently well defined there. It is nontrivial, since inversion acts nontrivially on $\pi_1(BC_3) = C_3$.

With constant coefficient $\mathbb{F}_3$ on $B\mathfrak{S}_3$, the degree-one fibre cohomology is

$$H^1(C_3; \mathbb{F}_3) = \mathrm{Hom}(C_3, (\mathbb{F}_3, +)) \cong \mathbb{F}_3,$$

and the base generator acts by -1. Its invariant subgroup is zero. The low-degree Leray sequence gives $H^1(\mathfrak{S}_3; \mathbb{F}_3) = 0$: the other term $H^1(C_2; \mathbb{F}_3)$ is zero, and positive-degree cohomology of C_2 with these coefficients vanishes by the averaging operator $\frac{1}{2}(1+\tau)$. Independently, the same answer follows from $\mathfrak{S}_3^{\mathrm{ab}} = C_2$. The fibre cohomology is locally constant on the base, but it is not a constant coefficient with trivial monodromy. This is the distinction that the printed qualifier about noncanonical identifications is meant to preserve; a nonsimply connected base can also carry trivial monodromy, as a product shows.

Théorème 2. *Soit* $\begin{array}{ccc} X' & \xrightarrow{f} & X \\ & {\scriptstyle p'}\searrow \quad \swarrow{\scriptstyle p} & \\ & S & \end{array}$ *un diagramme commutatif dans* Cat*, avec p, p' des* Hot*-fibrations, et soit $S_0 \subseteq S$ une partie de S telle que $S_0 \longrightarrow \pi_0(S)$ soit surjectif. Pour que f soit une* Hot*-équivalence, il faut et il suffit que les $f_s : X_s \longrightarrow Y_s$ $(s \in S_0)$ le soient.*

a) La suffisance se prouve comme tantôt, avec le critère de Artin-Mazur.

Notons que l'hypothèse sur S_0 assure que si F, F' sont deux faisceaux d'ensembles localement constants sur S, et $u : F \longrightarrow F'$ un homomorphisme tel que $u_s : F_s \xrightarrow{\sim} F'_s$ pour $s \in S$, alors u est [un] isomorphisme. [page 132]

1°) Soit F un faisceau d'ensembles localement constant sur X, F' son image inverse sur X', il faut prouver

$$H^0(X, F) \xrightarrow{\sim} H^0(X', F').$$

Or

$$H^0(X, F) \simeq H^0(Y, \underbrace{f_*(F)}_{\substack{\text{localement} \\ \text{constant sur } S}}) \longrightarrow H^0(Y, f'_*(F')) \simeq H^0(X', F'),$$

il faut prouver que

$$(*) \qquad p_*(F) \xrightarrow{\sim} p'_*(F')$$

est [un] isomorphisme. Or par hypothèse sur p, p', les deux faisceaux sont localement constants et se calculent fibre par fibre, d'où résulte que $(*)$ est un isomorphisme pour les fibres en $s \in S_0$, donc un isomorphisme partout. OK.

2°) Il en résulte déjà, si F est un faisceau en *groupes,* que le foncteur

$$(F\text{-torseurs sur } X) \longrightarrow (F\text{-torseurs sur } X')$$

est pleinement fidèle, donc $H^1(X,F) \longrightarrow H^1(X',F')$ [est] injectif; il reste à prouver que ce foncteur est essentiellement surjectif. À cause de la pleine fidélité, c'est *local sur* S (**NB** On voit directement que l'hypothèse fait sur les $s \in S_0$ implique la même hypothèse pour tout $s \in S$, en utilisant le fait que p, p' sont des fibrations) ([4]). Donc on est ramené au cas où $S = S/s_0$ a un objet final s_0.

Commentary · Exposition [ms. 132]

Testing one fibre in each component

Theorem 2 is the fibrewise Whitehead theorem for these categorical fibrations. Its fibre map is $f_s : X'_s \longrightarrow X_s$; the displayed $X_s \longrightarrow Y_s$ is an edition slip. Transport is natural with respect to f, so if f_s is a weak equivalence at one point of a component then it is a weak equivalence at every point of that component. The choice of S_0 therefore loses no information.

For sufficiency, the source compares direct images of local coefficients. Its degree-zero comparison should be written

$$H^0(X,F) = H^0(S,p_*F) \longrightarrow H^0(S,p'_*F') = H^0(X',F').$$

Both direct images are locally constant, and their values on S_0 are isomorphic by the fibre hypothesis. A morphism between locally constant diagrams is an isomorphism everywhere if it is so at one object of each component: propagate the property along an unoriented chain of arrows, whose transition maps are invertible. This proves degree zero and, by the isomorphism-sheaf argument, full faithfulness on torsors.

The local reduction for essential surjectivity is legitimate once it is applied to these groupoids of torsors, rather than only their sets of isomorphism classes. On each representable S/s, both total categories still satisfy the hypotheses. The torsor diagrams constructed above are locally constant there, and S/s has a final object. Their groupoids of global sections are thus equivalent to their values at that object. Fibrewise equivalence supplies local preimages of any torsor on X'. Full faithfulness uniquely lifts the overlap isomorphisms between these preimages; their cocycle follows from its validity after pullback and faithfulness. Effective descent for torsors gives the global preimage. This justifies both the phrase "local on S" and the degree-one edge identifications on manuscript page 133. The abelian comparison follows from Leray as before.

For necessity there is a shorter modern proof, complementary to the printed path-category argument. The preceding block identifies both strict fibres with homotopy fibres. An equivalence $BX' \longrightarrow BX$ over BS induces equivalences on all homotopy pullbacks along $\{s\} \longrightarrow BS$, so every Bf_s is a weak equivalence. Conversely, maps of spaces over a fixed base are detected on their homotopy fibres: on each base component the long exact homotopy sequences give the higher homotopy isomorphisms, and the action of $\pi_1(BS,s)$ on the components of the fibre identifies the components of the total space with its orbit set. A fibrewise equivalence preserves that action and those orbit sets. This also treats disconnected or empty fibres, which a statement only about based groups would overlook.

On a alors

$$H^1(X,F) \simeq H^0(S,R^1p_*(F))$$
$$H^1(X',F') \simeq H^0(S,R^1p'_*(F')),$$

p. 5 [page 133]

4. Les hypothèses faites sont bel et bien locales sur S (du moins si $S_0 = S$).

et on voit encore que

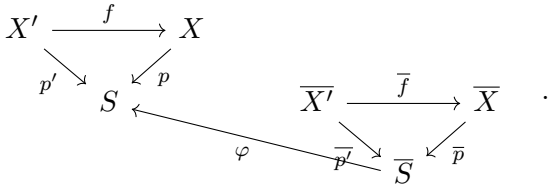
$$R^1p_*(F) \longrightarrow R^1p'_*(F')$$

est [un] isomorphisme (car il se calcule fibre par fibre, et on utilise l'hypothèse sur les f_s), donc induit un isomorphisme

$$H^1(X,F) \longrightarrow H^1(X',F').$$

3°) Si F est même abélien, on doit prouver

$$H^i(X,F) \xrightarrow{\sim} H^i(X',F')$$



pour tout i, et cela résulte encore de la suite spectrale de Leray pour (p,F) et pour (p',F').

b) Inversement, supposons que f soit une Hot-équivalence, et prouvons que les $f_s : X'_s \longrightarrow X_s$ sont des Hot-équivalences. Je vais utiliser le

Lemme. *Soit $S \in \mathrm{Ob}\,\mathrm{Cat}$, S 0-connexe. Alors il existe un $\overline{S} \in \mathrm{Ob}\,\mathrm{Cat}$, $\overline{S}$ Hot-asphérique, et $\overline{S} \longrightarrow S$ une Hot-fibration.*

Voyons comment ceci implique le théorème 2 (partie réciproque). On peut supposer S 0-connexe, et on fait le changement de base par $\overline{S} \longrightarrow S$

comme dans le lemme : [page 134]

Alors $\overline{p'}$ et $\overline{p}$ sont des Hot-fibrations, et comme φ est une Hot-fibration, le changement de base par φ transforme la Hot-équivalence f en une Hot-équivalence $\overline{f}$. Considérons alors $\overline{s} \in \mathrm{Ob}\,\overline{S}$, et le diagramme

$$\begin{array}{ccc} \overline{X'} & \xrightarrow{\overline{f}} & \overline{X} \\ {\scriptstyle i'}\uparrow & & \uparrow{\scriptstyle i} \\ \overline{X'}_{\overline{s}} & \xrightarrow{\overline{f}_{\overline{s}}} & \overline{X}_{\overline{s}} \end{array} \quad .$$

Comme $\{\overline{s}\} \longrightarrow \overline{S}$ est une Hot-équivalence, la flèche i qui s'en déduit par le changement de base $\overline{p} : \overline{X} \longrightarrow \overline{S}$ l'est aussi, puisque $\overline{p}$ est une Hot-fibration, et de même pour i'. Ainsi dans le carré commutatif précédent, $\overline{f}$, i et i' sont des Hot-équivalences, donc aussi $\overline{f}_{\overline{s}}$. Mais si $s = \varphi(\overline{s})$, $\overline{f}_{\overline{s}}$ s'identifie à $f_s : X'_s \longrightarrow X_s$. D'ailleurs, il est immédiat que φ, étant une Hot-fibration p. 6

à source non-vide, et à but connexe, est surjective. (**NB** toutes les fibres d'une même composante connexe de S sont Hot-équivalentes, donc si l'une est non-vide, toutes le sont.) Cela achève la démonstration, modulo le lemme. [page 135]

Commentary · Exposition [ms. 135]

A contractible replacement without a derivator

The lemma is not asserting the existence of a contractible covering space: a general connected homotopy type has no such covering. It asks for a fibration whose fibre retains the entire loop homotopy type. The source's based path category is designed to do exactly this. The dependency it leaves open at the end of the chapter concerns the proof that this specific categorical path construction is both proper and smooth.

For the existential lemma alone, Thomason's theory already gives an independent proof. Choose $s_0 \in S$ and factor its inclusion in the Thomason model category as

$$e \xrightarrow{i} E \xrightarrow{p} S, \qquad i \text{ a trivial cofibration}, \quad p \text{ a model fibration}.$$

Then BE is weakly contractible. Since $\mathrm{Ex}^2 N$ preserves pullbacks and sends p and all its base changes to Kan fibrations, right properness of simplicial sets proves that p is a Hot-fibration in the sense of a). The existence of the factorization is Thomason (1980, Theorem 4.9); its weak equivalences and fibrations are Definitions 2.1–2.2, and properness is Corollary 5.5.

The map p is surjective on objects when S is nonempty and connected. The object $i(*)$ supplies one nonempty fibre. Pull back over an arrow of S; both endpoint fibres have the homotopy type of that pullback, so one is nonempty if and only if the other is. A zigzag in S reaches every object of its connected component. This is the elementary justification of the surjectivity used on manuscript page 135. It gives the printed proof of the converse in Theorem 2 without invoking any derivator: pull back along $E \longrightarrow S$, use that the inclusions of its fibres are weak equivalences, and apply two-out-of-three.

This replacement does not diminish the purpose of Chapter XII. The abstract model factorization proves existence, whereas Grothendieck needs constructions with explicit categories of lifts, duality, and control of both direct images. The later smooth-and-proper factorization quoted above addresses that stronger requirement.

Il reste à prouver celui-ci. Comme $S = \emptyset$ [plutôt $S \neq \emptyset$], je peux choisir une 'origine'

$$s_0 \in S,$$

et regarder la catégorie

$$\underline{\mathrm{Ch}}_\infty(S; s_0, -)$$

des chemins infinis dans S, d'origine s_0, fibre de $\underline{\mathrm{Ch}}_\infty(S)$ par le foncteur-source

$$\sigma : \underline{\mathrm{Ch}}_\infty(S) \longrightarrow S.$$

On sait que les fibres de σ sont Hot-asphériques (VII), et la catégorie construite ici n'est autre que (avec les notations de VII, p. 152) que la catégorie $\overline{S'}$ qui entre dans la factorisation canonique de

$$f : \{s_0\} = S' \longrightarrow S$$

en

$$\{s_0\} = S' \underbrace{\longrightarrow}_{\text{Hot-équivalence}} \overline{S'} \xrightarrow{\overline{f}} S,$$

où ici $\overline{f}$ s'interprète simplement comme le foncteur but (i.e. le foncteur induit sur $\underline{\mathrm{Ch}}_\infty(S; s_0, -)$ par le foncteur but [page 136]

$$\beta : \underline{\mathrm{Ch}}_\infty(S) \longrightarrow S \ ).$$

On a prouvé dans loc. cit. que $\overline{f}$ est une Hot-fibration ('propre' et 'lisse'), mais dans un contexte qui semblait faire appel tacitement à la théorie du dérivateur HOT. Donc pour mettre les résultats 'topologiques' de loc. cit. sur une base solide, il faut développer les notions pertinentes de foncteur propre, foncteur lisse, sans référence à une théorie HOT. C'est ce que j'avais d'ailleurs fait déjà en 1983, du temps de Pursuing Stacks, mais sans rédaction en forme à ce sujet. Il me faut donc à présent revenir sur ces notions, de façon un peu systématique. D'ailleurs, j'aurais dû mal à construire un seul foncteur Hot-fibrant (sauf les exemples triviaux, tels les isomorphismes, ou les produits $Y \times Z \xrightarrow{\mathrm{pr}_1} Y$), si je ne disposais d'une théorie des foncteurs lisses et des foncteurs propres ([5]).

5. J'exagère un peu quand même – après tout il doit être assez évident que les foncteurs de Thomason-Kan sont des Hot-fibrations (mais il y en a encore un peu trop peu !).

Commentary · Context [ms. 136]

Why the next chapter starts again

Grothendieck's return to proper and smooth functors is an effort to remove a dependency, not a rejection of the homotopy theory just obtained. A path construction had been used to produce fibrations while some of its asserted properties still appealed to the derivator that those fibrations were meant to construct. Categories of lifts offer a direct combinatorial foundation for those properties.

The historical background is visible in *Pursuing Stacks*, §69: the coefficient theory is to remember categories of coherent diagrams together with both adjoints of restriction, rather than merely a single homotopy category (Grothendieck, 1983). The letter to Thomason of 2 April 1991 makes a related distinction explicit: the weak equivalences carry the intrinsic homotopy theory, while classes of fibrations and cofibrations make its operations calculable (Grothendieck, 1991a, §1). We refer to the commentary on Chapter I, manuscript p. 126 ("The later letter and the meaning of a fibration"), for the broader historical discussion.

The next pages isolate two different issues. One is to describe the maps along which categorical pullback behaves well. The other is to decide how much of the usual homotopy theory is forced by the proposed axioms on W. The revisions of terminology in Chapter XII are necessary because an axiom suitable for the full homotopy type can be too strong for a localization that deliberately forgets higher homotopy groups.

I Caractérisation de W_∞.

Je voudrais caractériser W_∞ en tant que partie de Fl(Cat), par ses propriétés comme localiseur, et sans faire appel à la connaissance de notions utilisant déjà W_∞, comme la propreté etc. Je voudrais tout au moins des propriétés sur un localiseur W, familières pour W_∞, qui soient si fortes qu'elles impliquent $W \subseteq W_\infty$. Bien sûr, dans les démonstrations je me permets d'utiliser tout ce que je sais sur W_∞.

Bien sûr, il faudra au moins une forme de saturation, peut-être très faible, je présume le suivant suffira ([6]).

W(1) (Axiome de saturation.) a) Les identités sont dans W, b) si f, g `[sont]` composables et deux parmi f, g, gf sont dans W, le troisième aussi, c) si $fg \in W$, $gf \in W$, alors $f, g \in W$.

Une propriété particulièrement cruciale, qui déjà distingue W_∞ de l'ensemble des homotopismes (notion trop stricte à beaucoup d'égards), est l'axiome que j'ai appelé L4 bis :

Commentary · Examples [ms. 1]

A contractible nerve without a categorical contraction

Grothendieck's insistence that homotopisms are too restrictive has a concrete explanation. Let P be the ordered set with objects $0, 1, 2, \ldots$ and nonidentity relations

$$0 < 1 > 2 < 3 > 4 < 5 > \cdots .$$

There are no composable pairs of nonidentity arrows. Its nerve therefore realizes to the half-line subdivided at the integers; in particular $P \to e$ belongs to W_∞.

Nevertheless $P \to e$ is not a homotopism in the sense used on the next manuscript page. Suppose that the identity of P could be joined to the constant functor at c by a zigzag of m natural transformations. Evaluating the zigzag at an integer n would give a path of at most m edges from n to c in the underlying undirected graph of P. Every arrow changes the integer by at most one. Thus $|n - c| \leq m$ for every n, which is impossible. A homotopy inverse to $P \to e$ would select precisely such a constant functor, so no homotopy inverse exists.

This example separates two finite conditions that are easily conflated. Each individual vertex can be connected to 0 by a finite path. A natural-transformation contraction would require one finite zigzag working simultaneously at every vertex. The localization axioms allow the classifying space to forget that uniform bound.

W(2) (Axiome de localisation.) Soit $f : X \longrightarrow Y$ une flèche dans Cat/S, telle que $\forall\ s \in \mathrm{Ob}\, S$, $f_s : X/s \longrightarrow Y/s$ soit dans W (on dira que f est dans W 'localement sur S'). Alors $f \in W$.

Commentary · Exposition [ms. 1]

The two directions of the characterization

Grothendieck wants the equivalences of ordinary homotopy theory to emerge from operations on categories. There are two logically different assertions to establish. The first says that the proposed axioms cannot identify too many maps: $W \subseteq W_\infty$. The second says that a sufficiently coherent theory cannot identify too few: $W_\infty \subseteq W$. This section attacks the first assertion by repeatedly taking fibres. The later minimal-localizer theorem supplies the second. Keeping these directions separate makes the successive changes of axioms intelligible.

Write $BA = |NA|$ for the classifying space of a small category, and let e be the terminal category. Here W_∞ consists of the functors u for which Bu is a weak homotopy equivalence. The expression W-aspherical means only $A \to e \in W$. It does not mean that A has vanishing higher homotopy

6. (non, j'ai dû le renforcer en 2 [?]).

groups until a comparison with W_∞ has been established. In particular, it is not the usual topological convention under which a connected $K(G,1)$ is called aspherical.

The local-to-global axiom W(2) tests a map $u : X \to Y$ over S on the comma categories $X/s \to Y/s$. These are not the strict fibres $X_s \to Y_s$. An object of X/s is a pair $(x, p(x) \to s)$, so the test retains all ways of approaching s. W(2 bis) is the absolute theorem-A form: contractibility, in the sense of W, of every X/y implies $u \in W$. The distinction matters: the source explicitly uses the relative form for Proposition 3, whereas the loop argument and the final nondegeneracy repair need only the absolute form.

The commentary on Chapter VI, manuscript pp. 44–45, explained why a fibre axiom begins to select ordinary homotopy theory. The present pages give the mechanism: any nonzero homotopy group of a W-aspherical category can be lowered, by looping, to a forbidden nontrivial set of components.

`[Les axiomes W(1) etc. sont appelés aussi ① etc. dans l'original.]`

Dans le cas $Y = S$, cela donne

Corollaire : *Si $f : X \longrightarrow Y$ est W-asphérique, i.e. $y\backslash X \longrightarrow y\backslash Y$* `[plutôt` $X/y \longrightarrow Y/y$`]` *dans W pour tout $y \in \mathrm{Ob}\, Y$, alors $f \in W$* ([7]).

Proposition 1. *Si W satisfait* W(1) *et* W(2)*, les propriétés suivantes sur W sont équivalentes :*

a) Pour tout X dans Cat*, $X \times \mathbf{\Delta}^1 \xrightarrow{\mathrm{pr}_1^X} X$ est dans W (i.e. $\mathbf{\Delta}^1 \longrightarrow e$ est 'universellement dans W ').*

b) Si X dans Cat *a un objet final, alors X est W-asphérique, i.e. $X \longrightarrow e$ est dans W.*

c) Tout homotopisme est dans W.

7. On peut considérer la validité du corollaire comme une variante affaiblie W(2 bis) de W(2) ci-dessus. Dans la proposition 1, on n'utilise que W(2 bis), forme faible de W(2).

Démonstration. b) $\Longrightarrow$ a) ([8]), car pour voir que $\mathrm{pr}_1 \in W$, en appliquant le corollaire ci-dessus, il faut prouver que $\forall\, x \in X$ p. 2

$$(*) \qquad (X \times \mathbf{\Delta}^1)/x \longrightarrow X/x$$

est dans W. Or

$$(X \times \mathbf{\Delta}^1)/x \simeq X/x \times \mathbf{\Delta}^1,$$

$$\begin{array}{ccccc} \mathbf{\Delta}^1 & \longleftarrow & X \times \mathbf{\Delta}^1 & \longleftarrow & X/x \times \mathbf{\Delta}^1 \\ \downarrow & & \downarrow & & \downarrow \\ e & \longleftarrow & X & \longleftarrow & X/x \end{array}$$

[la flèche verticale à droite est ajoutée] et les deux catégories X/x, $X/x \times \mathbf{\Delta}^1$ sont W-asphériques car elles ont un objet final, donc $(*)$ est dans W par saturation faible W(1).

a) $\Longrightarrow$ c). Je rappelle que

$$f : X \longrightarrow Y$$

est un homotopisme s'il existe [page 2]

$$g : Y \longrightarrow X$$

telle que

$$(*) \qquad gf \sim \mathrm{id}_X, \quad fg \sim \mathrm{id}_Y,$$

où la relation $(\sim)$ désigne l'homotopie dans $\underline{\mathrm{Hom}}(X, X)$ et $\underline{\mathrm{Hom}}(Y, Y)$ respectivement (définie par chemins allant d'un élément à l'autre). Prouvons le

Lemme. *Supposons que W satisfait* W(1) *et le* a) *de la proposition, i.e. $X \times \mathbf{\Delta}^1 \longrightarrow X$ dans W pour tout X dans* Cat. *Alors si X, Y* [sont] *dans* Cat *et f, g dans $\underline{\mathrm{Hom}}(X, Y)$ sont homotopes, on a*

$$\mathrm{hot}_W(f) = \mathrm{hot}_W(g).$$

De plus, $f \in W$ si et seulement si $g \in W$.

Commentary · Exposition [ms. 2]

Saturation at the point where it is used

The proof is carefully arranged so that equality after localization is not mistaken for membership in W. For a natural transformation $f \Rightarrow g$, let $F : X \times [1] \to Y$ be its corresponding functor and let $p : X \times [1] \to X$ be the projection. If $p \in W$, its sections i_0, i_1 lie in W by two-out-of-three. Since $pi_0 = pi_1 = \mathrm{id}_X$, their images in $\mathrm{Cat}[W^{-1}]$ are both p^{-1}. Thus $f = Fi_0$ and $g = Fi_1$ become equal there. Independently, two-out-of-three gives

$$f \in W \quad \Longleftrightarrow \quad F \in W \quad \Longleftrightarrow \quad g \in W.$$

Iteration handles a finite zigzag of transformations.

Now suppose f has a categorical homotopy inverse g. The preceding argument puts both gf and fg in W. The separate clause W(1c) then puts f and g in W. This last step would not follow merely from the existence of their inverse images in the localization unless strong saturation had already been proved.

Three usages of saturation should therefore remain distinct. Two-out-of-three is W(1b); the two-cycle condition is W(1c); strong saturation says that every map inverted by the localization already belongs to W. The modern weak-saturation axiom used for fundamental localizers asks, in addition to identities and two-out-of-three, only that $ri = \mathrm{id}$ and $ir \in W$ imply $r \in W$ (Cisinski, 2004, Definition 1.1.1). W(1c) implies this condition. Consequently the later results apply to the source's axioms without silently inserting strong saturation into this elementary proof.

8. n'utilise W(1) que sous forme faible, sans la condition de saturation c). NB Seul b) $\Longrightarrow$ c) utilise W(2 bis), les implications a) $\Longrightarrow$ c) $\Longrightarrow$ b) sont valables sous la seule hypothèse W(1).

Il suffit de le prouver quand il existe un homomorphisme $f \longrightarrow g$. Cela peut s'interpréter par l'existence d'une flèche

$$X \times \mathbf{\Delta}^1 \xrightarrow{F} Y$$

dont les restrictions à $X \times \{0\}$ et $X \times \{1\}$ respectivement soient f, g. Pour prouver que $\mathrm{hot}_W(f) = \mathrm{hot}_W(g)$, il suffit de prouver que

$$i_0, i_1 : X \longrightarrow X \times \mathbf{\Delta}^1 \qquad x \longmapsto (x, 0),\ x \longmapsto (x, 1)$$

sont égales dans Hot_W, puisque p. 3

$$f = F \circ i_0, \quad g = F \circ i_1.$$

Or cela résulte du fait que ce sont des sections de $X \times \mathbf{\Delta}^1$ sur X, et que dans Hot_W la projection $X \times \mathbf{\Delta}^1 \xrightarrow{p} X$ est [un] isomorphisme (donc $i_0 = i_1 = p^{-1}$ dans Hot_W). De plus, le diagramme

$$\begin{array}{ccc} X & \xrightarrow{i_0} & X \times \mathbf{\Delta}^1 \\ & \searrow^{f} & \downarrow{\scriptstyle F} \\ & & Y, \end{array}$$

où $i_0 \in W$, montre que $f \in W$ si et seulement si $F \in W$, et de même $g \in W$ si et seulement si $F \in W$, donc $f \in W \iff g \in W$.

Revenons à $(*)$, on voit que dans Hot_W $g \circ f = \mathrm{id}_X$, $f \circ g = \mathrm{id}_Y$, donc f et g sont des Hot_W-isomorphismes inverses l'un de l'autre. D'autre part, $gf \in W$, $fg \in W$, puisque $\mathrm{id}_X, \mathrm{id}_Y \in W$. Donc on gagne, si on a formulé W(1) de façon assez forte. On a prouvé donc a) $\Longrightarrow$ c).

c) $\Longrightarrow$ b) est trivial, puisque si X a un objet final, $X \longrightarrow e$ est un homotopisme.

On doit bien sûr par la suite supposer que W satisfait aux conditions équivalentes de la proposition. On prendra p. ex. la forme [page 3]

W(3) (Axiome de l'élément final.) Si X a un objet final, alors X est W-asphérique.

Commentary · Exposition [ms. 3]

Terminal objects, initial objects, and duality

The terminal-object axiom gives a usable supply of trivial categories. If t is terminal in A, the natural transformation $\mathrm{id}_A \Rightarrow \mathrm{const}_t$ makes $A \to e$ a homotopism; an initial object gives the transformation in the reverse direction. Proposition 1 therefore derives initial-object asphericity from the same axioms. No second axiom is being assumed.

For a functor $u : A \to B$, the category B/b has the terminal object (b, id_b). Hence two-out-of-three identifies the two formulations

$$A/b \longrightarrow B/b \in W \quad \Longleftrightarrow \quad A/b \longrightarrow e \in W.$$

This is why the corrected slice orientation in the source's first corollary is essential: it determines whether the subsequent notion is asphericity or coasphericity.

Proposition 2 next turns this one-sided language into a self-dual theory. The bridge is the twisted-arrow category $\Phi(A)$, with comparison functors to A and A^{op}. Their comma categories have explicit contractions, so absolute theorem A puts both comparisons in W. Naturality then compares u, $\Phi(u)$, and u^{op} by two-out-of-three. The construction and its variance were treated in the commentary on Chapter I, manuscript pp. 73–75, and are not repeated here. What is new in the present argument is its economy of hypotheses: the comparisons use W(2 bis), not the full relative W(2). Applying the same construction to u^{op} gives the reverse implication, so $u \in W$ if and only if $u^{\mathrm{op}} \in W$.

Corollaire 1. *Pour que $f : X \longrightarrow Y$ soit W-asphérique, il faut et il suffit que les X/y soient W-asphériques* ($y \in \mathrm{Ob}\, Y$).

Car pour que $X/y \longrightarrow Y/y$ soit dans W, comme Y/y est W-asphérique (objet final), il faut et il suffit que X/y le soit aussi.

Corollaire 2. *Si X dans* Cat *a un objet initial, il est W-asphérique.* (En effet, $X \longrightarrow e$ est un homotopisme, et on applique prop. 1.) ([9])

Je mettrai pour mémoire

Corollaire 3. *Tout homotopisme dans* Cat *est dans W. Si $f, g : X \rightrightarrows Y$ dans* Cat *sont homotopes, alors elles sont égales dans* Hot_W*, et f est dans W si et seulement si g l'est.*

Proposition 2. Soit $f : X \longrightarrow Y$ dans Cat. Si $f \in W$, $f^\circ \in W^\circ$ `[plutôt` $f^\circ \in W$`]`.

On utilise la démonstration de I, p. 75, à l'aide de la catégorie nommée $\Phi(X)$ ($\mathrm{Ob}\, \Phi(X) = \mathrm{Fl}(X)$, mais avec une notion de flèche dans $\Phi(X)$ un peu particulière). On trouve que $f \in W \iff \Phi(f) \in W$, et de même $f^\circ \in W \iff \Phi(f) \in W$. p. 4

NB. Dans la démonstration de la proposition 2, comme dans celle de la proposition 1 (pour l'implication b) $\Longrightarrow$ a)), on n'a utilisé la propriété de localisation W(2) que sous la forme faible du corollaire, i.e. sous la forme f W-asphérique $\Longrightarrow f \in W$.

Corollaire (de la prop. 2) : *Soit $W \subseteq \mathrm{Fl}(\mathrm{Cat})$ satisfaisant l'axiome* W(1) (saturation). *Alors la conjonction des axiomes* W(2), W(3) *équivaut à celle des axiomes duaux* W(2′), W(3′) ([5]).

Il suffit de prouver que 1,2,3 $\Longrightarrow$ 2′,3′.

Pour 2′ `[plutôt` 3′`]`, c'est le corollaire 2 ci-dessus. Pour 3′ `[plutôt` 2′`]`, cela résulte aussitôt de la proposition 2. (NB Cet énoncé resterait valable, si on aurait pris W(2) sous la forme faible seulement, cf. le NB page précédente.) [page 4]

Je dois encore mettre un axiome de la forme L5, L6 (cf. VI, p. 43-44). Mais l'énoncé de ces axiomes utilise la notion de Hot-fibrés, ou de foncteurs parfaits, i.e. fait appel à la connaissance de W_∞, ce que j'aimerais éviter (si je peux). Je dois donc introduire la notion de W-fibration, sur le modèle de ce que j'ai fait dans le contexte des dérivateurs, dans I (cf. p. 111-126). On introduit la notion de **D**-fibration à la page 117 (prop. 5), par `[des]` conditions équivalentes, dont certaines ont un sens en termes de la donnée de W sans plus. Soit donc

$$f : X \longrightarrow Y$$

dans Cat et considérons les conditions

Commentary · Exposition [ms. 4]

What the four fibration tests quantify over

Grothendieck is looking for a notion of family whose strict pullbacks compute homotopy-invariant changes of base. His strongest condition says that

$$f^* : \mathrm{Cat}/Y \longrightarrow \mathrm{Cat}/X$$

preserves the underlying W-maps. The intermediate condition tests this only between W-aspherical bases. The left-hand test asks that, for every $v : T \to Y$ whose domain T has a terminal object and every object $t \in T$, the inclusion of the strict fibre

$$X_{v(t)} \longrightarrow X \times_Y T$$

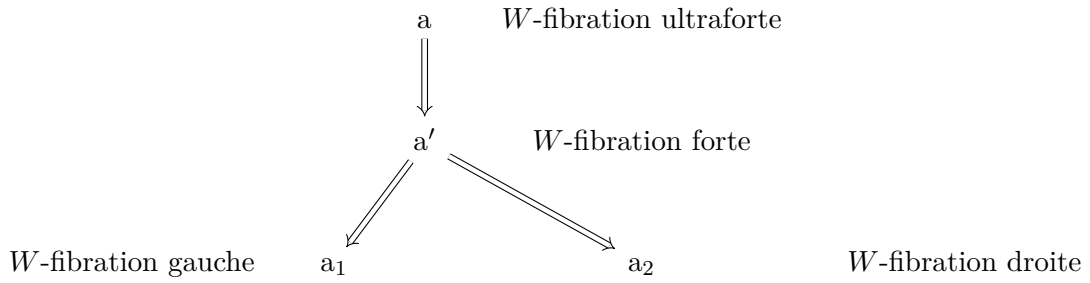
belong to W. The chosen t need not be the terminal object. The right-hand test uses bases with an initial object. This universal quantification over $T \to Y$ distinguishes the definition from an isolated comparison $X_y \to X/y$.

9. C'est donc l'énoncé dual de l'axiome W(3) de l'objet final.

5. Itou si on remplace dans cet énoncé W(2) par W(2 bis).

The arrows in the source's diagram follow at once because a terminal or initial category is W-aspherical. Their converses express additional mathematics. For W_∞, Chapter XI supplies them. For a general W, the step from a one-sided test to invariance under every W-map is precisely the proposed axiom W(4). One should not import it from the formalism of a model category: an arbitrary categorical functor is not a fibration of a model structure merely because it satisfies one of these tests.

The eventual terminology is settled only at XII, manuscript pp. 51–52. The early adjective *ultraforte* names preservation of all W-maps, and it is useful to retain that descriptive meaning while reading these pages. The later W-fibration is defined using categorical homotopisms in the base. In a truncated theory the distinction survives: the path family over an $(n+1)$-sphere passes the ordinary homotopy tests but does not preserve W_n-equivalences. The complete computation is given below at manuscript pp. 16–17.



a) Si $Y'' \longrightarrow Y'$ dans Cat/Y est dans W, alors $X'' \longrightarrow X'$ aussi (le changement de base par $X \longrightarrow Y$ transforme W dans W).

a′) Comme a), mais avec Y'', Y' W-asphériques.

a_1) Comme a), dans le cas particulier où Y' a un objet final et Y'' est la catégorie ponctuelle.

a_2) Dual de a_1), avec objet initial de Y'.

On a donc

et dans le cas $W = W_\infty$ toutes ces conditions sont équivalentes. J'ai envie [de] prendre la plus forte de ces conditions, mais je dois me donner des moyens pour trouver des W-fibrations en un sens aussi fort. Par exemple j'aurais envie de savoir que si X est dans Cat, alors $\underline{\mathrm{Ch}}_\infty(X) \longrightarrow X \times X$ ou $\underline{\mathrm{Ch}}(X) \longrightarrow X \times X$ est une W-fibration. Dans les deux cas, et (disons) pour W_∞, je le prouve en prouvant que p est à la fois lisse, et propre. Il faudrait donc revoir les notions de lissité et de propreté dans le contexte de la donnée d'un W. p. 5 [page 5]

Si je me rappelle bien, la propriété a′) [plutôt a_1)] était quelque chose d'assez aisément vérifiable, il suffisait de supposer que les

$$X_y \longrightarrow X/y \qquad \text{et} \qquad X/y \longrightarrow X/y'$$

(pour $y \in \mathrm{Ob}\, Y$ resp. $u : y \longrightarrow y'$ dans $\mathrm{Fl}\, Y$) sont dans W, et que ça reste vrai par tout changement de base - ce qui revient à la condition a_1) sur f. On pourrait donc formuler une condition sur W ainsi :

W(4) (Axiome des W-fibrations ([6]).) Soit $f : X \longrightarrow Y$ dans Cat satisfaisant la condition de W-fibration a_1) ci-dessus (p. 4), alors elle satisfait même à a), i.e. le changement de base par f transforme flèches dans W en flèches dans W ([7]).

Grâce à la proposition 2, il s'ensuit que la condition duale a_2) sur f implique la condition de W-fibration forte, donc l'axiome W(4), en apparence asymétrique, signifie aussi que les quatre conditions de fibration sur f sont équivalentes, il est donc en fait symétrique.

6. Voir variante affaiblie suffisante, dans le NB p. 10. Voir encore [?] de variantes pages 13, 14 ci-dessous.
7. i.e. une W-fibration à gauche est une fibration ultraforte.

NB Je ne vois pas, sans axiomes supplémentaires sur W, comment passer de a_1 à a' seulement. La difficulté, c'est de montrer, moyennant a_1 seulement, que si Y est W-asphérique, l'inclusion $X_y \longrightarrow X$ (où $y \in \mathrm{Ob}\, Y$) est dans W. Dans le contexte des dérivateurs **D**, cela se voyait par voie **D**-cohomologique.

Cet axiome très fort suffit à impliquer que si X, Y sont W-fibrés sur S, et si $f : X \longrightarrow Y$ est un S-morphisme qui est dans W, alors $f_s : X_s \longrightarrow Y_s$ est dans W ($\forall\ s \in S$). Montrons déjà au moins l'inverse.

Proposition 3. *Soient X, Y dans* Cat/S, *$f : X \longrightarrow Y$ une S-flèche. Supposons (X, Y W-fibrés) que $\forall\ s \in S$, $f_s : X_s \longrightarrow Y_s$ soit dans W, alors $f \in W$* ([8]). [page 6]

Il s'impose d'utiliser l'axiome de localisation, donc de regarder les f/s induits par f p. 6

$$\begin{array}{ccc} X/s & \xrightarrow[f/s]{} & Y/s \\ {\scriptstyle i_s^X}\uparrow & & \uparrow{\scriptstyle i_s^Y} \\ X_s & \xrightarrow{f_s} & Y_s \end{array} .$$

Commentary · Exposition [ms. 6]

From strict fibres to the total category

Proposition 3 is a descent statement, and the comma categories supply the descent data. Suppose $p : X \to S$ and $q : Y \to S$ satisfy the left fibration test and $u : X \to Y$ lies over S. Pulling p back to S/s, with terminal object (s, id_s), shows that the canonical inclusion $X_s \to X/s$ is in W; similarly for Y. The square in the text therefore gives

$$u_s \in W \quad \Longleftrightarrow \quad u/s \in W.$$

If this holds at every s, the relative axiom W(2) gives $u \in W$. The dual proof applies when both maps satisfy the right test. The maps must satisfy a common variance; a mixed pair is not covered by this argument.

There is also a direct reason why one representative per connected component suffices. For an arrow $a : s \to t$, the left fibration condition makes $X/s \to X/t$ and $Y/s \to Y/t$ weak equivalences. Comparing the two horizontal maps in the resulting square shows that $u_s \in W$ exactly when $u_t \in W$. Propagate this statement along a finite zigzag of arrows joining the chosen representative to any other object.

None of these steps uses W(4). That distinction is the point of the proposition: fibrewise equivalences imply a total equivalence by local-to-global descent, while a total equivalence need not be detectable on fibres without a stronger hypothesis on the theory. The path-space example below will show the failure sharply.

La condition a_1 suffit à impliquer que i_s^X et i_s^Y sont dans W, donc f/s est dans W si et seulement si f_s l'est. On n'a pas eu à utiliser l'axiome W(4), et il suffisait de supposer que X, Y soient fibrés 'W-cohomologiques' (ou W-fibrés à gauche) sur S, ou dualement, des W-fibrés à droite.

De plus :

Corollaire ([9]). *Soit $S_0 \subseteq \mathrm{Ob}\, S$ une partie de S telle que $S_0 \longrightarrow \pi_0(S)$ surjectif. Alors dans la proposition 3 il suffit de supposer $f_s \in W$ pour $s \in S_0$.*

Il suffit de voir que si $u : s \longrightarrow s'$ est une flèche dans S, alors $f_s \in W \iff f_{s'} \in W$. On utilise le fait que $f_s \in W \iff f/s \in W$, et de même pour $f_{s'}$. Donc à voir que

8. *Sans* axiome W(4). C'est la première fois qu'on a besoin de W(2) sous sa forme forte, à l'exclusion de W(2 bis).

9. Sans axiome W(4).

$f/s \in W \iff f/s' \in W$. Or on a

$$\begin{array}{ccc} X/s & \xrightarrow{f/s} & Y/s \\ {\scriptstyle X/u}\downarrow & & \downarrow{\scriptstyle Y/u} \\ X/s' & \xrightarrow{f/s'} & Y/s' \end{array} ,$$

où X/u et Y/u sont dans W, d'où le résultat.

Mais revenons à la réciproque : si $f \in W$, alors a-t-on $f_s \in W_S$? [plutôt $f_s \in W$?] Il y a un argument dans ce sens dans VI, p. 23, que je vais reprendre. L'idée est celle-ci. On considère la composante connexe Y_0 de Y [plutôt S_0 de S] contenant s, et on construit un W-fibré (au *sens fort* a))

$$S' \longrightarrow S_0 \subseteq S \qquad \text{[page 7]}$$

avec S' *W-asphérique.* Comme $X \longrightarrow Y$ sur S est dans W, il en sera donc de même de $X' \longrightarrow Y'$ sur S'. Comme les fibres de X', Y' en s' s'identifient à celles de X, Y en l'image de s' dans S, on est ramené au cas où S est W-asphérique. Mais alors on a

$$\begin{array}{ccc} X & \xrightarrow{f} & Y \\ {\scriptstyle i_s^X}\uparrow & & \uparrow{\scriptstyle i_s^Y} \\ X_s & \xrightarrow{f_s} & Y_s \end{array} ,$$

où i_s^X, i_s^Y sont dans W, car déduites de $\{s\} \longrightarrow S$ (qui est dans W, S étant W-asphérique) par les changements de base W-fibrants $X \longrightarrow S$, $Y \longrightarrow S$. Donc $f \in W \implies f_s \in W$. p. 7

NB On n'a utilisé la propriété de fibration pour X, Y qu'au sens a') ([10]).

Il faut donc prouver, si on peut, le

Lemme (?) ([11]). *Soit S un objet* 0*-connexe de* Cat. *Alors il existe un objet W-asphérique S' de* Cat*, et une W-fibration (au sens* fort *de a), page 4) $S' \longrightarrow S$.*

Commentary · Exposition [ms. 7]

A path cover makes the converse local

The converse fibre test needs a cover on which the base becomes aspherical without changing the homotopy type of the fibres. Fix s_0 in a connected component of S, and use the endpoint map

$$\beta : \underline{\mathrm{Ch}}(S; s_0, -) \longrightarrow S.$$

Its source is intended to model based paths with free endpoint. Every object in the chosen component is the endpoint of a finite zigzag starting at s_0, so this cover reaches each object of that component.

Assume the two properties under construction: $E = \underline{\mathrm{Ch}}(S; s_0, -)$ is W-aspherical and β is ultraforte. If $u : X \to Y$ over S is in W, then the pullback $u_E : X_E \to Y_E$ is in W. For any $e_0 \in E$, the point map $e \to E$ is in W, by two-out-of-three with $E \to e$. The strong-aspherical-base condition for X_E and Y_E now places both fibre inclusions in W. Their comparison square gives $u_{\beta(e_0)} \in W$.

This formulation avoids an unnoticed component restriction: one pulls back u along the actual composite $E \to S$. The inclusion $S_0 \to S$ of the selected component is a pullback of the point inclusion $e \to \pi_0 S$. A functor to a discrete category is perfect, so this inclusion is perfect as well; W(4) makes it preserve W under base change. The composite of this inclusion with the perfect path cover has the required property. No prior assertion that restriction of an arbitrary W-map to one component remains in W is needed here.

The dependency that remains is real but explicitly acknowledged: asphericity of E must be proved before the converse fibre theorem is used. Deriving it from the desired conclusion about fibres of $\underline{\mathrm{Ch}}(S) \to S$ would be circular. The next paragraph changes the base from S to the category of path types precisely to avoid that circle.

10. Et même, dans a') on pourrait exiger que $Y'' = e$, Y' W_ω-asphérique, où W_ω [est] défini page 14, $W_\omega \subseteq W \cap W_\infty \ldots$

11. Est prouvé moyennant l'axiome W(4) (+ des petites vérifications ultérieures).

L'idée naturelle, c'est de prendre, pour $s_0 \in \mathrm{Ob}\, S$ fixé,

$$S' = \underline{\mathrm{Ch}}(S; s_0, -) \qquad \text{ou} \qquad S' = \underline{\mathrm{Ch}}_\infty(S; s_0, -),$$

et la flèche

$$\beta : c \longmapsto \text{but } c : S' \longrightarrow S.$$

On sait que S' est W_∞-aphérique et que β est W_∞-fibrante (et même parfaite). Il faut voir que S' est aussi W-asphérique, et β W-fibrante. Il faut donc revoir la démonstration dans le cas de W_∞, et prouver qu'elle se transforme à W, moyennant les axiomes qu'il faut sur W. [page 8] J'ai envie de regarder d'abord le choix $S' = \underline{\mathrm{Ch}}(S; s_0, -)$, sans passage à une limite inductive qui m'obligerait à mettre un axiome de limites sur W. Les propriétés homotopiques délicates et essentielles de $\underline{\mathrm{Ch}}(S)$ sont établies dans VII, p. 157-169, savoir que dans le diagramme

$$S \xrightarrow{i_S} \underline{\mathrm{Ch}}(S) \xrightarrow{p_S} S \times S,$$

$i_S \in W_\infty$ et p_S est une W_∞-fibration (en fait, *propre* et *lisse* pour W_∞) ([12]). Le fait que $i_S \in W$ `[plutôt` $i_S \in W_\infty$`]` implique que les foncteurs source et but

$$\underline{\mathrm{Ch}}(S) \underset{\beta}{\overset{\sigma}{\rightrightarrows}} S \qquad \sigma = \mathrm{pr}_1 \circ p_S,\ \beta = \mathrm{pr}_2 \circ p_S$$

sont dans W_∞ (puisque $\sigma i_S = \beta i_S = \mathrm{id}_S$). Comme ce sont des Hot-fibrations, il en résulte que les fibres $\underline{\mathrm{Ch}}(S; s, -)$ resp. $\underline{\mathrm{Ch}}(S; -, s)$ sont Hot-asphériques. Mais même en admettant que σ, β sont dans W et sont des W-fibrations, je ne peux en conclure tout de suite que les fibres sont W-asphériques - il y aurait cercle vicieux! Il me faut donc une démonstration directe.

Considérons le foncteur

$$\begin{array}{c} \underline{\mathrm{Ch}}(S; s, -) \\ \Big\downarrow{\scriptstyle p} \\ \underline{Ty} \end{array},$$

c'est un foncteur Cat-fibrant, donc W-lisse (je devrai développer la notion de W-lissité ([13]) p. 8 avec soin, j'admettrai pour le moment les propriétés formelles familières, et les justifierai par la suite). À cause de la W-lissité, pour prouver $p \in W$, il suffit de prouver que les fibres de [page 9] p sont W-asphériques ([14]). Or les fibres sont les $Z_\tau = \underline{\mathrm{Ch}}_\tau(S; s, -)$, qui sont des catégories *contractiles* (i.e. $Z_\tau \longrightarrow e$ est un homotopisme), donc W-asphériques par W(3) (cf. cor. 3, page 3).

Commentary · Exposition [ms. 9]

Why finite path types avoid a limiting axiom

The projection to path types separates combinatorics from homotopy. For a fixed finite oriented interval τ, the category $\underline{\mathrm{Ch}}_\tau(S; s, -)$ consists of its diagrams in S whose initial endpoint is s. Replace the last vertex by its predecessor and the last edge by the identity. This defines a functor on the diagram category; the last arrow of each diagram, with identities at the other vertices, defines a natural transformation to or from the identity functor, according to the orientation of the edge. Its image is the subcategory of diagrams with final edge an identity, canonically identified with the diagram category for the shortened interval. Repeat there and include back into the original category. Induction on the number of edges gives a finite zigzag from the identity to the constant-path functor

12. Dans l'énoncé des 'propriétés essentielles' de $\underline{\mathrm{Ch}}(S)$, on peut travailler avec W_ω, la plus petite partie de Fl(Cat) satisfaisant les axiomes W(1), W(2 bis), W(3) (cf. page 14), donc $W_\omega \subseteq W \cap W_\infty$.

13. $f : X \longrightarrow Y$ est W-lisse si les $X_y \longrightarrow y\backslash X$ sont W-asphériques.

14. On utilise ici W(2 bis), pas $W(2)$.

at s. This supplies the fixed-type contraction which Chapter VII states and later leaves unwritten (Grothendieck, 1990–1991o, manuscript pp. 152, 160, 170).

The total category over $\underline{Ty}$ is a Grothendieck fibration. Therefore it is W-smooth: every required category of lifts with prescribed target has a terminal cartesian lift. Aspherical strict fibres then give a W-equivalence to $\underline{Ty}$, by the dual of absolute theorem A. The unit path type is terminal in $\underline{Ty}$, so W(3) makes this base W-aspherical as well (Grothendieck, 1990–1991o, manuscript pp. 160–161). A claim that the fibres alone make the total category aspherical would omit this base hypothesis. Thus the path cover is built from categorical contractions and theorem A, before invoking any stability of filtered colimits.

The same economy explains the lifting calculation for $\underline{\mathrm{Ch}}(S) \to S \times S$. For endpoint arrows $u : a' \to a$, $v : b' \to b$ and a path $c : a \rightsquigarrow b$, form the concatenation $\widetilde{c} = \mathrm{ch}(u)c\,\mathrm{ch}(v)^{\mathrm{op}}$. The category of lifts is compared with $\underline{\mathrm{Ch}}(S; a', b')/\widetilde{c}$, which has a terminal object. Chapter VII constructs both comparison functors and links their composites to the identities by natural transformations (Grothendieck, 1990–1991o, manuscript pp. 161–166). These are actual categorical homotopies, so W(1)–W(3) put the comparisons in W. Applying the construction to the opposite category supplies the other variance. This establishes properness and smoothness independently of W(4). Only afterwards does W(4) upgrade the family to preservation of arbitrary W-maps.

The lifting-category comparison is a proof by reference to Chapter VII; the audit checked the cited construction and retains that dependency. The mapping-path factorization then follows from base-change and composition of perfect maps, with its first map a section of a universally aspherical source projection (Grothendieck, 1990–1991o, manuscript pp. 170–171). The distinction between finite zigzags and the infinite completion $\underline{\mathrm{Ch}}_\infty$, already developed in the commentary on Chapter VII, manuscript pp. 157–170, explains why the present proof need not assume W(6).

D'autre part, si on admet que $\underline{\mathrm{Ch}}(S) \xrightarrow{p_S} S\times S$ est W-lisse (et W-propre), donc $\underline{\mathrm{Ch}}(S) \xrightarrow{\sigma_S} S$ aussi, étant à fibres W-asphériques comme on vient de voir, il s'ensuit que $\sigma_S \in W$, d'où $S \xrightarrow{i_S} \underline{\mathrm{Ch}}(S)$ aussi dans W (puisque $\sigma_S \circ i_S = \mathrm{id}_S$). Donc il reste à prouver seulement que

$$(*) \qquad \underline{\mathrm{Ch}}(S) \xrightarrow{p_S} S \times S$$

est W-propre et W-lisse. Il en résultera que

$$\underline{\mathrm{Ch}}(S; s_0, -) \xrightarrow{\beta} S$$

est lui aussi W-propre et W-lisse, car déduit de p_S par le changement de base

$$S \longrightarrow S \times S \qquad s \longmapsto (s_0, s).$$

Il faut ensuite voir que W-lisse et W-propre implique la propriété de W-fibration *sous sa forme la plus forte* a) (alors que je prévois qu'a priori on ne l'aura que sous les formes faibles a_1, a_2 - pas même sous la forme a'). C'est ici donc que l'axiome W(4) des W-fibrations sera essentiel ([15])!

Voici l'argument pour la lissité de $(*)$, dans loc. cit. p. 161 ff. Il faut prouver que pour $c \in \mathrm{Ob}\,\underline{\mathrm{Ch}}(S)$, et une flèche $u \in \mathrm{Fl}(S \times S)$ `[plutôt` $(u, v) \in$ `Fl(`$S \times S$`)]`, une certaine catégorie de 'relèvements de u de source c ' `[plutôt 'relèvements de` (u, v) `de but` c `']`, $\mathcal{C} = \mathcal{C}(c, u, v)$, est W-asphérique ([16]). Pour ceci, on la compare à une catégorie $\mathcal{C}'$ à objet final, donc contractile et a fortiori W-asphérique, à l'aide de deux foncteurs

$$\mathcal{C} \underset{\psi}{\overset{\varphi}{\rightleftarrows}} \mathcal{C}',$$

et des homotopies $\varphi\psi \sim \mathrm{id}_{\mathcal{C}'}$ (sans mérite, $\mathcal{C}'$ étant contractile) et $\psi\varphi \sim \mathrm{Id}_{\mathcal{C}}$ (on trouve même une flèche $\psi\varphi \longrightarrow \mathrm{id}_{\mathcal{C}}$). Ainsi φ est un homotopisme, donc une W-équivalence (cor. 3, p. 3), donc $\mathcal{C}$ est W-asphérique, $\mathcal{C}'$ l'étant. La propreté de p_S équivaut à la lissité de $p_{(S^\circ)}$, elle est donc prouvée du même coup. [page 10]

15. sous la forme affaiblie W(4a″) (p. 13).
16. En fait, on prouve que $\mathcal{C}(c, u, v)$ est *contractile*, donc elle est W_ω-asphérique. p. 9

Ainsi, le lemme de la page 7 est prouvé, moyennant l'axiome W(4) qui assure qu'une flèche qui est à la fois W-lisse et W-propre, satisfait à la condition très forte a) des W-fibrations.

NB En fait, il suffirait, au lieu de l'axiome W(4) sous sa forme forte, de supposer qu'une $f : X \longrightarrow Y$ qui est à la fois 'homotopiquement lisse' et 'homotopiquement propre', i.e. les fibres des $X/x \longrightarrow Y/y$ et des $x\backslash X \longrightarrow y\backslash Y$ sont contractiles (donc W-asphériques pour tout W satisfaisant W(1,2,3)), soit W-fibration forte. Énonçons quand même ce que nous avons prouvé.

Proposition 4. *Si W satisfait* W(1,2,3) ([17]) (nous le supposons toujours par la suite) *plus* W(4) (sous une forme un peu affaiblie suffisante, cf. remarque précédente), *on a ceci: Soit $f : X \longrightarrow Y$ une flèche dans* Cat$/S$*, avec X, Y des W-fibrés sur S. Si $f \in W$, alors $f_s : X_s \longrightarrow Y_s$ est dans W pour tout $s \in S$.*

Je me demande si j'en sais assez pour pouvoir prouver

$$W \subseteq W_\infty.$$

Il faut quand même éliminer des cas canularesques, comme $W = \mathrm{Fl}(\mathrm{Cat})$, donc mettre l'axiome

W(5) (Axiome de connexité ([18]).) Si $f : X \longrightarrow Y$ est dans W, $\pi_0(f) : \pi_0(X) \longrightarrow \pi_0(Y)$ `[est]` bijectif.

Je factorise alors f en ([19]) [page 11]

$$X \xrightarrow{i} \bar{X} \xrightarrow{\bar{f}} Y,$$

avec $\bar{f}$ une W_∞-fibration et une W-fibration ([20]), $i \in W \cap W_\infty$ - cela marche finallement, par la construction de VII, p. 170-171 (de Cartan-Serre), à partir des propiétés de $Y \longrightarrow \underline{\mathrm{Ch}}(Y) \longrightarrow Y \times Y$ sans plus. Comme $\bar{f}i = f \in W$ et $i \in W$, on en déduit $\bar{f} \in W$. Comme $i \in W_\infty$, on en conclut $f \in W_\infty \iff \bar{f} \in W_\infty$. Donc pour prouver que f est dans W_∞, on est ramené au cas où f est une W-fibration et une W_∞-fibration. Mais alors la proposition 4 nous montre que les fibres de f sont W-asphériques ([21]), et il suffit de voir qu'elles sont W_∞-asphériques (proposition 3 ([22]) appliquée à W_∞). Ainsi on est ramené au cas où $Y = e$, i.e. à prouver que si X dans Cat est W-asphérique, il est W_∞-asphérique.

Soit $x_0 \in \mathrm{Ob}\, X$, considérons comme tantôt

$$E = \underline{\mathrm{Ch}}(X, x_0, -) \xrightarrow{p} X,$$

on sait que E est $W \cap W_\infty$-asphérique, et que c'est une fibration pour W et pour W_∞. Comme p. 10
X est W-asphérique (comme E), $p \in W$, donc à nouveau par la proposition 4 ([23]), les fibres de p sont W-asphériques, en particulier (par W(5)) 0-connexes. On a donc prouvé le

Lemme. ([24]) *Soit (X, x_0) dans* Cat$_\bullet$. *Si X est W-asphérique, alors $\Omega(X, x_0) \overset{déf}{=}$* [page 12]
$\underline{\mathrm{Ch}}(X; x_0, x_0)$ *l'est aussi* (moyennant les axiomes W(1,2,3,4) sur W). *Donc (par itération) les $\Omega^n(X, x_0)$ sont W-asphériques* ($\forall\, n \in \mathbf{N}$).

Corollaire. *Si de plus W satisfait l'axiome* W(5) *de connexité, alors X est W_∞-asphérique.*

En effet, 'on sait' que cela signifie que tous les $\Omega^n(X, x_0)$ sont 0-connexes. Or l'axiome de connexité W(5) assure que W-asphérique implique 0-connexe.

---

17. Pour W(2), il le suffit sous la forme W(2 bis).
18. Voir à ce sujet le corollaire page 22.
19. À nouveau, dans ces arguments on a intérêt à travailler avec W_ω.
20. en fait, $\bar{f}$ est à la fois W_∞-parfait (i.e. W_∞-lisse et propre) et W-parfait (en fait, W_ω-parfait).
21. on n'a utilisé ici que cette propriété sur les fibres, comme consequence de W(4). (On utilise W(4) sous sa forme la plus faible W(4b″), cf. pages 13, 14).
22. on n'utilise la proposition 3 que dans le cas $Y = S$, pour lequel W(2 bis) suffit.
23. en fait, la condition W(4b″) sur W.
24. Utilise W(1, 2 bis, 3, 4b″) sur W.

Commentary · Exposition [ms. 12]

The loop comparison that closes Theorem 1

Grothendieck has isolated the decisive argument: a W-aspherical category remains W-aspherical after forming its based loop category. To obtain the theorem, these loops must detect the ordinary homotopy groups. This is the comparison left open in the running text, and it has a short proof once the ordinary fibration properties already used are available.

Let $E = \underline{\mathrm{Ch}}(X; x, -)$ and $F = \underline{\mathrm{Ch}}(X; x, x)$. The endpoint map $E \to X$ is a W_∞-fibration. Its strict fibre over x maps by a weak equivalence to the corresponding comma category, and the comma categories vary by weak equivalences along arrows of X. Quillen's theorem B therefore identifies BF with the homotopy fibre of $BE \to BX$ (Quillen, 1973, Theorem B and its corollary, pp. 97–98). Since BE is weakly contractible, this gives a pointed equivalence

$$B\underline{\mathrm{Ch}}(X; x, x) \simeq \Omega_x BX.$$

At the next step choose the constant loop as basepoint. Repeating the same argument gives

$$B\Omega^r(X, x) \simeq \Omega^r_x BX, \qquad \pi_0\Omega^r(X, x) \cong \pi_r(BX, x) \quad (r \geq 1),$$

with the right side regarded as its underlying pointed set where only connectivity is used.

Now W(4b″) applies to the perfect path map $E \to X$: both total space and base are W-aspherical, so their map is in W, and its fibre is W-aspherical. Induction gives this for every $\Omega^r(X, x)$. W(5) makes each of them nonempty and connected, hence all positive homotopy groups of BX vanish; W(5) applied to $X \to e$ gives connectivity in degree zero. Thus $X \to e \in W_\infty$.

Finally, for $u : A \to B \in W$, the canonical perfect replacement $A \to \bar{A} \to B$ has first map in both W and W_∞. The second map has W-aspherical fibres by W(4b″); the preceding argument makes those fibres weakly contractible. Its ordinary homotopy-fibre sequence makes it a weak equivalence, and two-out-of-three gives $u \in W_\infty$. The conclusion is proved; the source presents it with the loop comparison still deferred.

Mais le 'on sait' est un tout petit peu léger ([25]). Pour le justifier, il faudrait, ou bien que je fasse le lien avec la théorie 1/2-simpliciale classique, et prouver que les Ω^n que je construis sont 'les bons', i.e. que leur nerf redonne bien (à isomorphisme près dans Hot) les Ω^n classiques (??). En particulier, que le $\pi_0(\Omega^n(X, x_0))$ est bien le $\pi_n(X, x_0)$ 'de tout le monde'. Ou bien que je prouve directement que la 0-connexité des $\Omega^n(X, x_0)$ équivaut à la W_∞-asphéricité de X, définie cohomologiquement à la Artin-Mazur. C'est donc un travail qu'il me faudra faire absolument. Mais ce n'est plus qu'un simple travail de routine, et je peux énoncer dès maintenant le

Théorème 1. ([26], [27], [28]) *Soit* $W \subseteq \mathrm{Fl(Cat)}$ *satisfaisant les conditions* W(1,2,3,4,5) (axiome de saturation, de localisation, de l'objet final, de fibration, de connexité). *Alors*

$$W \subseteq W_\infty.$$

Corollaire. *On peut caractériser* W_∞ *comme la plus grande partie de* Fl(Cat) *satisfaisant aux conditions* W(1) *à* W(5) *précédentes.* [page 13]

Bien sûr, on aimerait un axiome 6 plus intéressant, qui joint aux précédents assure que $W = W_\infty$ ([29]). Ou est-ce que ces propriétés assurent déjà que $W = W_\infty$? Pour le voir, il faudrait peut-être que j'en sache plus sur la structure des objets W_∞-asphériques? Si c'était faux, je songe à un axiome de 'descente homotopique', qui impliquerait qu'un objet W_∞-asphérique est aussi W-asphérique.

25. C'est prouvé fort simplement dans le corollaire du 'theorème 1', page 190.

26. Il suffit même de W(4) sous une forme affaiblie, avec des foncteurs 'fibrants' dans un sens 'absolu'. Cf. le NB p. 10 - et surtout, cf. pages 13, 14.

27. NB Au lieu de W(5), il suffit de supposer $W \neq \mathrm{Fl(Cat)}$, cf. th. 2, p. 20.

28. Les hypothèses utiles sur W sont finalement W(1), W(2 bis), W(3), W(4b″), et $W \neq \mathrm{Fl(Cat)}$.

29. Cf. axiome W(6) page suivante.

Commentary · Present state [ms. 13]

The conjectural minimum is now known

The question on this page has a positive answer without the proposed additional axiom W(6). Cisinski proved that W_∞ is the smallest fundamental localizer (Cisinski, 2004, Theorem 2.2.11). The refinement to the absolute theorem-A axioms identifies it also as the smallest *weak* fundamental localizer (Cisinski, 2006a, Theorem 6.1.18). The source's W(1c) implies the weak-saturation condition in that theorem. Hence W(1), W(2 bis), and W(3) already give $W_\infty \subseteq W$.

Combining this inclusion with Theorem 1 gives $W = W_\infty$ under W(4b″) and W(5). The nondegeneracy argument at manuscript pp. 20–22 replaces W(5) by $W \neq \mathrm{Fl}(\mathrm{Cat})$. Accordingly, the conjecture at manuscript p. 15 is no longer open, and adding closure under retracts is unnecessary.

There is a local notational change to observe. On manuscript p. 13, W_ω is introduced as the intersection of classes satisfying W(1)–W(5). On the next page it denotes the minimum satisfying only the basic localizer axioms, preferably W(2 bis). These are different definitions during the exploration. The later theorem makes both classes equal to W_∞, but that equality must not be used to conceal their different roles in the original argument.

The proof strategy here also reappears in Cisinski's characterization by a theorem-B property: a fundamental localizer preserving components and making every locally constant equivalence aspherical must be W_∞ (Cisinski, 2004, Theorem 2.3.6). Its loop-space argument is the modern counterpart of the preceding manuscript proof.

p. 11

Je note dès maintenant que si des W_i ($i \in I$) satisfont aux axiomes W(1) à W(5), il en est de même de $\bigcap_i W_i$ ([30]). Donc il y a un plus petit ensemble de flèches W_ω satisfaisant à ces conditions. S'il n'est égal à W_∞, i.e. si les axiomes W(1) à W(5) ne caractérisent déjà W_∞, ce serait un localiseur vraiment très intéressant.

Je me rends compte que je n'ai utilisé qu'une forme assez faible de l'axiome W(4) - essentiellement, la validité de la proposition 4. Je vais résumer différentes variantes de l'axiome de fibration.

W(4)

a$_1$) Si $f : X \longrightarrow Y$ dans Cat est une W-fibration gauche, c'est une W-fibration ultraforte.

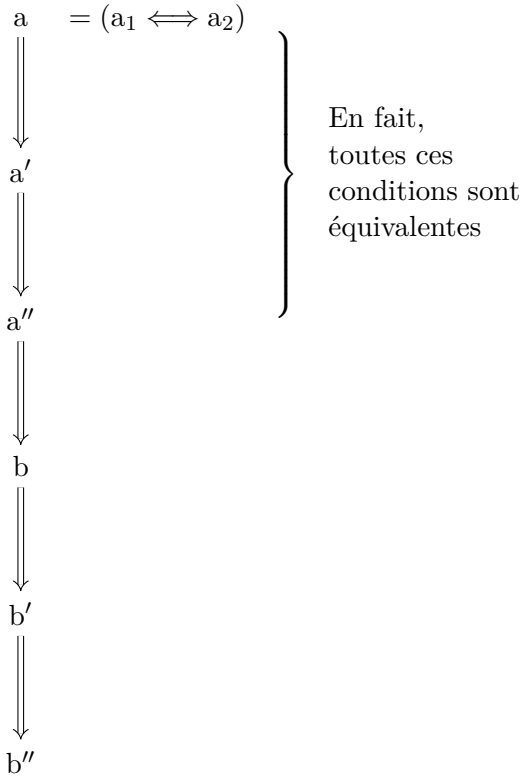
a$_2$) Si $f : X \longrightarrow Y$ est une W-fibration droite, c'est une W-fibration ultraforte.

a′) Si $f : X \longrightarrow Y$ est W-parfait, i.e. à la fois W-propre et W-lisse ([31]), alors f est une W-fibration ultraforte.

a″) Si $f : X \longrightarrow Y$ est à la fois homotopiquement propre et homotopiquement lisse (cf. NB page 10), f est une W-fibration ultraforte. (Il vaut mieux dire : Si f est W_ω-parfait, c'est une W-fibration ultraforte.)

b) Soit $f : X \longrightarrow Y$ une flèche dans Cat/S, avec X et Y des W-fibrés sur S. Si $f \in W$, alors $\forall\, s \in S$, $f_s : X_s \longrightarrow Y_s$ est `[dans]` W.

b′) Soit $f : X \longrightarrow Y$ une flèche de Cat/S qui soit W-parfaite et W_∞-parfaite, alors $f \in W$ implique que les fibres de f sont W-asphériques. (Il vaut mieux dire : Si f est W_ω-parfait, il est une W-fibration ultraforte.) `[Plutôt : Soit` $f : X \longrightarrow Y$ `une flèche dans` Cat/S `telle que` $X \longrightarrow S$ `et` $Y \longrightarrow S$ `soient` W_ω`-parfaites. Si` $f \in W$`, alors` $\forall\, s \in S$`,` $f_s : X_s \longrightarrow Y_s$ `est dans` W`.]`



[page 14]

b″) Soit $W_\omega \subseteq W \cap W_\infty$ la plus petite partie de Fl(Cat) satisfaisant les conditions W(1,2,3) ([32]) (axiomes de saturation, de localisation, de l'objet final). Soit $f : X \longrightarrow Y$ une flèche dans Cat qui soit W_ω-parfaite. Si $f \in W$, alors les fibres de f sont W_ω-asphériques `[plutôt` W`-asphériques]`.

Entre ces propriétés de W, on a les implications tautologiques (sauf a″) $\Longrightarrow$ b), qui est essentiellement la proposition 4)

p. 12

30. C'est vrai pour tout ensemble d'axiomes dans la nature d'axiomes de stabilité.
31. ce qui implique que c'est une W-fibration gauche *et* droite.
32. Il vaut mieux prendre W(2 bis) au lieu de W(2), pour trouver W_ω la plus petite possible!

([33]).

Eh bien, dans le lemme page 12, il suffisait de supposer que W satisfait à la version la plus faible b″) de l'axiome des fibrations (sept versions!). En effet, les fibrations $\bar{X} \longrightarrow Y$ et $E \longrightarrow X$ utilisées dans la démonstration du lemme sont W_ω-parfaites, et il suffisait de savoir que si elles sont dans W, alors les fibres sont W-asphériques.

Commentary · Exposition [ms. 14]

What the weakest fibre axiom actually needs

The list of seven variants is an attempt to reduce the amount of fibration theory needed for the characterization. Its least demanding member, W(4b″), asks only this: a W-equivalence which is W_ω-perfect has W-aspherical strict fibres. The conclusion is relative to W, as the editors correct; it does not assert that the fibres are already W_ω-aspherical.

For the proof of Theorem 1 this is enough because the maps to which the axiom is applied have a special origin. The replacement $\bar{A} \to B$ and the based-path projection $\underline{\mathrm{Ch}}(X; x, -) \to X$ are W_ω-perfect before any fibration axiom for W is assumed. Two-out-of-three puts these maps in W, and W(4b″) then supplies exactly the asphericity required. Arbitrary W-fibrations need not be considered.

The distinction between preservation and detection also explains the middle variants. W(4a″) requires base change along an absolute perfect map to preserve W. W(4b′) concerns a map *between* two absolute perfect families over the same base. W(4b″) concerns one perfect map and compares it to the identity family on its target. The editorial replacement of the entire statement of b′ restores this intended progression.

The brace printed on this page spans the three a-conditions; it should not be read as a proof of every converse in the seven-term chain. Section IV returns to those converses and to the saturation needed for the localization arguments. In the modern setting, minimality and the nondegeneracy criterion below identify the two possibilities as W_∞ and the class of all maps, so these different rigidity axioms ultimately select the same possibilities. That later conclusion is stronger than the argument supplied by the diagram itself.

33. Je reviens sur les diverses variantes de W(4) plus bas, p. 53-56.

Mais je ne pense pas que même la version la plus forte W(4a) de l'axiome des fibrations, jointe aux trois axiomes précédents et à W(5) (connexité), implique $W = W_\infty$. Il faudrait tout au moins y joindre l'axiome

W(6) (Axiome des limites filtrantes.) Soit $X = \varinjlim_i X_i$ une limite inductive filtrante dans Cat. Si les X_i sont W-asphériques, X aussi.

Ceci devrait être équivalent à la propriété, en apparence plus forte, en termes de flèches de W :

Proposition 5. *Supposons qu'on ait* W(6) (en plus de W(1) à W(4) ([34])), *et soit* [page 15]

$$(f_i)_{i\in I} : (X_i)_{i\in I} \longrightarrow (Y_i)_{i\in I}$$

un homomorphisme de systèmes inductifs dans Cat*, indexé par un ensemble ordonné filtrant,* p. 13 *soient* $X = \varinjlim X_i$, $Y = \varinjlim Y_i$, $f = \varinjlim f_i$, $f : X \longrightarrow Y$. *Si* f_i *est dans* W *pour tout* i*, alors* $f \in W$.

On factorise chaque f_i en

$$X_i \xrightarrow{\alpha_i} \bar{X}_i \xrightarrow{\bar{f}_i} Y_i, \qquad \alpha_i \in W_\omega,\ \bar{f}_i \in \operatorname{Parf} W_\omega$$

([35]) suivant le système breveté. La construction étant fonctorielle, les $\bar{X}_i$ forment eux aussi un système inductif. De plus, comme le foncteur $S \longrightarrow \underline{\mathrm{Ch}}(S)$ qui donne naissance à la factorisation canonique des morphismes, commute aux $\varinjlim$ filtrantes (immédiat), il s'ensuit que, si on pose

$$\bar{X} = \varinjlim_i \bar{X}_i$$

et qu'on regarde les flèches

$$X \xrightarrow{\alpha} \bar{X} \xrightarrow{\bar{f}} Y, \qquad \alpha = \varinjlim \alpha_i,\ \bar{f} = \varinjlim \bar{f}_i,$$

avec $\bar{f}\alpha = \bar{f}$, cette factorisation de f est bien sa factorisation canonique. Donc $\alpha \in W$, $\bar{f} \in \operatorname{Parf} W_\omega$. Ceci vu, en vertu de prop. 3, $f \in W$, i.e. $\bar{f} \in W$, est vrai si les fibres de $\bar{f}$ sont W-asphériques. Mais les fibres de $\bar{f}$ s'interprètent comme limites inductives filtrantes de fibres des $\bar{f}_i$, lesquelles sont W-asphériques par la condition W(4b″) des fibrations. Donc l'axiome W(6) donne ce qu'il faut.

Commentary · Exposition [ms. 15]

Filtered fibres require a moving basepoint

Proposition 5 turns an axiom about aspherical objects into an axiom about maps by making the fibres of those maps explicit. Two finite-presentability assertions are implicit in the sketch, and both can be checked directly.

First, a path of a fixed finite type is a functor from a finite category, and a morphism between two such paths is specified by finitely many arrows and equations. If $S = \varinjlim_i S_i$ is a filtered colimit, any path or morphism of paths in S is represented at one stage, and an equality between representatives holds at some later common stage. Thus $\underline{\mathrm{Ch}}(-)$, including its source and target maps, commutes with filtered colimits. Since filtered colimits of sets commute with finite limits, the finite pullbacks defining the mapping-path replacement commute with them as well.

Second, a fibre over $y \in Y = \varinjlim_i Y_i$ is not the colimit of fibres over an unspecified fixed y. Choose a representative $y_i \in Y_i$, and let y_j be its image for $j \geq i$. There is a canonical isomorphism

$$(\bar{X})_y \ \cong\ \varinjlim_{j\geq i} (\bar{X}_j)_{y_j}.$$

34. W(4) sous la forme la plus faible W(4b″) .

35. W_ω introduit dans la condition W(4b″), page 14.

For objects, a representative x_j mapping to y has image equal to y_k at a sufficiently late stage k, so it becomes an object of the indicated fibre. For arrows, the condition that the image be the identity of y is likewise witnessed at a later stage. The same finite-stage argument proves injectivity and compatibility with composition. Passing to $j \geq i$ is cofinal and remains filtered.

Each map $\bar{f}_j$ belongs to W, since f_j and its replacement inclusion do. W(4b″) makes its fibres W-aspherical, W(6) makes their displayed colimit W-aspherical, and theorem A for a proper or smooth map gives $\bar{f} \in W$. Finally $\alpha \in W_\omega \subseteq W$, so $f = \bar{f}\alpha \in W$. The printed equation $\bar{f}\alpha = \bar{f}$ is a slip retained in the source.

For fundamental localizers in the modern sense, filtered-colimit stability is already a theorem, with no accessibility assumption (Cisinski, 2006a, Corollary 4.2.22). The calculation here remains useful because it shows exactly how a fibre argument reduces that stability to the object form.

Conjecture (hardie? sotte?). *Si* $W \subseteq \mathrm{Fl}(\mathrm{Cat})$ *satisfait les axiomes* W(1) *à* W(6) *(avec* W(4) *sous sa forme la plus faible* W(4b″) ([36])*), alors* $W = W_\infty$.

Mais il est bien possible qu'il faille renforcer un peu W(1) (saturation), en exigeant que tout rétracte d'un $f \in W$ soit dans W. [page 16]

Commentary · Present state [ms. 16]

The proposed retract axiom is unnecessary

The possible need for an extra retract axiom is resolved by the later theory. Every fundamental localizer with the relative theorem-A axiom W(2) is strongly saturated and consequently closed under retracts (Cisinski, 2006a, Proposition 4.2.4). In the weaker setting using W(2 bis), the specific equality conjectured here already follows from the weak minimal-localizer theorem and the fibre argument, so no independent retract hypothesis is required for that conclusion either. This does not assert strong saturation for every weak fundamental localizer before the fibre axiom is imposed.

This does not retroactively make every appeal to an isomorphism in Hot_W valid under two-out-of-three alone. The elementary proofs above deliberately establish membership in W directly. The later strong-saturation theorem explains when such arguments may be shortened; it should be cited at the point where that stronger conclusion is used.

Remarque. Considérons, pour $n \in \mathbf{N}$, l'ensemble $W_n \subseteq \mathrm{Fl}(\mathrm{Cat})$ des 'n-équivalences d'homotopie' dans Cat :

$$f \in W_n \iff \pi_0(f) \text{ bijectif, et } \pi_i(f,x) : \pi_i(X,x) \longrightarrow \pi_i(Y,f(x)) \text{ bijectif pour } 0 < i \leq n.$$

Je croyais que ça satisfaisait à tout ce qu'on peut demander à un localiseur, sans avoir pris la peine de l'écrire avec soin. Ma ça ne peut satisfaire à W(1) jusqu'à W(4b″), puisqu'on n'a pas $W_n \subseteq W_\infty$!

Commentary · Exposition [ms. 16]

Truncated equivalences really are localizers

The class W_n is not a defective homotopy theory. It is the ordinary theory observed through the first n homotopy groups. More precisely,

$$u \in W_n \quad \Longleftrightarrow \quad \tau_{\leq n} Bu \text{ is an equivalence,}$$

where $\tau_{\leq n}$ is Postnikov truncation. This functor is left adjoint to the inclusion of n-types (Lurie, 2009, Proposition 5.5.6.18). Its universal property gives a direct modern proof of the assertions the source recalls without repeating.

Identities, two-out-of-three, and the two-cycle condition hold because they hold for equivalences of n-types. Strong saturation follows too: the functor $\tau_{\leq n}B$, regarded as taking values in the homotopy category of n-types, factors through $\mathrm{Cat}[W_n^{-1}]$. Hence any map inverted there induces an equivalence of n-types and therefore was in W_n already. Categories with terminal objects have contractible nerves, giving W(3).

36. et peut-être W(2) sous la forme plus faible W(2 bis).

For the relative axiom W(2), let $X \to S$ be any functor. The simplicial bar construction on the covariant diagram $s \mapsto N(X/s)$ has bisimplices consisting of

$$x_0 \to \cdots \to x_q, \qquad p(x_q) \to s_0 \to \cdots \to s_r.$$

For a fixed q-simplex of NX, its r-direction is the nerve of $p(x_q)\backslash S$, which has an initial object. Realizing this direction therefore gives a weak equivalence of the diagonal bar construction with NX. In other words,

$$BX \simeq \operatorname*{hocolim}_{s \in S} B(X/s).$$

This is a homotopy colimit of spaces, retaining the arrows of S, rather than a colimit of their homotopy categories. If $X/s \to Y/s$ is in W_n for every s, apply $\tau_{\leq n}$ to the displayed colimits. As a left adjoint, truncation preserves them as colimits in the category of n-types. The resulting objectwise equivalence induces an equivalence of colimits, proving $X \to Y \in W_n$.

Finally, the nerve commutes with filtered colimits because each finite chain of arrows and each relation is witnessed at a finite stage. A Kan replacement such as Ex^∞ also commutes with filtered colimits: each simplex of Ex is represented by a map from a finite subdivision, and its sequential iteration commutes with colimits. Homotopy groups of Kan complexes are computed by finite simplicial spheres and finite homotopies. They consequently commute with filtered colimits, with basepoints represented at sufficiently late stages. This proves W(6) for W_n. What fails is the fibre axiom, as the next computation shows.

W(1) est trivial sur la définition (et on a sans larmes même la *saturation forte* de W_i, i.e. si f dans Cat est `[un]` isomorphisme dans $\mathrm{Hot}_{W_i} = (\mathrm{Cat})W_i^{-1}$, alors $f \in W_i$). Je crois me rappeler avoir vérifié W(2), par la même méthode que pour W_∞, en utilisant un critère cohomologique à la Artin-Mazur, pour exprimer $f \in W_i$, et en utilisant les suites spectrales de Leray pour $X \longrightarrow S$ et $Y \longrightarrow S$. La condition W(3) est trivialement satisfaite puisque $W_n \supseteq W_\infty$ et qu'elle l'est pour W_∞. Donc ça canule là où je m'y

attendais le moins : l'axiome des fibrations. Prenons la forme faible : Soit $f : X \longrightarrow Y$ p. 14
une W_ω-fibration et $f \in W_i$, les fibres X_s sont elles W_i-asphériques ([37])? On peut supposer X et Y 0-connexes, soit $x \in X_s$, la suite exacte d'homotopie donne

$$\pi_{i+1}(X) \xrightarrow[\text{si } i \leq n-1]{\text{iso}} \pi_{i+1}(Y) \longrightarrow \pi_i(X_s) \longrightarrow \pi_i(X) \xrightarrow[\text{si } i \leq n]{\text{iso}} \pi_i(Y),$$

donc

$$\pi_i(X_s) = 1 \qquad \text{si } 0 \leq i \leq n-1,$$

mais pour $i = n$ on trouve [page 17]

$$\pi_n(X_s) = \mathrm{Coker}\left(\pi_{n+1}(X) \longrightarrow \pi_{n+1}(Y)\right),$$

il n'y a aucune raison que ce soit nul, comme ça devrait si $X_s \longrightarrow e$ était dans W_n.

Commentary · Examples [ms. 17]

The missing group occurs one degree higher

Grothendieck's exact sequence identifies the precise loss of information. For a connected homotopy fibre F of an n-equivalence $E \to B$, with $n \geq 1$, exactness gives

$$\pi_i F = 0 \quad (0 \leq i < n), \qquad \pi_n F \cong \operatorname{coker}\bigl(\pi_{n+1}E \to \pi_{n+1}B\bigr).$$

At $n = 1$, the cokernel is still meaningful: the connecting homomorphism from the abelian group $\pi_2 B$ surjects onto $\pi_1 F$, so the latter group is abelian in this situation. The long exact sequence and its low-dimensional interpretation are recalled in Hatcher (2002, Theorem 4.41).

37. $\omega > \infty$, $W_\omega \subset W_\infty \subset W_n$

For an example entirely within Cat, take S to be the poset of nonempty proper faces of an $(n+2)$-simplex. Then BS is the barycentric subdivision of its boundary, hence has the homotopy type of S^{n+1}. Choose a vertex s, and use

$$E = \underline{\mathrm{Ch}}(S; s, -) \xrightarrow{\beta} S.$$

The total space BE is contractible, and β is W_ω-perfect by the construction recalled on manuscript pp. 8–11. Since the homotopy groups of the sphere vanish through degree n, $\beta \in W_n$. Its fibre $F = \underline{\mathrm{Ch}}(S; s, s)$, however, satisfies

$$BF \simeq \Omega S^{n+1}, \qquad \pi_n BF \cong \mathbb{Z}.$$

Thus $F \to e \notin W_n$, contradicting W(4b″). The same square shows that β does not preserve all W_n-equivalences under base change: $e \to S$ is in W_n, whereas its pullback $F \to E$ is not.

For $n = 0$, the sphere example remains valid, with $\pi_0 \Omega S^1 \cong \mathbb{Z}$, but the displayed *group cokernel* in the source requires correction. In general $\pi_0 F$ is the pointed coset set of the image of $\pi_1 E$ in $\pi_1 B$, not its quotient by the normal closure. Take $G = S_3$, $H = \langle (12) \rangle$, and the action groupoid $E = (G/H) /\!\!/ G$. The projection $E \to BG$ is both a Grothendieck fibration and an opfibration; its strict fibre is the discrete three-element set G/H. Both $E \simeq BH$ and BG are connected, so the projection is in W_0. Yet the group cokernel of $H \to G$ is trivial, since the conjugates of (12) generate S_3. The fibre has three components. This is a genuine degree-zero qualification, not a defect in the argument for positive n.

Il est vrai que parfois on renforce justement la condition pour W_n, disons qu'on définit $W'_n \subseteq W_n$ par

$$f \in W'_n \iff \begin{cases} \text{a)} & \pi_0(f) \text{ bijectif,} \\ \text{b)} & \pi_i(f,x) : \pi_i(X,x) \longrightarrow \pi_i(Y, f(x)) \text{ bijectif pour } 0 < i \leq n \text{ et } x \in X, \\ \text{c)} & \pi_{n+1}(f,x) : \pi_{n+1}(X,x) \longrightarrow \pi_{n+1}(Y, f(x)) \textit{ surjectif,} \end{cases}$$

c'est à dire aussi

$$f \in W'_n \iff \begin{cases} \text{les 'fibres homotopiques' } Z \text{ de } X \longrightarrow Y \text{ (i.e. les fibres de } \bar{X} \xrightarrow{\bar{f}} Y) \\ \text{sont } n\text{-connexes, i.e. 0-connexe et } \pi_i(Z_y, z) = 0 \text{ pour } 1 \leq i \leq n. \end{cases}$$

Alors X dans Cat sera W'_n-asphérique si et seulement s'il est W_n-asphérique, i.e. n-connexe. Donc par la forme 2 de la définition de W'_n, l'axiome W(4b″) est satisfait. Il faut croire que ça pèche ailleurs! Peut-être déjà la saturation.

Commentary · Examples [ms. 17]

Connectivity repairs fibres but loses cancellation

The strengthened class W'_n measures a connectedness condition on a map: its homotopy fibres are n-connected. The long exact sequence makes this equivalent to bijectivity on $\pi_0, \ldots, \pi_n$ and surjectivity on π_{n+1}. For the terminal map $X \to e$, the last surjectivity condition is automatic, so W_n and W'_n have exactly the same aspherical objects.

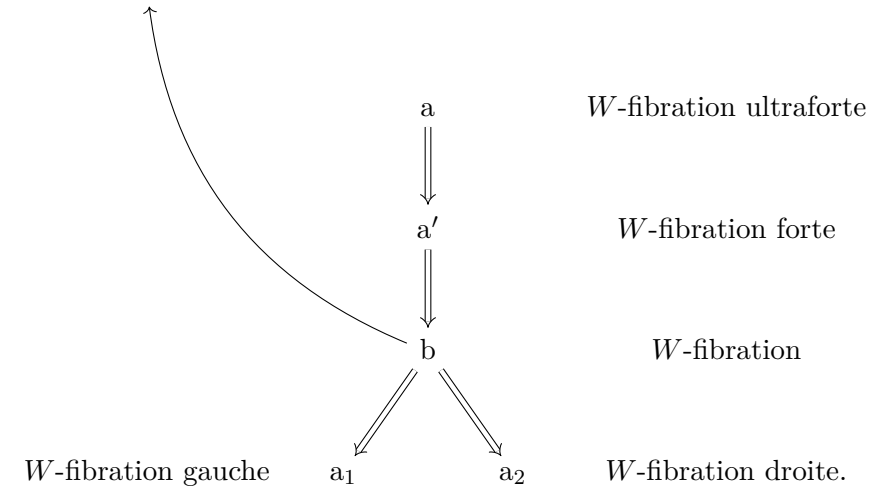
The failure of two-out-of-three can be seen with the same finite category S modeling S^{n+1}. Let $a : e \to S$ select a vertex and let $b : S \to e$ be the terminal functor. Then $ba = \mathrm{id}_e \in W'_n$. Also $b \in W'_n$: it is an isomorphism on homotopy groups through degree n, and the map $\mathbb{Z} = \pi_{n+1} S \to 0$ is surjective. But $a \notin W'_n$, because $0 \to \mathbb{Z}$ is not surjective. This works also for $n = 0$, using the circle.

Thus the problematic cancellation is exactly

$$b,\ ba \in W'_n \quad \not\Rightarrow \quad a \in W'_n.$$

The source's informal argument about surjective homomorphisms is correct; the example supplies actual functors and verifies every homotopy group involved. A class of connected maps can be stable under many geometric operations without being the class inverted by a localization. The modern theory treats connectedness as one side of a factorization system; it is not required to satisfy the cancellation law for equivalences.

Si gf et g sont dans W'_i, il n'est pas forcément de même de f,



car si $\bar{g}\bar{f}$ (et donc $\bar{g}$) est surjectif, il n'en est par forcément de même pour $\bar{f}$! Donc W'_n ne mérite pas le nom de 'localiseur'.

Par contre, W_n me paraît excellent, si on ne lui demande pas l'impossible - de satisfaire à un 'axiome de fibration' qui semble bien (à peu de choses près) caractériser le seul W_∞ parmi les 'bons' localiseurs. En tous cas l'axiome de connexité W(5) est satisfait, et l'axiome des limites filtrantes W(6) aussi. Par ailleurs W(1) (et même la saturation forte), W(2), W(3) sont satisfaits par tout $W_{\mathbf{D}}$ associé à un dérivateur - ce qui confirme à nouveau leur importance. Les axiomes W(4) (l'axiome 'draconien' des fibrations, ± spécial à W_∞), W(5) (connéxité) et W(6) (limites) m'apparaissent comme de nature plus spéciale, je ne songerais à imposer aucun d'eux pour l'usage terminologique de 'localiseur fondamental'. p. 15 [page 18]

II Perplexités sur les axiomes et la terminologie. p. 16

Dans I et la plupart du temps, en travaillant avec les dérivateurs, j'ai supposé $\boxed{W_{\mathbf{D}} \supseteq W_\infty}$, hypothèse qui m'a parue essentielle (à tort ([38]) ou à raison). On voit donc que si $W_{\mathbf{D}}$ satisfait à l'axiome de fibrations W(4), même sous sa forme la plus faible W(4b″), il est *égal* à W_∞. Cela montre bien que cet axiome doit être vu comme pratiquement une *caractérisation* de W_∞ (parmi les localiseurs fondamentaux qui contiennent W_∞ – et ces localisateurs me paraissent les plus importants, et peut-être les seuls vraiment utiles).

La théorie des **D**-fibrations dans I, p. 111-126, a été faite dans l'esprit qu'on vient de dire, en supposant $W_{\mathbf{D}} \supseteq W_\infty$. La notion de **D**-fibrations à laquelle je m'étais finalement arreté était par suite différente des notions envisagées ici dans un esprit différent (page 4). Elle revient à tester la condition a) (trop forte presque toujours, sauf pour $W = W_\infty$), caractérisant les W-fibrations ultrafortes, par des $Y'' \longrightarrow Y'$, où Y'', Y' sont tous deux W_∞-asphériques (ce qui est plus exigeant que W-asphérique). C'est seulement quand Y'' et Y' sont W_∞-asphériques (au lieu de W-asphériques), qu'on demande que $X'' \longrightarrow X'$ soit dans W. On trouve donc une [page 19] notion moins exigeante que celle de W-fibration forte. Si on dénote ici cette condition par b), on trouve (sous réserve que $W_\infty \subseteq W$), avec les notations de la page 4 ([39])

a_1), a_2) étaient aussi appelées **D**-fibrations cohomologique resp. **D**-fibrations homologiques ([40]). Quand **D** satisfait Der 3a′ (I, p. 111) sur les **D**-coefficients localement constants sur les X W_∞-asphériques, alors les notions b), a_1), a_2) sont équivalentes. (Je présume que c'est le cas pour tous les **D** et tous les W vraiment intéressants.) Par contre, j'ai l'impression que la notion de W-fibration forte, voire ultraforte, n'est guère utilisable que dans le cas $W = W_\infty$, où elle coïncide avec les précédentes. C'est dire qu'on peut probablement oublier la terminologie, et se rappeler par contre que dans le cas $W = W_\infty$, les W-fibrations ont des propriétés d'une p. 17 force extrême, s'exprimant par les deux propriétés dégagées dans W(4a) et W(4b).

Commentary · Exposition [ms. 19]

Changing the test bases changes the theory

The revised hierarchy separates the homotopy type of the indexing category from the coefficients used to observe it. A W_∞-aspherical category is an absolutely contractible test shape. A W-aspherical category may instead be invisible only after truncation or after a chosen cohomological localization. Demanding preservation over the latter shapes is stronger when $W_\infty \subseteq W$.

38. à *tort* il s'avère maintenant.

39. Cf. la bonne notion de W-fibration dans un contexte où on ne suppose pas $W_\infty \subseteq W$, dans th. 3 et déf. 3, p. 51, 52.

40. Non, c'est une notion encore plus forte, à coups de coefficients localement constants, cf. I, p. 121.

For W_n, the sphere category used above is W_n-aspherical but not W_∞-aspherical. It is therefore an admissible base in the early strong test a', and the path family fails that test; it is not an admissible base in the new condition b. This is the concrete reason that the revised notion can accommodate truncated homotopy theories. The source's footnote 40 also corrects a different confusion: a condition tested using every locally constant coefficient is stronger than a condition on the underlying localizer alone. The two distinctions should not be merged.

The opening inference of section II needs the nondegeneracy hypothesis that Theorem 2 will make explicit. From $W_{\mathbf{D}} \supseteq W_\infty$ and W(4), one cannot conclude $W_{\mathbf{D}} = W_\infty$ without excluding $W_{\mathbf{D}} = \mathrm{Fl}(\mathrm{Cat})$. The terminal derivator, whose value on every indexing category is the terminal category, gives $W_{\mathbf{D}} = \mathrm{Fl}(\mathrm{Cat})$; all the fibration implications then hold trivially. With $W_{\mathbf{D}} \neq \mathrm{Fl}(\mathrm{Cat})$, the corrected inference follows from Theorems 1 and 2. This is the degenerate exception already recognized at manuscript p. 10, rather than a new obstruction.

[page 20]

Dans la théorie de HOT_W, influencé par la réflexion générale sur les dérivateurs et l'axiome Der 3b, j'ai travaillé sous l'hypothèse $W \supseteq W_\infty$, mais en utilisant un axiome de fibration L5 = W(4b) qui, il s'avère, implique finalement $W = W_\infty$. J'ai l'impression que je n'ai jusqu'à présent (propriétés de $f_!$ pour HOT) pas utilisé $W \supseteq W_\infty$, donc ça peut être utile, comme 'ça ne coûte pas plus cher' (et oblige d'être plus attentif à ce qu'on utilise), de laisser tomber $W \supseteq W_\infty$ (impliquant $W = W_\infty$), et de mettre par contre sur W des axiomes aussi forts (notamment de fibration) que les propriétés de W_∞, 'sans se priver en rien'. Je supposerai donc W(1), W(2), W(3), W(4a) (la forme la plus forte de l'axiome de fibration, cf. pages 13, 14) - c'est tout ce qui a été utile jusqu'à présent. Si on y joint W(5) (axiome de connexité) ça implique $W \subseteq W_\infty$. Mais pour l'instant je ne crois pas en avoir un besoin.

Commentary · Development (commentators') [ms. 20]

A fibre criterion that avoids component restriction

Grothendieck wants to deduce preservation of components from the nontriviality of the theory. The displayed proof begins by restricting a W-map to each component of its target; footnote 42 correctly observes that this invokes a stronger fibre-detection statement than W(4b″). The theorem can be proved with the weaker axiom. The following formulation isolates the repair. We did not find this exact formulation in the sources checked for this audit; it is an elementary reorganization of the fibre argument, with no claim of priority.

Proposition (two-step nondegeneracy criterion). [ours] Let V be a class of functors containing the categorical homotopisms and satisfying two-out-of-three and absolute theorem A: if every $A/b \to e$ lies in V, then $A \to B$ lies in V. Suppose also that for every $u : A \to B$ in V and every $b \in B$, its ordinary homotopy fibre has the weak homotopy type of a category F_b with $F_b \to e \in V$. Then either every map of V induces a bijection on components, or $V = \mathrm{Fl}(\mathrm{Cat})$.

Proof. We first record two consequences of the stated axioms. If $\emptyset \to e \in V$, then every $\emptyset \to C$ belongs to V by absolute theorem A, since all its comma categories are empty. Two-out-of-three applied to $\emptyset \to C \to e$ gives $C \to e \in V$. Applying it once more to $C \to D \to e$ gives every functor $C \to D \in V$.

If $D \to e \in V$, then $D \times D \to e \in V$. Indeed, for $d \in D$, the comma category of the second projection is $(D \times D)/d \cong D \times (D/d)$. The category D/d has a terminal object, so the projection $D \times (D/d) \to D$ is a categorical homotopism: its section at that terminal object has composite naturally joined to the identity. Hence $(D \times D)/d \to e \in V$. Absolute theorem A gives $D \times D \to D \in V$, and composition gives the assertion. When D is empty the assertion is immediate.

Now take $u \in V$ for which $\pi_0 u$ is not bijective. If a component of B is missed, choose b in it. The homotopy fibre of Bu at b is empty: a point in that fibre would supply a path from an image point to b. Consequently its categorical model F_b is empty as well, because a category with an object has nonempty realization. The preceding paragraph gives $V = \mathrm{Fl}(\mathrm{Cat})$.

Suppose instead that two distinct components of A map into the same component of B. Choose one object in each and paths from their images to some b. These give two points of the homotopy fibre which cannot lie in the same component, since projection to BA would connect the chosen objects. Its categorical model $D = F_b$ is therefore disconnected and V-aspherical. The product argument makes $D \times D$ V-aspherical, so its diagonal $d : D \to D \times D$ belongs to V. Choose objects d_0, d_1 in different components of D. The homotopy fibre of Bd at (d_0, d_1) is empty: it would

otherwise provide a point connected to both d_0 and d_1. Apply the fibre hypothesis to this diagonal. It again gives $\emptyset \to e \in V$, and hence $V = \mathrm{Fl(Cat)}$. This proves the proposition.

For the source's class W, the hypothesis about homotopy fibres follows from its canonical factorization $A \to \bar{A} \to B$. The first arrow belongs to $W_\omega \subseteq W \cap W_\infty$; the second is W_ω-perfect and lies in W, so W(4b″) makes its strict fibres W-aspherical. Ordinary theorem B identifies those fibres with the homotopy fibres of the original map. The proposition therefore proves Theorem 2 using W(1), W(2 bis), W(3), and W(4b″), including the weakened hypotheses asserted in footnote 28 of Theorem 1.

Mais méditant sur la question, je crois avoir trouvé le

Théorème 2 (!) ([41]) : *Soit* $W \subseteq \mathrm{Fl(Cat)}$ *satisfaisant* W(1,2,3,4b″)*. Si* W *ne satisfait pas à* W(5)*, alors* $W = \mathrm{Fl(Cat)}$.

Démonstration. Soit $f : X \longrightarrow Y$ dans Cat, tel que $\pi_0(f)$ ne soit pas bijectif. Soit I la catégorie discrète ayant pour ensemble d'objets l'ensemble $\pi_0(Y)$, on a donc un diagramme commutatif

$$\begin{array}{ccc} X & \xrightarrow{\quad f \quad} & Y \\ & {\scriptstyle p}\searrow \quad \swarrow{\scriptstyle q} & \\ & I, & \end{array}$$

d'autre part un foncteur d'une catégorie dans une catégorie discrète est toujours W_ω-parfait, donc p, q sont des W-fibrations. Comme $f \in W$, il s'ensuit $f_i \in W$ pour tout $i \in I$ ([42]).

Si $\pi_0(f)$ n'était pas surjective, prenant i qui n'est pas dans l'image, on aurait $X_i = \emptyset \longrightarrow Y_i \neq \emptyset$, qui serait dans W. Soit donc [page 21]

$$f : X = \emptyset \longrightarrow Y$$

dans W. Alors $\forall$ Z dans Cat, $f \times \mathrm{id}_Z : \underbrace{X \times Z}_{=\emptyset} \longrightarrow Y \times Z$ est dans W (car Z est W-fibrée sur e), donc $\emptyset \longrightarrow Y \times Z$ est dans W. Donc aussi la projection $Y \times Z \longrightarrow Y$. Comme [p. 18]

$$\begin{array}{ccc} Y \times Z & \longrightarrow & Y. \\ & \nwarrow \quad \nearrow & \\ & \emptyset & \end{array}$$

cette projection est une W-fibration, il s'ensuit par W(4b″) que ses fibres sont W-asphériques. Comme $Y \neq \emptyset$, il y a une telle fibre, elle est $\simeq Z$. Donc Z est W-asphérique. Donc on trouve que *toute* catégorie Z dans Cat est W-asphérique. Donc toute flèche $Z \longrightarrow Z'$ dans Cat est dans W, q.e.d.

Supposons maintenant $\pi_0(f)$ surjective, mais non injective. Il y aurait une fibre de $\pi_0(X) \longrightarrow \pi_0(Y) = I$ qui serait de cardinal > 1. En prenant le f_i correspondant, on trouve $X_i \longrightarrow Y_i$ avec Y_i 0-connexe et $\mathrm{card}\,\pi_0(X_i) \geq 2$. Donc on est ramené au cas

$$f : X \longrightarrow Y \qquad \begin{cases} f \in W \\ Y \text{ 0-connexe} \\ \mathrm{card}\,\pi_0(X) \geq 2. \end{cases}$$

Considérons la factorisation canonique

$$X \xrightarrow{i_f} \bar{X} \xrightarrow{\bar{f}} Y,$$

avec $i_f \in W$, donc $\bar{f} \in W$. Donc par W(4b″) les fibres de $\bar{f}$ sont W-asphériques. Mais on voit tout de suite, en décomposant $\bar{X}$ suivant les composantes connexes X_i de X, que ces fibres ont un π_0 de cardinalité $\geq \mathrm{card}\,\pi_0(X) \geq 2$. Donc on est ramené au cas où $Y = e$, i.e.

$$X \text{ } W\text{-asphérique}, \qquad \mathrm{card}\,\pi_0(X) \geq 2.$$

41. Cf. pour un résultat plus fort XV 9.12, p. 133 bis. **NB** Le résultat est plus général, mais pas vraiment plus fort, car il ne donne pas $W = \mathrm{Fl(Cat)}$.

42. On utilise W(4) sous forme plus forte que W(4b″)!

Considérons $X \times X$, qui est aussi W-asphérique, et l'application diagonale [page 22]

$$d : X \longrightarrow X \times X = Y,$$

qui est donc dans W. Mais $\pi_0(d)$ s'identifie à l'application diagonale $\pi_0(X) \longrightarrow \pi_0(X) \times \pi_0(X)$, qui n'est pas surjective puisque $\operatorname{card} \pi_0(X) \geq 2$. Donc pour la première partie, $W = \mathrm{Fl}(\mathrm{Cat})$.

Donc sous forme plus positive :

Corollaire. *Soit* $W \subseteq \mathrm{Fl}(\mathrm{Cat})$ *qui satisfait à* W(1,2,3,4b″)*, et telle que* $W \neq \mathrm{Fl}(\mathrm{Cat})$. *Alors* W *satisfait l'axiome de connexité* W(5)*, et par suite (th. 1, page 12)* $W \subseteq W_\infty$.

p. 19

III Classes remarquables de foncteurs liés à W.

Finalement, j'appelerai *'localiseur fondamental'* une partie W de Fl(Cat) satisfaisant les trois conditions suivantes :

(i) Saturation W(1) (cf. rappel p. 1).

(ii) Axiome de l'élément final W(3) (page 3).

(iii) La variante affaiblie W(2 bis) de l'axiome de localisation W(2) donnée dans le corollaire page 1 (anciennement c'était L4′ dans Pursuing Stacks).

Quand j'aurai besoin de plus sur W, je le dirai explicitement. Ces trois axiomes ont suffi pour pratiquement tout ce que j'ai fait avec W dans Pursuing Stacks, la seule exception étant un usage (si je me rappelle) unique, quelque part, d'une variante affaiblie de W(2) (pour les S-foncteurs *cartésiens* entre S-catégories *fibrées* - si sur toute fibre il est dans W, il est lui-même dans W).

Commentary · Exposition [ms. 22]

The localizer retained for the geometric argument

Grothendieck now separates the part of his theory that depends on a notion of weak equivalence from the much stronger requirements imposed on fibrations. This is the point of retaining only W(1), W(3), and W(2 bis). The distinction is consequential: a map can have a well-behaved theory of lifting along arrows without preserving every weak equivalence under pullback. Throughout this section, a category is *W-aspherical* when its map to the terminal category belongs to W. For $W = W_\infty$, this means that its nerve has weakly contractible realization. The word does not mean that only its higher homotopy groups vanish; connectedness and trivial fundamental group are included.

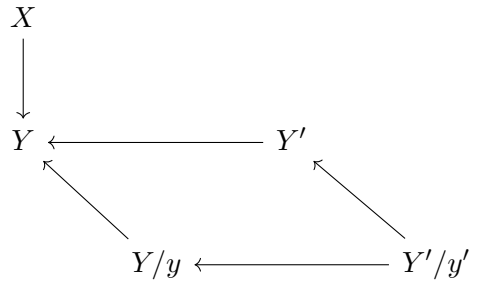
The notation for comma categories fixes the direction of every assertion that follows. For $f : X \to Y$, an object of X/y is a pair $(x, \alpha : f(x) \to y)$, whereas an object of $y\backslash X$ is $(x, \alpha : y \to f(x))$. The strict fibre X_y contains the objects mapping *equal* to y and only those arrows mapping to 1_y. Even when several objects of Y are isomorphic to y, they do not enter this strict fibre. These three categories solve different problems. The comma categories allow a comparison with y; the strict fibre requires equality over y.

An aspherical functor has all X/y aspherical. W(2 bis) then says that it belongs to W. This is the absolute form of Quillen's Theorem A. W(2), by contrast, tests a map $X \to Y$ over an arbitrary common base S through all $X/s \to Y/s$. The formally stronger axiom will be named again at the corollary on manuscript page 30; it is not imported into the preceding elementary proofs. In later terminology, the distinction is between the absolute and relative Theorem A axioms: Maltsiniotis (2012, §1.1) calls the version with the absolute axiom a *weak* fundamental localizer and reserves "fundamental localizer" for the relative version. Cisinski (2006a, Theorem 6.1.18) proves that the minimal weak fundamental localizer is W_∞. That minimality theorem does not assert that every weak fundamental localizer satisfies the relative axiom. The manuscript's terminology is still settling here.

The next propositions convert these axioms into geometric tests. Their economy comes from arranging a comparison so that a category with a terminal or initial object appears, and then using two-out-of-three. No model structure on Cat, and no derived direct-image functor, is needed for that argument.

On suppose donc par la suite donné un localiseur fondamental

$$W \subseteq \mathrm{Fl}(\mathrm{Cat}).$$



Proposition 1. *Soit $f : X \longrightarrow Y$ dans* Cat. *Conditions équivalentes :*

a) Pour tout isomorphisme local $Y' \longrightarrow Y$, $f' : X' \longrightarrow Y'$ est $\in W$.

b) Même condition, dans le cas particulier $Y' = Y/y \longrightarrow Y$, donc $\forall\ y \in Y$, $X/y \simeq X \times_Y (Y/y)$ est W-asphérique.

Définition 1. Sous ces conditions équivalentes a), b) de la proposition 1, on dit que f est *W-asphérique.* On dit [que] f est *W-coasphérique* si f° est W-asphérique, i.e. si les $y\backslash X$ sont W-asphériques (pour $y \in \mathrm{Ob}\, Y$). [page 23]

Démonstration. Il suffit de prouver b) $\Longrightarrow$ a). Par définition d'un isomorphisme local, on voit que la condition b) est stable par changement de base $Y' \longrightarrow Y$, avec Y' un isomorphisme local (puisque les $Y'/y' \xrightarrow{\sim} Y/y$, donc $X'/y' \xrightarrow{\sim} X/y$). Il suffit donc de voir que si f satisfait à b), alors $f \in W$. Mais c'est l'axiome W(2 bis).

Remarque. Si f a un adjoint à droite g, alors pour tout $y \in Y$, $X/y \simeq X/g(y)$, donc X/y a un objet final et est donc W-asphérique. Donc si f a un adjoint à droite (à gauche), alors f est W-asphérique (W-coasphérique). p. 20

Mais même si f n'a pas d'adjoint à droite, il y a quand même un adjoint généralisé

$$g : Y \longrightarrow X^\wedge$$

et on a

$$X/y \simeq X/g(y) \qquad \text{(pour l'inclusion pleinement fidèle } X \hookrightarrow X^\wedge),$$

donc $\mathrm{Top}(X/y)$ s'identifie au topos induit $\mathrm{Top}(X)/g(y)$. La condition f W-asphérique signifie donc que les faisceaux $g(y)$ dans $\mathrm{Top}(X)$ sont W-asphériques. Pour de nombreuses autres formulations équivalentes, je renvoie à Pursuing Stacks. [page 24]

Commentary · Exposition [ms. 23]

The generalized right adjoint is a presheaf of arrows

The passage through presheaves explains why the comma categories are the correct substitutes for an adjoint. Define

$$g(y)(x) = \mathrm{Hom}_Y(f(x), y), \qquad g : Y \longrightarrow [X^{\mathrm{op}}, \mathrm{Set}].$$

Precomposition makes $g(y)$ a presheaf on X, and postcomposition makes g covariant in y. Its category of elements has objects (x, α) and arrows $h : x \to x'$ satisfying $\alpha = \alpha' f(h)$. It is therefore exactly X/y. If $f \dashv r$, the adjunction identifies $g(y)$ with the representable presheaf $X(-, r(y))$; the category of elements then becomes $X/r(y)$ and has terminal object $1_{r(y)}$. The asphericity of a functor admitting a right adjoint is thus the representable case of the construction in the text.

The asserted identification of topoi can also be made explicit. For any presheaf P on X, a presheaf $A \to P$ determines on its category of elements the presheaf

$$(x, p) \longmapsto \{a \in A(x) : a \mapsto p\}.$$

Conversely, from a presheaf B on $\int_X P$, recover $A(x)$ as the disjoint union of $B(x,p)$ over all $p \in P(x)$. Restriction along $h : x \to x'$ uses the arrow $(x, P(h)p') \to (x', p')$. These operations are inverse up to their canonical isomorphisms and yield

$$[(\textstyle\int_X P)^{\mathrm{op}}, \mathrm{Set}] \simeq [X^{\mathrm{op}}, \mathrm{Set}]/P.$$

Taking $P = g(y)$ proves the statement about $\mathrm{Top}(X/y)$. Its use here is interpretive: the failure of an actual right adjoint is measured by the homotopy type of a presheaf of possible arrows, rather than by the absence of a distinguished representing object.

The commentary on Chapter I, manuscript pages 64–66, discusses local constancy and the Yoneda argument. Here the additional point is that an adjoint is sufficient but far from necessary: it supplies a terminal element of every comma category, while W-asphericity requires only their homotopical triviality.

Proposition 2. *Soit* $X \xrightarrow{f} Y \xrightarrow{g} Z$ *dans* Cat. *Si* f *et* g *sont* W*-asphériques (*W*-coasphériques), de même* gf*. Si* gf *et* f *sont* W*-asphériques (*W*-coasphériques),* g *aussi.*

Rappel. Un morphisme $p : S' \longrightarrow S$ dans Cat est un *isomorphisme local* si $\forall\ s' \in \mathrm{Ob}\, S'$, le morphisme induit

$$p_{s'} : S'/s' \xrightarrow{\sim} S/s \qquad (s = p(s'))$$

est un isomorphisme : p induit un isomorphisme sur les 'localisées' de S' et S en s' et $s = p(s')$ respectivement. Il est immédiat que cette notion est stable par composition, que si gf et g sont des isomorphismes locaux, alors f l'est aussi, que tout isomorphisme est un isomorphisme local. De plus, les isomorphismes locaux sont *stables par changement de base,* ce qui résulte du fait (trivial et important) que si on a un carré cartésien dans Cat

$$\begin{array}{ccc} X & \xleftarrow{q} & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ S & \xleftarrow{p} & S', \end{array}$$

et si $x' \in \mathrm{Ob}\, X'$ a pour image x, s', s dans X, S', S, alors le diagramme

$$\begin{array}{ccc} X/x & \xleftarrow{q/x'} & X'/x' \\ {\scriptstyle f/x}\downarrow & & \downarrow{\scriptstyle f'/x'} \\ S/s & \xleftarrow{p/s'} & S'/s' \end{array}$$

est également cartésien. (Donc si p/s' est `[un]` isomorphisme, q/x' aussi.)

Commentary · Exposition [ms. 24]

Local isomorphisms and the scope of cancellation

The "local isomorphisms" in this argument are discrete fibrations. Indeed, an isomorphism $S'/s' \to S/p(s')$ says that every arrow ending at $p(s')$ has exactly one lift ending at s', and that its factorization triangles lift uniquely. Conversely, that unique-lifting property gives the displayed isomorphism of slice categories. The categories of elements of presheaves supply the basic examples. In particular, $Y/y \to Y$ is such a map.

This description makes Proposition 1 transparent. If every X/y is W-aspherical and $q : Y' \to Y$ is a local isomorphism, then, for $y' \in Y'$ with image y, strict pullback gives

$$(X \times_Y Y')/y' \cong X/y.$$

Theorem A applied over Y' puts $X \times_Y Y' \to Y'$ in W. Conversely, the particular base changes $Y/y \to Y$ recover the same condition because Y/y has a terminal object.

The cancellation in Proposition 2 uses precisely this class of allowed base changes. Given $X \xrightarrow{f} Y \xrightarrow{g} Z$ and a local isomorphism $Z' \to Z$, form the three pullbacks X', Y', Z'. Its pullback $Y' \to Y$ is again a local isomorphism. Thus asphericity of f gives $f' \in W$. If g is also aspherical, $g' \in W$ and hence $g'f' \in W$. If instead gf is aspherical, then $g'f' \in W$ and two-out-of-three gives $g' \in W$. Proposition 1 now gives the two assertions. The opposite-category argument proves the coaspherical forms.

There is no cancellation statement with g and gf implying asphericity of f. For example, let f select the terminal object of [1], and let $g : [1] \to e$. Both g and gf are aspherical, whereas the comma category of f over 0 is empty. For any W with $\varnothing \to e \notin W$, f is not aspherical. This elementary directional distinction is exactly what the local-isomorphism proof preserves.

p. 21
[page 25]

Revenons à la proposition 2. La stabilité de la notion de morphisme asphérique par composition résulte aussitôt de la forme a) de la condition. De même pour la condition que si gf et f sont W-asphériques, g aussi - il faut montrer que si $Z' \longrightarrow Z$ est `[un]` isomorphisme local, alors g' est dans W, or l'hypothèse implique que $g'f'$ et f' le sont.

$$\begin{array}{ccc} X & \xleftarrow{r} & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ Y & \xleftarrow{q} & Y' \\ {\scriptstyle g}\downarrow & & \downarrow{\scriptstyle g'} \\ Z & \xleftarrow{p} & Z' \end{array}$$

Corollaire 1. *L'image inverse d'un $f : X \longrightarrow Y$ qui est W-asphérique (resp. W-coasphérique) par un isomorphisme local (resp. par un coïsomorphisme local) est W-asphérique (W-coasphérique).*

$$\begin{array}{ccccc} X & \longleftarrow & X' & \longleftarrow & X'' \\ \downarrow & & \downarrow & & \downarrow \\ Y & \underset{\text{iso local}}{\longleftarrow} & Y' & \underset{\text{iso local}}{\longleftarrow} & Y'' \end{array}$$

Résulte formellement de la définition par a) et du fait qu'un composé de deux isomorphismes locaux (resp. coïsomorphismes locaux) est itou.

NB Bien sûr, la notion de foncteur W-asphérique n'est pas stable par changement de base quelconque. Par exemple, l'inclusion $X = \{y_0\} \longrightarrow Y$ est W-asphérique si et seulement si les catégories discrètes $\mathrm{Hom}(y_0, y)$ sont W-asphériques, i.e. (sous réserve que l'on ait W(5), axiome de connexité) si et seulement si les $\mathrm{Hom}(y_0, y)$ sont de cardinal 1, i.e. y_0 *objet initial* de Y. Mais si $Y \neq \{y_0\}$, prenant y dans Y, $y \neq y_0$, et posant $Y' = \{y\} \longrightarrow Y$, on a $X' = X \times_Y Y' = \emptyset$ et $\emptyset \longrightarrow e$ n'est pas asphérique!

[page 26]

Par contre, on s'attend que les morphismes W-asphériques soient stables par changements de base W-*lisses* (qui généralisent les isomorphismes locaux), et les morphismes W-coasphériques par changements de base W-propres. Cf. plus bas.

Commentary · Exposition [ms. 26]

Properness asks for contractible categories of lifts

The anticipated base-change theorem needs a condition on the map along which one pulls back. Grothendieck finds it by inspecting every possible lift of an arrow. For $f : X \to Y$, an object $x \in X$, and $u : f(x) \to y$, write $L_f(x, u)$ for the category whose objects are arrows $a : x \to z$ with $f(a) = u$

and whose morphisms are arrows $h : z \to z'$ over 1_y satisfying $ha = a'$. Its morphisms matter as much as its objects: merely asking for at least one lift would lose the homotopy information.

Let $j_y : X_y \to X/y$ send z to $(z, 1_y)$. The object (x, u) of X/y gives an equality of categories

$$(x, u)\backslash j_y \cong L_f(x, u).$$

The same category is the strict fibre over u of $x\backslash X \to f(x)\backslash Y$. These identifications prove the equivalence of conditions (a), (b), and (d) in Proposition 3. The edition's intermediate list "a) b) c)" on manuscript page 27 should read "a) b) d)"; the remaining argument establishes (c).

To see that argument without suppressing an endpoint, pull f back along the arrow $u : [1] \to Y$. Write $E = X \times_Y [1]$. For an object in E_1, the comma category into $E_1 \hookrightarrow E$ has an initial object. For an object $(x, 0)$ in E_0, that comma category is $L_f(x, u)$. Consequently $E_1 \hookrightarrow E$ is coaspherical exactly when all these lift categories are aspherical. This is why a test over the walking arrow is sufficient for *properness*: the test asks for coasphericity of the inclusion, not merely that its total homotopy type be an equivalence.

The dual incoming-lift category consists of arrows $a : z \to x$ over a fixed $u : y \to f(x)$. Its morphisms are vertical factorizations. Requiring these categories to be W-aspherical defines smoothness. The terminology records two directions of the same lifting geometry. The commentary on Chapter I, manuscript pages 52 and 68, explains the coefficient-theoretic origin; here Grothendieck obtains the criterion directly from W.

Corollaire 2. *Soit $f : X \longrightarrow Y$ dans* Cat *une* équivalence *de catégories. Alors f est W-asphérique et W-coasphérique.*

En effet, f a un adjoint à gauche et un adjoint à droite, et on utilise la remarque page 23.

Proposition 3. *Soit $f : X \longrightarrow Y$ dans* Cat. *Conditions équivalentes :* p. 22

a) Pour tout $y \in \mathrm{Ob}\, Y$, le foncteur d'inclusion

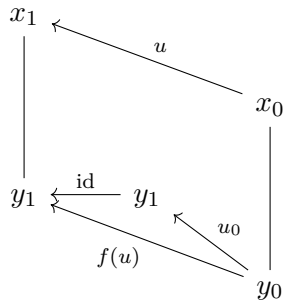
$$(*) \qquad X_y \longrightarrow X/y$$

*est W-co*asphérique.*

b) Pour tout $x_0 \in X$, le morphisme induit pour les colocalisées

$$x_0\backslash X \longrightarrow y_0\backslash Y \qquad (\text{où } y_0 = f(x_0))$$

est à fibres W-asphériques.



c) Pour tout morphisme $\mathbf{\Delta}^1 = Y' \longrightarrow Y$, considérons $X' = X \times_Y Y'$ sur $\mathbf{\Delta}^1$, l'inclusion $X'_1 \longrightarrow X'$ de la fibre fermée de X' (fibre sur le point fermé de Y') est W-coasphérique.

d) Pour toute flèche $u_0 : y_0 \longrightarrow y_1$ dans Y, et tout x_0 dans X_{y_0}, la catégorie $X(x_0; u_0)$ formée des flèches $u' : x_0 \longrightarrow x$ dans X de source x_0, et qui relèvent u `[plutôt` u_0`]`, *est W-asphérique.*

Démonstration. Pour expliciter la condition a), il faut expliciter la catégorie $\xi_0\backslash(X_y)$, [page 27] pour un objet quelconque $\xi_0 = (x_0, u_0)$ de X/y, $x_0 \in \mathrm{Ob}\, X$,

$$u_0 : y_0 \longrightarrow y_1 = y \quad \text{dans } Y, \text{ avec } y_0 = f(x_0).$$

Cette catégorie $\xi_0\backslash X_{y_1}$ s'explicite alors comme la catégorie des x_1 dans X_{y_1}, *munis* d'une flèche de ξ_0 dans l'image $\xi_1 = (x_1, \mathrm{id}_{f(x_1)} = \mathrm{id}_{y_1})$ de x_1 dans X/y_1 dans ξ_0 `[‘dans` ξ_0`’ à effacer]`, i.e. d'une flèche u de x_0 dans x_1, telle que $f(u)$ donne lieu au triangle commutatif dans Y, i.e. $f(u) = u_0$.

Donc c'est la catégorie notée $X(x_0; u_0)$ dans d). On voit tout de suite qu'elle est aussi isomorphe à la fibre de $x_0\backslash X \longrightarrow y_0\backslash Y$ en l'élément u_0 de $y_0\backslash Y$, dont il est question dans b). D'où l'équivalence de a) b) c). D'autre part, la donnée de u_0 dans Y équivaut à celle d'un foncteur $\mathbf{\Delta}^1 \longrightarrow Y$, comme dans c), et pour exprimer alors que $\underbrace{X'_1}_{\simeq X_{y_1}} \longrightarrow X'$ est coasphérique, il suffit d'exprimer que les $x'\backslash X'_1$ ($x' \in \mathrm{Ob}\, X'$) sont W-asphériques. Or c'est trivial si $x' \in \mathrm{Ob}\, X'_1$ (objet initial), donc il suffit de le vérifier pour x' dans $X'\backslash X'_1 = X'_0 \simeq X_{y_0}$. Alors x' s'identifie à un élément x_0 de X_{y_0}, et on vérifie tout de suite que $x_0\backslash X'_1$ est isomorphe à la catégorie $X(x_0; u_0)$ de d). Cela achève la démonstration.

Définition 2. Sous les conditions de la proposition 3, on dit que f est *W-propre.* On dit que f est *W-lisse* si f° est W-propre, i.e. si les morphismes d'inclusion $(*)$ `[plutôt` $X_y \longrightarrow y\backslash X$`]` sont W-asphériques etc. (conditions duales de celles de la proposition 3). p. 23 [page 28]

Remarque. La condition a) de la proposition 3 est satisfaite en particulier si l'inclusion $(*)$ a un adjoint à gauche (cf. remarque page 23). Cela signifie que les catégories $X(x_0; u)$ ont un objet initial. Cela signifie aussi que la catégorie X sur Y est Cat-cofibrée sur Y au sens faible, i.e. qu'il existe, pour $u_0 : y_0 \longrightarrow y_1$ flèche dans Y, et x_0 dans X_{y_0}, un objet $u_{0*}(x_0)$ dans X_{y_1} qui représente le foncteur covariant $X_{y_1} \longrightarrow$ (Ens), $x_1 \longmapsto \mathrm{Hom}_u(x_0, x_1)$. Ainsi, si X est Cat-cofibrée au sens faible sur Y, et a fortiori si elle est Cat-cofibrée, alors $f : X \longrightarrow Y$ est W-propre. Dualement, si f est faiblement Cat-fibrée, f est `[`W`-]`lisse.

Commentary · Examples [ms. 28]

Representable lifts and their homotopical relaxation

Grothendieck first places ordinary fibred categories inside the new theory. Fix $x \in X$ and $u : f(x) \to y$. An initial object $a : x \to u_*x$ of $L_f(x, u)$ gives, for every $z \in X_y$, a bijection

$$\mathrm{Hom}_{X_y}(u_*x, z) \xrightarrow{\sim} \{b : x \to z : f(b) = u\}, \qquad h \longmapsto ha.$$

Conversely, such a representing arrow is initial in $L_f(x, u)$. Choosing it for all (x, u) is the weak cofibred condition used here. It only asserts this factorization property for arrows over the fixed arrow u; the stronger condition on composition is part of the usual opfibration formalism. Either condition gives properness, since initial categories are W-aspherical. The dual argument gives smoothness for prefibrations.

A useful calculation shows how much weaker asphericity can be than representability. Let C be the poset with three objects b, d, e and relations $b < d$, $b < e$. Form its left cone $X = C^{\triangleleft}$ by adjoining an initial object a, and let $p : X \to [1]$ send a to 0 and C to 1. The outgoing-lift category from a over $0 \to 1$ is C itself. It is contractible because b is initial. This example is already a weak opfibration. To remove representability while retaining contractibility, replace C by the four-object fence

$$b < d, \qquad e < d, \qquad e < c.$$

Its nerve is the path $b - d - e - c$, hence contractible, but it has no initial object. In the corresponding cone, $L_p(a, 0 \to 1) \cong C$ is therefore aspherical without being representable by a universal lift. For every identity in the base, the lift category is a coslice in the appropriate fibre and has an initial object. There are no other base arrows to test. Thus this p is W_∞-proper but is not weakly opfibred.

The dual cone gives a smooth map without the prefibration property. Maltsiniotis (2005, Proposition 4.3 and Example 4.17) places these criteria in the broader language of asphericity

structures; for a structure coming from a fundamental localizer, the resulting weak smoothness criterion recovers W-smoothness. For an arbitrary asphericity structure those notions need not agree.

Proposition 4. ([43]) *La notion de morphisme W-propre est stable par composition, par changement de base. Les coisomorphismes locaux sont propres (trivial sur b)), a fortiori les isomorphismes sont propres, les immersions fermées sont propres.*

Énoncé dual pour les morphismes lisses : stabilité par changement de base, par composition, les isomorphismes locaux sont lisses, notamment les immersions ouvertes.

[page 29]

La stabilité par changement de base est immédiate sur la forme c). La stabilité par composition `[est]` moins triviale :

$$\begin{array}{lccccc} x & X & \longleftarrow & x\backslash X & \longleftarrow & \bar{X} \\ & \downarrow{\scriptstyle f} & & \downarrow & & \downarrow \\ y & Y & \longleftarrow & y\backslash Y & \longleftarrow & \bar{Y} \\ & \downarrow{\scriptstyle g} & & \downarrow & & \downarrow \\ z & Z & \longleftarrow & z\backslash Z & \longleftarrow & \{u\} \end{array}$$

Dans le diagramme à carrés cartésiens ci-contre `[plutôt dont les deux carrés de droite sont cartésiens]` (déduit de $x \in \mathrm{Ob}\, X$, d'où $y = f(x)$, $z = g(y) = gf(x)$, et de $u \in \mathrm{Ob}\, z\backslash Z$), il faut prouver que $\bar{X}$ est W-asphérique. On sait que $\bar{Y}$ l'est (g propre) et que $\bar{X} \longrightarrow \bar{Y}$ est à fibres W-asphériques. Il suffit donc d'utiliser la proposition 5 ci-dessous, et la remarque immédiate

Lemme. *Si f est propre, il en est de même de $x\backslash f : x\backslash X \longrightarrow y\backslash Y$, pour tout x dans X, $y = f(x)$.*

En effet, si u' est dans $x\backslash X$ et v' dans $y\backslash Y$, et si x', y' sont leurs images dans X, Y respectivement, alors

p. 24

$$u'\backslash(x\backslash X) \simeq x'\backslash X, \qquad v'\backslash(y\backslash Y) \simeq y'\backslash Y,$$

et la flèche entre les deux s'identifie à la flèche de localisation

$$x'\backslash X \longrightarrow y'\backslash Y.$$

Commentary · Exposition [ms. 29]

The composition proof has no circular dependence

The proof of composition proceeds by factoring a category of lifts through another category of lifts. It uses Proposition 5, but Proposition 5 itself needs only the definition of properness and the already established base-change stability. Thus its appearance after Proposition 4 does not create a circular proof.

First prove the part of Proposition 5 that will be used. If $q : A \to B$ is proper and every strict fibre A_b is aspherical, then $A_b \to A/b$ is coaspherical and hence belongs to W. Two-out-of-three makes A/b aspherical, and W(2 bis) gives $q \in W$. The same reasoning applies after every base change, because properness and the asphericity of the fibres persist. The smooth version follows by taking opposites.

Now let $X \xrightarrow{f} Y \xrightarrow{g} Z$ be proper. Fix $x \in X$ and $u : gf(x) \to z$. There is a functor

$$L_{gf}(x, u) \longrightarrow L_g(f(x), u), \qquad a \longmapsto f(a).$$

43. Dire aussi : Si $X \xrightarrow{f} Y \xrightarrow{g} Z$, si gf et f W-lisses, alors g est lisse en les points de $\mathrm{Im}\, f$, idem pour propre.

It is the base change of $x\backslash f : x\backslash X \to f(x)\backslash Y$ along the fibre of $f(x)\backslash g$ over u. The coslice functor $x\backslash f$ is proper: taking the coslice at an arrow $x \to x'$ reduces its incoming data to $x'\backslash X \to f(x')\backslash Y$, precisely the original lifting test. Its displayed base change is therefore proper. The fibre over a lift $v : f(x) \to y'$ is $L_f(x, v)$, which is aspherical. Proposition 5 makes the displayed functor a W-equivalence. Since its target is aspherical by properness of g, its source is aspherical too. This proves properness of gf.

The same diagram proves the observation in footnote 43. If f and gf are proper, its source is aspherical, and the displayed proper functor still has aspherical fibres. Its target is therefore aspherical. This proves the lifting condition for g at every object $f(x)$ in the strict image of f; it does not assert anything about objects outside that image. Duality proves the smooth statement. These arguments require W(2 bis), not the full relative axiom W(2).

Proposition 5. *Soit $f : X \longrightarrow Y$ dans* Cat*, supposons f W-propre ou W-lisse, et à fibres W-asphériques, alors $f \in W$ (et même f est* universellement *dans W, i.e. il est dans W et le reste par tout changement de base).*

Comme les hypothèses sont stables par changement de base, il suffit de prouver $f \in W$. [page 30] Supposons p. ex. f propre, prouvons que f est *W-asphérique*, i.e. que les X/y ($y \in \mathrm{Ob}\ Y$) sont W-asphériques. Mais $X_y \longrightarrow X/y$, étant W-coasphérique par hypothèse de propreté, est dans W (par W(2 bis)), et comme X_y est W-asphérique par hypothèse, X/y aussi. Mais par W(2 bis), f W-asphérique $\Longrightarrow f \in W$. Le cas f lisse est dual.

Remarque. Ainsi, si f est propre, s'il est à fibres W-asphériques il est 'universellement W-asphérique', i.e. est et reste W-asphérique par tout changement de base. Inversement, si f est universellement dans W (pas forcément propre), alors en particulier ses fibres sont W-asphériques. Mais ça n'implique bien sûr pas que f soit propre, ou lisse ([44]).

Commentary · Examples [ms. 30]

A universal equivalence with neither lifting property

The qualification after Proposition 5 has a small model which makes the role of the lifting condition visible. Let P be the poset with objects u, v, w, z and exactly the strict relations

$$u < v, \qquad u < z, \qquad w < z.$$

Define $p : P \to [1]$ by $p(u) = p(v) = 0$ and $p(w) = p(z) = 1$. Both fibres are intervals, and the nerve of P is the path $v - u - z - w$. More is true than the contractibility of these three nerves: p has a contraction over its base.

The section $s : [1] \to P$ selects u and z. Let $R : P \to P$ send v to u and fix u, w, z. Each displayed relation is preserved, so R is a functor over $[1]$. The pointwise inequalities give natural transformations over $[1]$

$$\mathrm{id}_P \longleftarrow R \longrightarrow sp.$$

For the first transformation use $u \to v$ at v; for the second use $w \to z$ at w; all remaining nonidentity components are absent. Since $ps = \mathrm{id}_{[1]}$, these transformations exhibit p as a homotopy equivalence of categories over $[1]$. After any base change $T \to [1]$, the section and both transformations pull back, so $P \times_{[1]} T \to T$ is still a homotopy equivalence. It therefore belongs to every W considered in this section.

Nevertheless p is not W_∞-proper: the arrow $0 \to 1$ has no outgoing lift from v, so its lift category is empty. Nor is it W_∞-smooth: the same arrow has no incoming lift ending at w. Thus universal membership in W does not imply either geometric lifting property. The same failure holds for any W for which the empty category is not aspherical.

This also verifies the terminology in footnote 44. A universal W-equivalence is universally aspherical because, after any base change and any further local-isomorphism test, one is still taking a base change of the original map. The four-object example is universally aspherical and universally coaspherical without being proper or smooth. The latter properties inspect the lift category at each particular object, which a relative contraction may move.

44. Mais 'universellement dans W' implique déjà 'universellement W-asphérique', puisque la notion de W-asphéricité est définie par `[la]` proposition 1 a).

Corollaire. *Si W satisfait* W(2) (pas seulement W(2 bis))*, alors pour un S-morphisme $X \longrightarrow Y$ de catégories qui sont toutes deux W-propres sur S, ou toutes deux W-lisses, si $f_s : X_s \longrightarrow Y_s$ est dans W pour tout $s \in S$, alors $f \in W$.*

Supposons p. ex. f propre, considérons, pour $s \in \mathrm{Ob}\ S$ [page 31]

$$\begin{array}{ccc} X_s & \xrightarrow{f_s} & Y_s \\ {\scriptstyle i_s^X}\downarrow & & \downarrow{\scriptstyle i_s^Y} \\ X/s & \xrightarrow{f/s} & Y/s, \end{array}$$

comme X, Y [sont] propres, les flèches verticales sont dans W (il suffirait de beaucoup moins que la propreté …), donc $f_s \in W \Longrightarrow f/s \in W$. Ainsi, '$f$ est dans W localement sur S', ce qui implique $f \in W$ par W(2).

Commentary · Exposition [ms. 31]

Fibrewise comparison uses the structural maps

The corollary compares two families over S; it does not assume that the comparison $f : X \to Y$ is itself proper. The phrase "Supposons p. ex. f propre" at the start of the proof is an edition slip. The case being considered is that both structural maps $X \to S$ and $Y \to S$ are proper. This is confirmed by the next sentence and by the two vertical arrows in the displayed square.

In fact, the proof needs only

$$X_s \longrightarrow X/s \in W, \qquad Y_s \longrightarrow Y/s \in W \quad \text{for every } s \in S.$$

If the fibre map f_s belongs to W, the commutative square and two-out-of-three imply $f/s \in W$. The remaining step from all these slice comparisons to $f \in W$ is exactly the relative axiom W(2). Replacing all slices by coslices gives the smooth case, using the opposite form of the same axiom.

This distinction will persist when properness is weakened to preproperness. The geometric hypothesis supplies comparisons between fibres and comma categories; the relative localization axiom assembles the comma comparisons over the whole base. There is no appeal to the converse assertion that a weak equivalence between total categories must be a weak equivalence on fibres. That substantially stronger assertion belongs to the fibration discussion later in this chapter.

p. 25

Proposition 6. *Soit*

$$\begin{array}{ccc} X & \xleftarrow{q} & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ S & \xleftarrow[p]{} & S', \end{array}$$

cartésien dans Cat. *Si f* [est] *W-asphérique, p W-lisse, alors f' est W-asphérique.*

Il faut prouver [que] $X' \times_{S'} S'/s'$ est W-asphérique ($s' \in \mathrm{Ob}\ S'$). Soit $s = p(s')$, on a

$$\begin{array}{ccccc} S & \xleftarrow{p} & S' & & \\ & \nwarrow & & \nwarrow & \\ & & S/s & \xleftarrow[p_0]{} & S'/s', \end{array}$$

avec p_0 W-lisse (lemme p. 28 [plutôt 29]) et à fibres W-asphériques, donc une W-équivalence universelle (prop. 5). Comme l'image inverse de X sur S/s est W-asphérique (hypothèse pour f), il [s'ensuit]

que dans le carré cartésien ci-contre [ci-dessous] [page 32]

$$(*)\qquad \begin{array}{ccc} X/s & \xleftarrow{W} & X'/s' \\ \downarrow & & \downarrow \\ S/s & \xleftarrow{W} & S'/s' \end{array}$$

les flèches horizontales sont dans W, et la première flèche verticale l'est par hypothèse sur f, donc la seconde aussi, donc X'/s' `[est]` W-asphérique.

Commentary · Exposition [ms. 32]

Why smooth base change preserves asphericity

Grothendieck's anticipated stability theorem now follows from the same categories of lifts, with the two variables interchanged. For a smooth $p : S' \to S$ and $s' \in S'$, put $s = p(s')$ and consider

$$p_{s'} : S'/s' \longrightarrow S/s.$$

The dual of the coslice lemma makes $p_{s'}$ smooth. Its strict fibre over an arrow $v : t \to s$ is the category of incoming lifts of v ending at s'. Smoothness of p says that this category is aspherical. Proposition 5 therefore makes $p_{s'}$ a universal W-equivalence.

For an arbitrary $X \to S$, the square

$$\begin{array}{ccc} (X \times_S S')/s' & \longrightarrow & X/s \\ \downarrow & & \downarrow \\ S'/s' & \xrightarrow[p_{s'}]{} & S/s \end{array}$$

is a strict pullback. An object of either description of its upper-left corner is a pair (x, t') together with an arrow $t' \to s'$ and the equality $f(x) = p(t')$; the arrow conditions agree as well. Its top map belongs to W, independently of any assumption on X. If $X \to S$ is aspherical, X/s is aspherical, so the top map makes the upper-left category aspherical. This proves Proposition 6.

For the corollary, apply this same universal equivalence once to X and once to Y. If $f : X \to Y$ over S satisfies $f/s \in W$, the commutative comparison square with horizontal arrows in W gives $f'/s' \in W$. Thus smooth pullback preserves W_S^{g}, the class detected on all over-categories. Opposite categories give the preservation of W_S^{d} by proper pullback. Neither argument needs the extra inference $W_S^{\mathrm{g}} \subseteq W$; accordingly the proof works with W(2 bis) alone.

Corollaire (généralise `[1a]` prop. 6, obtenue en faisant $Y = S$). *Soit $p : S' \longrightarrow S$* `[un]` *morphisme W-lisse dans* Cat. *Alors le foncteur changement de base*

$$\mathrm{Cat}/S \longrightarrow \mathrm{Cat}/S'$$

est compatible avec les localiseurs W_S^{g}, $W_{S'}^{\mathrm{g}}$, i.e. transforme $f : X \longrightarrow Y$ qui est dans W localement *sur S, dans $f' : X' \longrightarrow Y'$ dans W localement sur S'.*

Cette fois, on regarde le diagramme similaire à $(*)$

$$\begin{array}{ccccc} X/s & \xleftarrow{W} & X'/s' & & \\ & \searrow^{f/s} & \downarrow & \searrow^{f'/s'} & \\ & & Y/s & \xleftarrow{W} & Y'/s' \\ \downarrow & \swarrow & \downarrow & \swarrow & \\ S/s & \xleftarrow{W} & S'/s', & & \end{array}$$

où les flèches horizontales sont dans W, donc $f/s \in W$ (hypothèse) implique $f'/s' \in W$.

Dualement, si p est W-propre, le foncteur image inverse est compatible avec les localiseurs W_S^{d}, $W_{S'}^{\mathrm{d}}$. p. 26 [page 33]

Commentary · Later developments [ms. 33]

The passage from lifting categories to exact squares

The geometry just proved is the ingredient that later formulations package as exactness of squares. The term "proper" is justified by a universal base-change property; "smooth" describes the corresponding property when it is the map of bases that varies. The connection with the geometric proper and smooth base-change theorems, already discussed in the commentary on I.72, is made explicit in Maltsiniotis (2005, Introduction and Theorem 1.2).

The precise categorical statement appears in Maltsiniotis (2012, Propositions 2.12–2.13): a cartesian square with proper right side or smooth bottom side is W-exact, and the universal square condition characterizes properness. Its derivator interpretation is given by Theorem 4.32 of that paper, where cohomological base change is characterized through the appropriate weak exactness condition. These assertions explain why the lifting categories in the present text are sufficient; they are the categories appearing in pointwise base-change comparisons.

There is a convention to keep visible when comparing modern derivator texts. Grothendieck's coefficients here are contravariant diagrams. If a derivator is written with covariant diagrams instead, opposite categories exchange fibrations and opfibrations and interchange the two directions of the statement. In that convention Groth (2013, Propositions 1.24 and 1.26) proves base change for cartesian squares with a Grothendieck fibration on the right or an opfibration at the bottom, and identifies this property with the pointwise Kan-extension axiom. The apparent reversal has this variance explanation.

These developments do not identify every strict pullback with a homotopy pullback. An exact square controls a specified comparison of Kan extensions. Here the point is that properness or smoothness makes the relevant comma-category comparison cofinal in the required direction. The construction can therefore be transported to other coefficient theories without choosing path objects in each one separately.

Si $f : X \longrightarrow S$ est W-propre, on va définir un foncteur canonique

$$\begin{array}{rccc} \mathrm{hot}_*^{X/S,W} : S & \longrightarrow & \mathrm{Hot}_W \overset{\text{déf}}{=} (\mathrm{Cat})W^{-1} \\ \text{donné sur les objets par} \quad s & \longmapsto & \mathrm{hot}_W(X_s). \end{array}$$

Il faut définir, pour une flèche u dans S, $u : s \longrightarrow s'$, une flèche

$$\mathrm{hot}_W(X_s) \longrightarrow \mathrm{hot}_W(X_{s'})$$

dans Hot_W - flèche que nous pouvons noter $\mathrm{hot}_*^{X/S,W}(u)$. On la définit par le diagramme

$$\begin{array}{ccc} X_s & \cdots\cdots\cdots\cdots\cdots\cdots\rightarrow & X_{s'} \\ \Big\downarrow{\scriptstyle i_s^X} & & \Big\downarrow{\scriptstyle i_{s'}^X} \\ X/s & \xrightarrow{X/u} & X/s', \end{array}$$

où les flèches verticales sont W-coasphériques, donc dans W. Ce sont donc des isomorphismes dans Hot_W, d'où l'unique flèche en pointillés dans Hot_W, rendant le carré commutatif. Sur cette définition il est immédiat que

$$u \longmapsto \mathrm{hot}_W(u)$$

est compatible avec composition, et unités.

Ce foncteur est donc défini en supposant seulement que les [page 34]

$$X_y \longrightarrow X/y$$

sont dans W, ce qui est nettement moins fort que propre. Si on suppose que cette hypothèse est satisfaite 'universellement' (i.e. reste satisfaite après tout changement de base $S' \longrightarrow S$)

([45]), alors on a donc, pour tout S' dans Cat/S, un foncteur

$$\mathrm{hot}_*^{X'/S',W} : S' \longrightarrow \mathrm{Hot}_W,$$

et on vérifie tout de suite que ce n'est autre que le composé dans

p. 27

$$(*) \qquad \begin{array}{ccc} S' & \xrightarrow{\quad p \quad} & S \\ & {\scriptstyle \mathrm{hot}_W^{X'/S'}} \searrow \quad \swarrow {\scriptstyle \mathrm{hot}_W^{X/S}} & \\ & \mathrm{Hot}_W & \end{array}$$

[plutôt $\mathrm{hot}_*^{X'/S',W}$ resp. $\mathrm{hot}_*^{X/S,W}$]. On a des observations duales si X est lisse sur S, plus généralement si les inclusions

$$X_s \longrightarrow s\backslash X$$

sont dans W. On trouve alors un contrafoncteur

$$\begin{cases} S^\circ & \longrightarrow & \mathrm{Hot}_W \\ s & \longmapsto & \mathrm{hot}_W(X_s) \\ u & \longmapsto & \mathrm{hot}^*_{X/S,W}(u) \text{ ou } \mathrm{hot}^*_{X/S}(u) \end{cases}$$

et une compatibilité similaire à $(*)$, si l'hypothèse est satisfaite *universellement* sur S, p. ex. f W-lisse. [page 35]

Commentary · Exposition [ms. 35]

Transport obtained by conjugating the comma functor

To construct transport, Grothendieck uses a functor that already exists before localization. Let $Q : \mathrm{Cat} \to \mathrm{Hot}_W$ be the localization. The assignment

$$s \longmapsto X/s, \qquad (u : s \to t) \longmapsto (X/u) : (x, \alpha) \longmapsto (x, u\alpha)$$

is a strict functor $S \to \mathrm{Cat}$. If $i_s : X_s \to X/s$ belongs to W for every s, define

$$\lambda(u) = Q(i_t)^{-1} Q(X/u) Q(i_s).$$

The existence of the inverse is the only use of the hypothesis. For $s \xrightarrow{u} t \xrightarrow{v} r$, multiplication cancels $Q(i_t)$ against its inverse and gives

$$\lambda(v)\lambda(u) = Q(i_r)^{-1} Q(X/v) Q(X/u) Q(i_s) = \lambda(vu).$$

The identity case follows in the same way. Thus the word "functor" is justified by the comma construction, not by a choice of lifts in the strict fibres.

For base change $q : S' \to S$, the canonical maps $X'/s' \to X/q(s')$ form a natural transformation of these comma diagrams, and the square with $X'_{s'} \cong X_{q(s')}$ and the two inclusions commutes. If both inclusions belong to W, two-out-of-three puts the comma comparison in W and the displayed formula gives precisely the compatibility asserted in the text. Requiring the inclusion hypothesis after every base change is the definition of W-preproperness in footnote 45. Opposite categories give W-presmoothness, called W-prélissité in the source, and a contravariant transport functor.

Properness is a practical sufficient condition because it says more: each i_s is coaspherical. Preproperness keeps the universal weak-equivalence conclusion and discards its local lifting explanation. Neither should be confused with the condition on the two endpoint inclusions over individual arrows considered on manuscript page 36. As the development below shows, those individual comparisons need not obey the displayed composition law.

Proposition 7. *Supposons $f : X \longrightarrow S$ à la fois W-propre et W-lisse, plus généralement que les morphismes*

$$X_s \longrightarrow X/s, \qquad X_s \longrightarrow s\backslash X \qquad (s \in S)$$

45. On dira que f est *W-préproper.*

soient dans W, et que cette hypothèse reste verifiée après tout changement de base. Alors les foncteurs correspondants

$$\lambda = \mathrm{hot}_*^{X/S,W} : \quad S \longrightarrow \mathrm{Hot}_W$$
$$\lambda^\circ = \mathrm{hot}^*_{X/S,W} : \quad S^\circ \longrightarrow \mathrm{Hot}_W$$

transforment toute flèche u de S en [un] *isomorphisme de* Hot_W*, et on a*

$$\lambda^\circ(u) = \lambda(u)^{-1} \qquad \textit{dans} \quad \mathrm{Hot}_W,$$

i.e. $\lambda(u)$ et $\lambda^c irc(u)$ sont inverses l'un de l'autre.

Démonstration. La donnée de $u : s_0 \longrightarrow s_1$ équivaut à celle de

$$S' = \mathbf{\Delta}^1 \longrightarrow S,$$

d'où

$$X' = X \times_S S' \qquad \text{sur } S' = \mathbf{\Delta}^1,$$

avec les deux fibres

$$X'_0 \simeq X_{s_0}, \qquad X'_1 \simeq X_{s_1}.$$

L'hypothèse assurant l'existence de λ s'exprime par la condition que

$$X'_1 \longrightarrow X'/1 \simeq X'$$

est dans W, de sorte que le diagramme

$$X'_0 \xrightarrow{i_0} X' \xleftarrow[W]{i_1} X'_1$$

p. 28
[page 36]

définit une flèche $\lambda(u) : X'_0 \longrightarrow X'_1$ dans Hot_W, savoir $\lambda(u) = i_1^{-1} i_0$. L'hypothèse qui assure l'existence de λ° s'exprime par la condition symétrique $i_0 \in W$, qui permet de définir la flèche $\lambda^\circ(u) : X'_1 \longrightarrow X'_0$ par $\lambda^\circ(u) = i_0^{-1} i_1$. Quand les deux conditions sont satisfaites simultanément, on voit donc que $\lambda(u)$, $\lambda^\circ(u)$ sont inverses l'un de l'autre.

Commentary · Examples [ms. 36]

Two directions of transport give monodromy

Proposition 7 says that the two canonical transports become inverse when both comma comparison hypotheses hold universally. Pulling back over $u : [1] \to S$ gives $E = X \times_S [1]$ and inclusions $i_0 : X_{s_0} \to E$, $i_1 : X_{s_1} \to E$. Preproperness makes i_1 a W-equivalence, and presmoothness makes i_0 one. The already constructed functors therefore satisfy

$$\lambda(u) = Q(i_1)^{-1} Q(i_0), \qquad \lambda^{\mathrm{op}}(u) = Q(i_0)^{-1} Q(i_1).$$

These formulas prove the claimed inverse relation without an additional saturation assumption. The covariant functor factors through the ordinary groupoid completion $S[\mathrm{Mor}(S)^{-1}]$. It records transport around loops, or monodromy, at the level of the homotopy category.

For a concrete example, let $C_2 = \{1, \sigma\}$ act on the discrete set $F = \{0, 1\}$ by interchange. Regard BC_2 as the one-object groupoid. The action groupoid E has objects $0, 1$ and an arrow labelled g from x to gx. The projection $E \to BC_2$ is both a fibration and an opfibration: every base arrow has a unique incoming and a unique outgoing lift once the appropriate endpoint is specified. Its strict fibre is F. The transport along σ interchanges the two points, in both directions, since $\sigma^{-1} = \sigma$.

The action is free and transitive, so there is exactly one arrow between each ordered pair of objects of E. Either object is consequently both initial and terminal, and BE is contractible. The base has fundamental group C_2, while the fibre consists of two points. This is the usual universal two-sheeted covering expressed entirely by categories. It illustrates why the fibre functor and its monodromy carry information that the homotopy type of the total category alone does not retain. It also illustrates the scope of Proposition 7: it gives a functor into Hot_W, not a claim that ordinary homotopy-category monodromy classifies all homotopy-coherent families.

Remarques. Pour définir λ 'universellement', il n'était pas indispensable de considérer les X/s et les inclusions $X_s \longrightarrow X/s$, au lieu de cela il suffisait de regarder les changements de base $S' = \mathbf{\Delta}^1 \xrightarrow{u} S$, et de faire l'hypothèse que pour tout tel changement de base, l'inclusion $X'_1 \xrightarrow{i_1} X' = X_{(\mathbf{\Delta}^1, u)}$ est dans W. Cette hypothèse est automatiquement stable par changement de base arbitraire. (La W-propreté de $f : X \longrightarrow S$ signifie que $X'_1 \longrightarrow X'$ est non seulement dans W, mais même W-coasphérique.) Dualement, pour la définition 'universelle' de λ°, il suffirait que pour tout changement de base $\mathbf{\Delta}^1 \longrightarrow S$ comme dessus, l'inclusion $X'_0 \xrightarrow{i_0} X'$ est dans W.

Commentary · Development (commentators') [ms. 36]

An eight-object obstruction to edge transport

Grothendieck proposes to replace the universal comma comparisons by endpoint comparisons over the walking arrow. Those tests do define a morphism for each arrow of the base, but they do not by themselves make these morphisms functorial. The distinction is already visible on connected components, and also answers the question about pseudofibrations on manuscript page 40.

Proposition (edge tests do not force coherence). [ours] There exists a functor $p : P \to [2]$ such that, for every $u : [1] \to [2]$, both endpoint inclusions into $P \times_{[2]} [1]$ belong to W_∞, but the resulting edge transports fail the composition law. Moreover, p does not satisfy the fibration test over contractible bases.

Proof. Indices will be taken modulo 2. Let P have eight objects

$$a_0, a_1, b_0, b_1, d_0, d_1, c_0, c_1,$$

and exactly the following nonidentity order relations:

$$a_i < d_i, \qquad b_i < d_i, \qquad b_i < c_i, \qquad a_i < c_{1-i} \quad (i = 0, 1).$$

Every relation starts at an a_i or a b_i and ends at a d_i or a c_i. Thus no two strict relations are composable, and the list already defines a transitive partial order. Define $p(a_i) = 0$, $p(b_i) = p(d_i) = 1$, and $p(c_i) = 2$. All listed relations preserve this order, so p is a functor.

The fibre P_0 is the discrete pair $\{a_0, a_1\}$, the fibre P_1 is the disjoint union of the two intervals $b_i < d_i$, and P_2 is the discrete pair $\{c_0, c_1\}$. For the nonidentity base arrow $0 \to 1$, the pullback is the disjoint union of the two posets $a_i < d_i > b_i$. Each component has terminal object d_i, and each endpoint fibre meets it in a nonempty contractible subcategory. Both endpoint inclusions are therefore weak homotopy equivalences. For $1 \to 2$, the two components are $d_i > b_i < c_i$; each has initial object b_i, and the same conclusion follows. For $0 \to 2$, the pullback consists of the two intervals $a_i < c_{1-i}$, so again both endpoint inclusions are weak equivalences. A constant functor $[1] \to [2]$ has pullback $P_j \times [1]$; its endpoint inclusions are categorical homotopy equivalences. These six functors exhaust all $[1] \to [2]$, proving every required edge test.

Label the two connected components of each fibre by i. The span through the $0, 1$ pullback identifies component i with component i; so does the span through the $1, 2$ pullback. The $0, 2$ pullback instead identifies i with $1 - i$. Thus the maps induced on π_0 satisfy

$$\pi_0\lambda(0 \to 1) = 1, \qquad \pi_0\lambda(1 \to 2) = 1, \qquad \pi_0\lambda(0 \to 2) = (0\ 1).$$

Since π_0 sends W_∞ to bijections, it factors through Hot, and these unequal functions prove that the proposed transports cannot form a functor into Hot.

For completeness, the nerve of P has eight vertices, eight nondegenerate edges, and no higher nondegenerate simplices. Those edges form exactly the cycle

$$a_0 - d_0 - b_0 - c_0 - a_1 - d_1 - b_1 - c_1 - a_0.$$

Its realization is therefore a circle. Each fibre has two connected components, whereas P is connected. Consequently none of the inclusions $P_j \to P$ is in W_∞, although the base $[2]$ has both an initial and a terminal object. This disproves the stronger fibration condition over contractible bases and completes the proof.

The counterexample also satisfies the edge tests for W_0, the localizer detected by connected components, and has the same failure of composition there. The issue is therefore not a higher-dimensional obstruction inside the fibres. The missing information is how transports for composable

arrows agree across a triangle in the base. The universal comma hypotheses used in Proposition 7 supply precisely the strict diagram from which that agreement was obtained. We checked the lift-category and smoothness treatments in Maltsiniotis (2005, §4) and Maltsiniotis (2012, §§1–2); we did not find this finite example there. This is a development of the manuscript's question, with no claim of priority.

La notion la plus faible raisonnable de W-fibré, me semble être celle où on suppose les [page 37]
deux choses à la fois. Les hypothèses qu'on a faites jusqu'à présent, à l'exclusion de la forme forte de W-propreté ou de W-lissité, reviennent toujours à supposer que le *changement de base par* $f : X \longrightarrow S$ transforme certaines flèches dans Cat/S en `[élément de]` W : Pour définir λ, ces flèches sont

$$\text{soit } \{s\} \longrightarrow S/s, \qquad \text{soit } \{1\} \longrightarrow \mathbf{\Delta}^1(\longrightarrow S),$$

pour définir λ°, ce sont

$$\text{soit } \{s\} \longrightarrow s\backslash S, \qquad \text{soit } \{0\} \longrightarrow \mathbf{\Delta}^1(\longrightarrow S),$$

le 'soit' suivant la définition qu'on a adoptée. Dans ces exemples, il s'agit toujours de l'inclusion de l'objet final d'une catégorie S', dans ladite, ou inversement de l'objet initial. Cela montre d'ailleurs (si on exige l'universalité), que la première hypothèse (assurant λ) est *exactement* cela (cas de l'inclusion d'un objet final s' - puisque pour un tel objet, on a $S'/s' \simeq S'$), tandis que la deuxième hypothèse exige moins, seulement pour le cas de $\mathbf{\Delta}^1$. Et dualement pour λ' `[plutôt` λ°`]`. Mais il convient de noter que pratiquement, la façon la plus commode, et de loin,

pour vérifier de telles propriétés, c'est soit par la W-propreté de f, soit par la W-lissité - ce qui ramène à vérifier que certaines catégories bien précisées sont W-asphériques, sans avoir [page 38]
à se soucier de changements de base et de vérifier que les flèches construites en termes de changements de base arbitraires sont dans W. Et l'emploi de la W-propreté et de la W-lissité est d'autant plus sympathique, que ces notions sont stables par composition,

alors que toutes les notions dérivées, ainsi que les notions de fibrations à la clef, ont une fâcheuse tendance à ne *pas* être stable par composition. p. 29

On pourrait appeler pseudo-W-propre resp. quasi-W-propre (un peu mieux que pseudo) ce qu'on vient de dégager - j'entends des ricanements! Et si on veut les deux à la fois - λ et λ° associés comme on a dit? Je vois le même principe de description avec des $S'' \longrightarrow S'$ sur S, d'exiger que $X'' \longrightarrow X'$ soit transformé en des `[éléments de]` W. Avec les choix suivants qui ont l'air sympathique

a$_1$) Y' a un objet final, $Y'' = e$. La définition revient donc à la condition que les [page 39]

$$X_s \longrightarrow X/s, \qquad X/s' \longrightarrow X/s$$

(pour $s \in \mathrm{Ob}\, S$ où $u : s' \longrightarrow s$ dans S) soient dans W, et que ça reste comme ça après tout changement de base $S' \longrightarrow S$.

a$_2$) Y' a un objet initial, $Y'' = e$, c'est la condition duale à coups de

$$X_s \longrightarrow s\backslash X, \qquad s\backslash X \longrightarrow s'\backslash X.$$

a$_0$) $Y' = \mathbf{\Delta}^1$, $Y'' = e$ ([46]).

b) Y' est contractile, Y'' aussi (ou au choix, Y' contractile, $Y'' = e$)

donc la condition revient à ceci : pour toute Y' sur Y *contractile* (notion indépendante de W, c'est ça son principal avantage) les inclusions des fibres de $X' = X \times_Y Y'$ sur Y' dans X' sont `[dans]` W.

46. NB a$_1$), a$_2$) sont notés pareil p. 4, mais a$_0$) a été oublié.

Commentary · Exposition [ms. 39]

The test objects explain the hierarchy

The proposed definitions differ by the category that is allowed to serve as a test base. For condition a_1, a base T with terminal object t is tested at *every* object $r \in T$, not only at t. Testing the terminal object gives preproperness. Once it is available, the unique arrow $r \to t$ identifies the comparison $X_r \to X_T$ with transport to the terminal fibre. Requiring that comparison to belong to W adds the demand that all such transports be weak equivalences. The dual reading gives a_2.

Condition a_0 restricts the base to [1] and allows either endpoint. The preceding eight-object example shows that it cannot be substituted for a_1 or a_2, even for ordinary weak homotopy equivalences. In particular, existence of individually invertible edge roofs is not a substitute for a functor of fibres. This is the reason for keeping the preproper or presmooth hypothesis in the equivalences proved later in the section.

For condition b, the equivalence of the two tests stated in the text has a short proof. Suppose all fibre inclusions are in W over every categorically contractible test base. If $v : T'' \to T'$ is a map between two such bases, choose an object t''; contractibility ensures that an object exists. In the pullback square, the fibre at t'' identifies with the fibre at $v(t'')$. The two inclusions from that common fibre into the total categories both belong to W, so their commutative triangle puts the total pullback map in W by two-out-of-three. The converse is the special case $T'' = e$.

Condition b' allows W-aspherical bases instead. Condition c allows every map in W as a change of base. Its stronger quantifier is substantial: it asks for preservation of a whole class of weak equivalences, whereas the earlier conditions test selected contractible shapes. The terminology at this point is provisional, but these quantifiers are exact and should be retained when comparing later definitions.

Je sens que même pour des W générales, b) reste du domaine du vérifiable, tandis qu'on mollit si on passe à l'extrême en généralité dans ce sens :

b′) Comme b), mais en supposant seulement Y' W-asphérique ([47]).

Enfin (la condition a) de la page 4)

c) Si $Y'' \longrightarrow Y'$ est `[dans]` W sans plus, $X'' \longrightarrow X'$ aussi.

La seule de ces notions qui ait la moindre envie d'être stable par composition, c'est la plus forte c). Par contre, la notion de flèche W-parfaite (cf. déf. 3) est stable spontanément par composition : p. 30 [page 40]

Définition 3. On dit que $f : X \longrightarrow S$ est *W-parfaite* si elle est à la fois W-propre et W-lisse.

Commentary · Exposition [ms. 40]

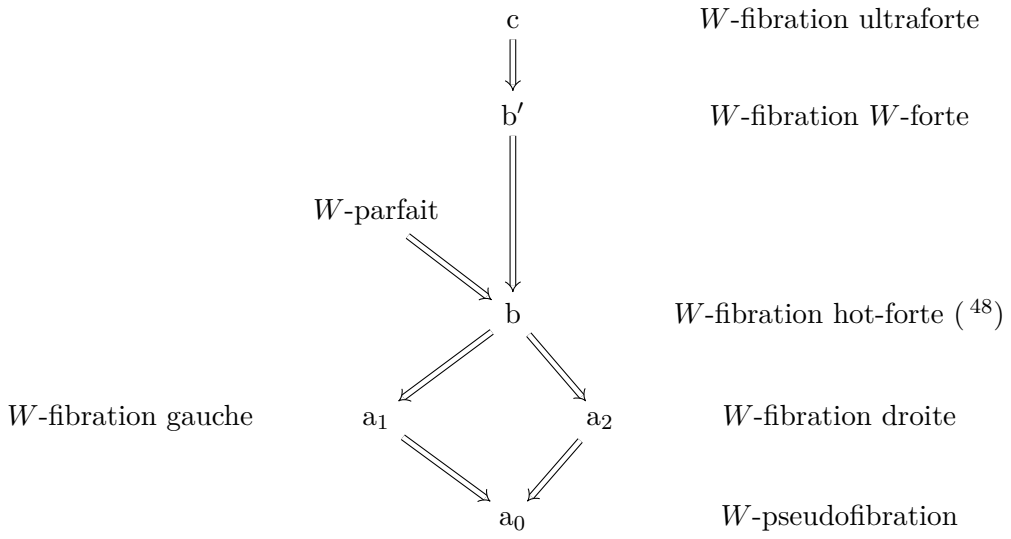
The interval test and the full fibration condition

Grothendieck is trying to retain the mobility of fibres without asking that every weak equivalence survive every pullback. The latter requirement is exceptionally strong when W forgets some homotopy groups. The useful intermediate condition asks instead that a categorically contractible base make the family constant up to W. Here "contractible" means that its identity functor is joined to a constant functor by a finite zigzag of natural transformations. This is the notion of homotopy already used in section I; it must not silently be replaced by weak contractibility of the nerve.

The weakest test in the diagram examines only $[1] \to S$. It gives, for each arrow $u : s \to t$, a span

$$X_s \longrightarrow X \times_S [1] \longleftarrow X_t$$

whose arrows belong to W. Inverting them produces an isomorphism between the two fibres in Hot_W. What it does not supply is the compatibility of this isomorphism with composition of arrows of S. The development "An eight-object obstruction to edge transport" above gives a finite poset over [2] for which all these endpoint tests are weak equivalences, whereas the transports along $0 \to 1 \to 2$ and $0 \to 2$ disagree already on connected components. Its total category has the homotopy type of



47. C'est essentiellement le a′) de p. 4

a circle and each fibre has two components. It therefore answers negatively the question about a_0 raised in the next paragraph.

Proposition 8 adds precisely the missing global control. Universal preproperness identifies a fibre with the appropriate comma category; the comma categories carry genuinely functorial transport, because postcomposition in S is an actual functor. This explains why preproperness together with the interval test succeeds where the interval test alone fails. Perfectness is a convenient sufficient condition, since it supplies both universal comma comparisons. It is stronger than the fibration condition being isolated here.

Dans le cas $W = W_\infty$, toutes les variantes de la page précédente, à l'exclusion seulement de a_0), sont équivalentes. Ce serait intéressant de dégager des conditions minimales sur W pour assurer qu'il en soit ainsi. (Et il se pose la question si dans le cas de W_∞, a_0) suffit pour impliquer le reste - je ne m'y attends guère …)

Dans le cas général, on a le diagramme d'implications (et encore je me suis limité)

[‘W-parfait $\Longrightarrow$ b’ encerclé].

Proposition 8. *Soit $f : X \longrightarrow S$ dans* Cat. *Les conditions suivantes sont équivalentes.* [page 41]

a) f est une W-fibration gauche, i.e. la condition a_1 *de la page 39 est vérifiée.*

b) f est W-prépropre, et $\forall\ s_0 \longrightarrow s_1$ dans S, $X/s_0 \longrightarrow X/s_1$ est dans W.

c) f est W-prépropre, et une W-pseudofibration, i.e. la condition a_0 de la page 39 est vérifiée.

([49]).

NB Ces conditions sont satisfaites si f est en même temps W-prélisse, cf. prop. 7. p. 31

Commentary · Exposition [ms. 41]

Completing the terminal-object test

Grothendieck wants a condition that can be checked on the original base, while remaining valid after every change of base. We spell out the argument because the compressed reference to Y/s and Y/s' hides the universal quantifier.

Write $E_u = X \times_S [1]$ for $u : s_0 \to s_1$. If the terminal-object test holds, apply it first to $T/t \to T \to S$, for an arbitrary $T \to S$ and $t \in T$. Its terminal fibre is X'_t and its total category is

48. Il semblerait que ce soit ça, finalement, la ‘bonne notion’ de W-fibration, *équivalente* à a_1 et a_2, lesquelles seraient équivalentes entre elles. Cf. prop. 9, p. 48.

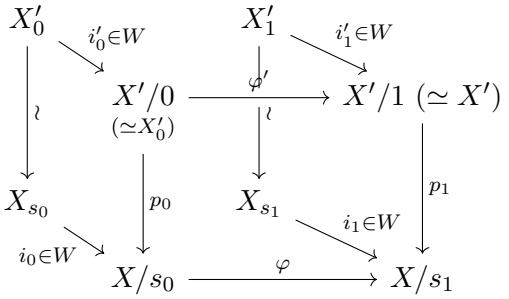
49. **Corollaire.** *Quand f est* Cat*-cofibrant, alors ces conditions équivalent aussi à ceci : $\forall\ u : s_0 \longrightarrow s_1$ dans S, $u_* : X_{s_0} \longrightarrow X_{s_1}$ est dans W.*

X'/t, where $X' = X \times_S T$. Thus $X'_t \to X'/t$ belongs to W: this is universal preproperness. Next apply the same test to S/s_1. Both the object $(s_1, 1)$ and the object (s_0, u) give fibre inclusions into X/s_1 in W. Since the latter factors as

$$X_{s_0} \longrightarrow X/s_0 \longrightarrow X/s_1,$$

two-out-of-three gives $X/s_0 \to X/s_1 \in W$. This supplies the missing detail in $a) \Rightarrow b)$.

Assume now universal preproperness. The canonical functor $E_u \to X/s_1$ restricts on the terminal fibre to $X_{s_1} \to X/s_1$. Both this inclusion and $X_{s_1} \to E_u$ belong to W, so $E_u \to X/s_1$ belongs to W. Its restriction to the initial fibre is the composite displayed above. Consequently

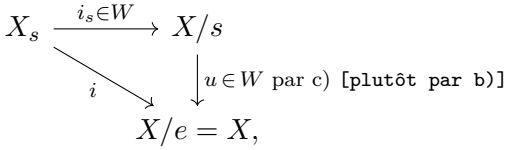


$$X_{s_0} \to E_u \in W \quad \Longleftrightarrow \quad X/s_0 \to X/s_1 \in W.$$

The other endpoint inclusion is already in W. This proves $b) \Longleftrightarrow c)$, including the asserted stability under arbitrary base change, since preproperness and the interval condition both have that stability by definition.

Finally, after any base change to a category T with terminal object t, the inclusion of the fibre over $s \in T$ factors through $X'/s \to X'/t = X'$. Both factors belong to W, proving $a)$. The dual argument uses initial objects and the categories $s\backslash X$. For an ordinary opfibration the inclusions $X_s \to X/s$ have adjoints and are homotopy equivalences; its postcomposition maps identify, up to these comparisons, with the pushforward functors u_*. This proves the corollary in footnote 49 with its stated variance.

DÉMONSTRATION. On a a) $\Longrightarrow$ b) trivialement (faire $Y'' = Y/s$, $Y'' = Y/s'$ `[lien avec l'assertion? Cf. p. 4.]`).



b) $\Longleftrightarrow$ c) par le raisonnement de la proposition 7, car en termes de $X' = X_u = X \times_S (\mathbf{\Delta}^1, u)$, la condition b) pour $u : s_0 \longrightarrow s_1$ donné s'interprète dans le diagramme commutatif

`[il y a quelques` W `redondants dans le diagramme original]` où i_0, i_1, i'_0, i'_1 sont dans W à cause de l'hypothèse de W-prépropreté (stable par changement de base).

Donc p_0, p_1 sont `[dans]` W, donc $\varphi \in W$ si et seulement si $\varphi' \in W$, or $\varphi' \in W$ est la condition a_0.

Prouvons enfin que b), c) impliquent a). Comme c) (donc aussi b)) est stable par changement [page 42] de base, il suffit de montrer ceci : Si S a un objet final e, alors pour tout $s \in \mathrm{Ob}\, S$, l'inclusion $X_s \xrightarrow{i} X$ est dans W. Or on a le diagramme commutatif

qui montre bien $i = ui_s \in W$.

Dualement, si f est W-prélisse, alors la condition a_0 (f une W-pseudofibration) est équivalente à a_2 (f une W-fibration droite), et signifie aussi que les

$$s_1\backslash X \longrightarrow s_0\backslash X$$

sont dans W. Mais la notion de 'W-fibration' sur laquelle on tombe (si on ne se contente du minable a_0!) est différente dans les deux cas duaux l'un de l'autre. On aimerait dans les deux cas trouver des W-fibrations 'hot-fortes' (condition b), tout au moins en mettant le paquet (s'il le faut) - i.e. pour f W-parfait. Ça revient donc à ceci.

Question : *Soient* $X \xrightarrow{f} S$, *avec* f W*-parfait,* S *contractile,* $s \in \mathrm{Ob}\, S$. *L'inclusion* $X_s \longrightarrow X$, *est-elle dans* W*?*

p. 32
[page 43]

On va supposer seulement que f est W-lisse et une W-fibration gauche [plutôt que f est simplement une W-fibration à droite, i.e que f est W-prélisse et une W-pseudofibration] (cf. prop. 8). On va se ramener au cas où X est même fibrant sur S, en introduisant $\Phi_S(X)$ [catégorie fibrée définie par le foncteur $S^\circ \longrightarrow \mathrm{Cat}$, $s \longmapsto s\backslash X$] et

$$X \xrightarrow{i_X} \Phi_S(X).$$

Commentary · Exposition [ms. 43]

The split replacement and its actual comparison maps

Grothendieck now replaces a family by a split fibration so that transport can be written before localization. The replacement is legitimate for a more concrete reason than an appeal to a previously constructed derivator.

An object of $\Phi_S(X)$ is a triple (s, x, a) with $a : s \to p(x)$. A morphism to (t, y, b) is a pair $(u : s \to t, v : x \to y)$ satisfying $p(v)a = bu$. The structural projection sends this object to s. Its fibre at s is $s\backslash X$, and an arrow $u : s \to t$ acts by precomposition. This is a strict functor $S^{\mathrm{op}} \to \mathrm{Cat}$, hence a split Grothendieck fibration.

The comparison i_X sends x to $(p(x), x, 1)$. The forgetful functor $r : \Phi_S(X) \to X$ satisfies $ri_X = 1_X$, and the arrows $(a, 1_x)$ define a natural transformation $1_{\Phi_S(X)} \Rightarrow i_X r$. In fact r is left adjoint to i_X. Thus i_X is a categorical homotopy equivalence and belongs to every W under consideration. On the fibre at s it is exactly

$$X_s \longrightarrow s\backslash X.$$

For a universally prelisse X/S, these fibre comparisons belong to W after every base change. The comparison of total categories and the comparison of individual fibres are therefore two separate, verified assertions.

If X/S is also a pseudofibration, the dual of Proposition 8 says that every precomposition $t\backslash X \to s\backslash X$ is in W. Consequently $\Phi_S(X)$ is a split fibration with transport in W. In a square comparing a fibre inclusion for X with the corresponding inclusion for $\Phi_S(X)$, both horizontal arrows are in W; two-out-of-three transfers the desired conclusion. No saturation argument is needed for this step. The familiar free-fibration construction and its variance were discussed in the commentary on Chapter VI, manuscript pp. 53–60; the additional point here is the universal fibre comparison that permits its use over an arbitrary new base.

L'ennui, c'est que j'ai fait la théorie de HOT_W jusqu'à maintenant avec l'hypothèse (qui s'avère idiote) que $W \supseteq W_\infty$ - je serai donc obligé de revoir rapidement sous quelles hypothèses plus raisonnables sur W les résultats familiers sont valables. Par exemple j'aimerais que $i_X \in W$ ([50]), de sorte qu'on ait

$$\begin{array}{ccc} X_s & \xrightarrow[\text{car } X \text{ } W\text{-lisse}]{i_s \in W} & \Phi_S(X)_s = s\backslash X \\ {\scriptstyle j_s^X}\downarrow & & \downarrow{\scriptstyle j_s^{\Phi_S(X)}} \\ X & \xrightarrow{i_X \in W} & \Phi_S(X), \end{array}$$

on voit donc que pour prouver que l'inclusion j_s^X est [dans] W, il suffit de prouver la même chose pour $\Phi_S(X)$, qui est fibrant (pas seulement W-lisse). De plus, l'hypothèse pseudo-

50. en fait, $i_X \in (W_\omega)_S^{\mathrm{d}} \subseteq W_S^{\mathrm{d}} \subseteq W_S$.

fibration sur X passe sûrement à $\Phi_S(X)$ (je réserve les deux vérifications à plus tard ([51])). On est donc ramené au cas de

$$X \in \mathrm{Ob}\,\underline{\mathrm{Fib}}_0 S, \qquad S \text{ contractile},$$

à prouver que l'inclusion

$$X_s \longrightarrow X$$

est dans W. Je vais prouver ceci : [page 44]

Lemme. *Soient S dans* Cat, $X \in \mathrm{Ob}\,\underline{\mathrm{Fib}}_0 S$, *et considérons, pour un S' dans* Cat,

$$\begin{array}{rcl} f & \longmapsto & f^*(X/S) = X \times_S (S', f) \\ \underline{\mathrm{Hom}}(S', S)^\circ & \longrightarrow & \underline{\mathrm{Fib}}_0 S'. \end{array}$$

(Ce foncteur est défini grâce au fait que X est fibrant sur S, et peut s'interpréter donc, à S-équivalence près, en termes d'un foncteur $S^\circ \longrightarrow$ Cat … ([52])). Les flèches de $\underline{\mathrm{Hom}}(S', S)$ sont transformées en flèches $\in W^{\mathrm{d}}_{S'}$.

En effet, en termes de foncteurs p. 33

$$S'^\circ \longrightarrow \mathrm{Cat},$$

si X est définie par

$$S^\circ \xrightarrow{\mathscr{X}} \mathrm{Cat},$$

alors $f^*(X)$ est définie par $\mathscr{X} \circ f$, et la flèche

$$\mathscr{X} \circ f \longrightarrow \mathscr{X} \circ g$$

définie par $u : f \longrightarrow g$ n'est autre que $\mathscr{X} * u$. Sa valeur en $s' \in \mathrm{Ob}\, S'$ est obtenue en prenant

$$u(s') : f(s') \longrightarrow g(s'),$$

d'où par $\mathscr{X}$

$$\mathscr{X}(u(s')) : \underbrace{\mathscr{X}(g(s'))}_{(\mathscr{X}\circ g)(s')} \longrightarrow \underbrace{\mathscr{X}(f(s'))}_{(\mathscr{X}\circ f)(s')}$$

([53]). Mais l'hypothèse $X \in \underline{\mathrm{Fib}}_0 S$ signifie que les $\mathscr{X}(v)$, $v \in \mathrm{Fl}(S)$, sont tous dans W. Donc $\mathscr{X}$ est dans W fibre par fibre, donc dans $W^{\mathrm{d}}_{S'}$.

[page 45]

Commentary · Exposition [ms. 45]

Transport along a natural transformation

The purpose of the lemma is to turn a homotopy of indexing functors into an actual zigzag of families. For this purpose it is useful to work with the split fibration just constructed. Let $F : S^{\mathrm{op}} \to \mathrm{Cat}$ be its classifying functor, with every $F(u)$ in W, and let $\alpha : f \Rightarrow g$ be a natural transformation of functors $T \to S$.

Contravariance gives the strict natural transformation

$$F(g(-)) \longrightarrow F(f(-)), \qquad t \longmapsto F(\alpha_t).$$

Its Grothendieck construction is a Cartesian functor $g^*X \to f^*X$ over T. Each component belongs to W. The relative localization axiom, applied in the dual comma convention, implies that this total functor belongs to W as well. Explicitly, the inclusion of the fibre of a Grothendieck fibration into its under-comma category has an adjoint, so the componentwise assertion gives an equivalence on those comma categories; the dual of W(2) then gives the total equivalence.

51. O.K.
52. **NB** $\Phi_S(X)$ était même déjà scindée, définie par le foncteur $s \longmapsto s\backslash X$.
53. à dégager un énoncé à part.

The first displayed arrow in the source proof points in the opposite direction from the correctly written component immediately below it. It is an edition slip: the transformation is $F \circ g^{\mathrm{op}} \Rightarrow F \circ f^{\mathrm{op}}$. Composition is nevertheless completely controlled: for $\beta : g \Rightarrow h$, the identity

$$F(\beta_t \alpha_t) = F(\alpha_t) F(\beta_t)$$

identifies the transport for $\beta\alpha$ with the composite of the two transports, in the contravariant order. Units are identities. After localization every such transport is invertible, and one may use its inverse when writing the covariant version of the functor in the next paragraph.

The factorization through the groupoid completion of $\underline{\mathrm{Hom}}(T, S)$ follows from its universal property. Connected functors therefore induce isomorphic pullbacks, but a connected component does not choose a particular path, and different paths may induce different isomorphisms. This is the precise reason for the parenthetical qualification "non canoniquement".

Corollaire 1. *Le foncteur du lemme, composé avec*

$$\underline{\mathrm{Fib}}_0 S' \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(S') \overset{\text{déf}}{=} (\underline{\mathrm{Fib}}_0 S')(W^{\mathrm{d}}_{S'})^{-1}$$

se factorise par le groupoïde fondamental de $\underline{\mathrm{Hom}}$ *:*

$$\begin{array}{ccc} \underline{\mathrm{Hom}}(S', S)^{\circ} & \longrightarrow & \underline{\mathrm{Fib}}_0 S' \\ \downarrow & & \downarrow \\ \prod(\underline{\mathrm{Hom}}(S', S))^{\circ} & \longrightarrow & \mathrm{HOT}^{\mathrm{lc}}_W(S'). \end{array}$$

Si f, g sont dans une même composante connexe de $\underline{\mathrm{Hom}}(S', S)$, alors f^*X et g^*X sont isomorphes (non canoniquement, en général) dans $\mathrm{HOT}^{\mathrm{lc}}_W(S')$.

Commentary · Examples [ms. 45]

A loop can act on the fibre even when the functor is fixed

Grothendieck's qualification about noncanonical isomorphisms concerns genuine monodromy. It can be seen without higher homotopy groups. Let $S = BC_2$, the one-object category with automorphism group $C_2 = \{1, \tau\}$, and let $F : S^{\mathrm{op}} \to \mathrm{Cat}$ take its value in the discrete category $D = \{0, 1\}$, with $F(\tau)$ exchanging the two objects. All transports are isomorphisms.

There is only one functor $e \to BC_2$, but it has two natural automorphisms. Pullback along this functor is the fibre D. The identity natural transformation induces 1_D, whereas the transformation τ induces the transposition of D. These are different even after localization at W_∞, because they induce different maps on $\pi_0(D)$. Thus "the two indexing functors are homotopic" cannot single out an isomorphism between their pullbacks.

The total category $\int F$ is equally explicit. Its objects are $0, 1$, and a morphism $d \to d'$ is an element $g \in C_2$ with $d = F(g)(d')$. There is exactly one such element for each ordered pair. The total category is therefore equivalent to e, whereas the fibre has two components. Its map to BC_2 is the categorical model of the universal two-sheeted covering. The inclusion of the fibre is not a weak equivalence; the base is not contractible. This example also shows why the word "contractile" in the next argument is a mathematical hypothesis, not a convenient choice of coordinates.

Il est plus astucieux de ne pas fixer X et de considérer

$$(*) \qquad \underline{\mathrm{Hom}}(S', S) \longrightarrow \underline{\mathrm{Hom}}(\mathrm{HOT}^{\mathrm{lc}}_W(S), \mathrm{HOT}^{\mathrm{lc}}_W(S'))$$

correspondant à

$$\begin{array}{ccccc} \underline{\mathrm{Hom}}(S', S) & \times & \mathrm{HOT}^{\mathrm{lc}}_W(S) & \longrightarrow & \mathrm{HOT}^{\mathrm{lc}}_W(S') \\ (f & , & \xi) & \longmapsto & f^*(\xi). \end{array}$$

p. 34
[page 46]

Le lemme dira que les flèches de $S' \longrightarrow S$ sont transformées par $(*)$ en isomorphismes, d'où

$$\prod \underline{\mathrm{Hom}}(S', S) \longrightarrow \underline{\mathrm{Hom}}(\mathrm{HOT}^{\mathrm{lc}}_W(S), \mathrm{HOT}^{\mathrm{lc}}_W(S')),$$

donc si $f, g : S' \rightrightarrows S$ sont deux foncteurs homotopes, alors

$$f^* \simeq g^* : \mathrm{HOT}^{\mathrm{lc}}_W(S) \rightrightarrows \mathrm{HOT}^{\mathrm{lc}}_W(S').$$

Il s'ensuit aussitôt ceci

Corollaire 2. *Si f est un homotopisme, $f^* : \mathrm{HOT}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(S')$ est une équivalence de catégories.*

En effet, prenant $g : S \longrightarrow S'$ telle que

$$fg \sim \mathrm{id}_S, \qquad gf \sim \mathrm{id}_{S'},$$

on trouve que

$$g^* f^* \simeq (\mathrm{id}_S)^* = \mathrm{id}_{\mathrm{HOT}^{\mathrm{lc}}_W(S)}$$
$$f^* g^* \simeq (\mathrm{id}_{S'})^* = \mathrm{id}_{\mathrm{HOT}^{\mathrm{lc}}_W(S')},$$

donc on trouve que (quitte à ajuster ces isomorphismes fonctoriels) f^* et g^* sont des équivalences quasi-inverses l'une de l'autre.

J'ai l'impression ([54]) que tout ça ne doit pas utiliser plus que les axiomes standard sur W comme localiseur fondamental, tout au plus W(2) au lieu de la forme faible W(2 bis).

Revenons à X lisse sur S contractile. Le corollaire 2 implique que

$$\mathrm{Hot}_W \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(S)$$
$$\xi \longmapsto p_S^*(\xi),$$

où $p_S : S \longrightarrow e$, est une équivalence. Donc dans la catégorie $\mathrm{HOT}^{\mathrm{lc}}_W(S)$, X est isomorphe à un Cat-fibré de la forme $Z \times S \xrightarrow{\mathrm{pr}_2} S$, avec Z dans Cat. Or pour $X_1 = Z \times S \longrightarrow S$, [page 47]
il est immédiat que $X_{1\,s} \longrightarrow X_1$ est dans W, car un produit cartésien de flèches [dans] W (savoir id_Z et $s \longrightarrow S$) est dans W. (En fait, l'inclusion est même un homotopisme!) Notons maintenant que si X_0, X_1 sont deux objets dans $\underline{\mathrm{Liss}}_0 S$, tels qu'il existe une S-flèche $X_0 \longrightarrow X_1$ qui soit dans W^{d}_S, alors $X_{0\,s} \longrightarrow X_0$ est dans W si et seulement si $X_{1\,s} \longrightarrow X_1$ l'est. En effet, on a

$$\begin{array}{ccc} X_{0\,s} & \xrightarrow{\in W} & X_{1\,s} \\ {\scriptstyle i_s^{X_0}}\downarrow & & \downarrow{\scriptstyle i_s^{X_1}} \\ X_0 & \xrightarrow{\in W} & X_1 \end{array}$$

ici on utilise sans doute
W(2), non seulement W(2 bis),

qui prouve le résultat. p. 35

Commentary · Exposition [ms. 47]

The finite zigzag that makes contraction effective

Grothendieck correctly notices, immediately below, that an isomorphism in a localization does not by itself provide a zigzag consisting entirely of the specified weak equivalences. The contraction supplies such a zigzag directly.

54. O.K.

Suppose $F : S^{\mathrm{op}} \to \mathrm{Cat}$ sends arrows into W, and choose a finite zigzag

$$1_S = \varphi_0 \iff \varphi_1 \iff \cdots \iff \varphi_m = c_t$$

of natural transformations, with the displayed double arrows indicating a choice of one direction at each step. Set $X_j = \int (F \circ \varphi_j^{\mathrm{op}})$ over S. Transport along the chosen transformation gives, in the appropriate direction, a functor $X_j \to X_{j+1}$ over S which is in W on every fibre. By the argument of the preceding block it is also in W on total categories.

For every $s \in S$ the resulting square

$$\begin{array}{ccc} (X_j)_s & \longrightarrow & (X_{j+1})_s \\ \downarrow & & \downarrow \\ X_j & \longrightarrow & X_{j+1} \end{array}$$

has horizontal arrows in W; if the chosen natural transformation points backwards, reverse the horizontal arrows. Two-out-of-three says that one vertical arrow belongs to W exactly when the other does. At the last stage the family is $F(t) \times S \to S$. The map $e \to S$ selecting s is a categorical homotopy equivalence: a contraction to t, evaluated at s, supplies a zigzag between s and t, which joins the constant functors c_s and c_t. Multiplying this homotopy by $F(t)$ shows that

$$F(t) \cong F(t) \times \{s\} \longrightarrow F(t) \times S$$

is a categorical homotopy equivalence, hence is in W. Moving back through the finite zigzag proves $X_s \to X \in W$.

The replacement comparison at p. 43 transfers this conclusion to every prelisse pseudofibration; the dual argument treats preproper pseudofibrations. This proves the question of p. 42 and the contractible-base part of Proposition 9 under W(1,2,3). It uses the explicit contraction, componentwise transport, the relative localization axiom, and two-out-of-three. Strong saturation is not needed for this particular conclusion.

Il est vrai que le fait que $X = X_0$ et $X_1 = Z \times S$ soient isomorphes dans $\mathrm{HOT}^{\mathrm{lc}}_W(S)$ n'implique pas, par lui-même, l'existence d'une chaîne d'isomorphismes provenant de flèches [page 48] dans W^{d}_S. Mais en fait, si dans l'énoncé du corollaire 2 ci-dessus on compare X dans $\underline{\mathrm{Fib}}_0 S$ à $g^*f^*(X)$, grâce à une homotopie $\mathrm{id}_S \sim fg$, on trouve bel et bien une suite de foncteurs $\varphi_i : S \longrightarrow S$, avec $\varphi_0 = \mathrm{id}_S$, $\varphi_N = fg$, et φ_i et φ_{i+1} reliés par une flèche dans $\underline{\mathrm{Hom}}(S, S)$, donc on a une suite d'objets $X_i = \varphi_i^*(X)$ de $\underline{\mathrm{Fib}}_0 S$ (avec $X_0 = X$, $X_N = g^*f^*X$), et X_i et X_{i+1} reliés par une flèche *dans* $\underline{\mathrm{Fib}}_0 S$ (pas seulement dans $\mathrm{HOT}^{\mathrm{lc}}_W(S)$), laquelle flèche est dans $W^{\mathrm{d}}_S = W^{\mathrm{f}}_S$. Donc on gagne, sous réserve de vérifications de routine diverses ([55]). Donc modulo celles-ci, on aura

Proposition 9 ([56], [57]). *Supposons que X dans* Cat/S *soit une W-fibration à gauche (cf. prop. 8). Alors c'est même une W-fibration (au sens de b), page 40, où c'est appelé 'W-fibration* hot*-forte'), en d'autres termes, si $S'' \longrightarrow S'$ est sur S avec S'', S' contractiles, alors $X'' \longrightarrow X'$ est dans W ([58]). On a sans doute mieux : si $S'' \longrightarrow S'$ est un homotopisme, alors $X'' \longrightarrow X'$ est dans W.*

Commentary · Exposition [ms. 48]

What the localization argument proves

Grothendieck next asks for invariance under an arbitrary categorical homotopy equivalence of bases. Here the argument changes: he identifies the map of total categories with a map of homotopy colimits and applies an adjunction. Let $v : T \to S$ be a homotopy equivalence and let ξ be a locally

55. O.K.
56. C'est ok en supposant que W est *fortement* saturé, i.e. $\mathrm{hot}_W(f)$ isomorphisme $\Longrightarrow f \in W$.
57. Donc W-fibration à gauche $\iff$ W-fibration à droite $\iff$ W-fibration.
58. on trouve seulement que $\mathrm{hot}_W(X'') \longrightarrow \mathrm{hot}_W(X')$ `[est un]` isomorphisme.

constant coefficient represented by the family. The contraction argument for the two composites of a homotopy inverse shows that restriction

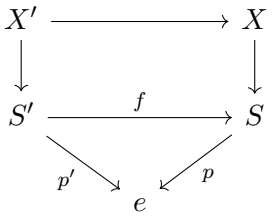
$$v^* : \mathrm{HOT}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(T)$$

is an equivalence. Once the comparison with strict pullback and the adjunction $p_! \dashv p^*$ have been established, the displayed Hom calculation on p. 50 proves that the actual map of total categories becomes invertible in Hot_W.

This is an assertion about the specified map, rather than merely an abstract isomorphism between its source and target. The last inference to membership in W requires strong saturation. The footnote makes that distinction correctly. Later theory proves that every fundamental localizer in the modern, stronger sense is strongly saturated; see the status discussion at p. 16 and (Cisinski, 2006a, Proposition 4.2.4). Here the stronger sense includes the relative axiom W(2), not merely W(2 bis) in the terminology fixed at the beginning of section III. Theorem 3 explicitly assumes W(1,2,3), so that later theorem removes its additional saturation hypothesis. We are not asserting this consequence for an arbitrary weak fundamental localizer satisfying only W(2 bis).

The finite-zigzag argument in the preceding block already proves the contractible-base tests directly in W. Thus it is consistent for Theorem 3 to state those equivalences under W(1,2,3), while presenting its more general assertion *d*) first in the localized category.

[page 49]



Prouvons (si nous pouvons) ce complément sympathique. Je précise que j'ai eu à faire l'hypothèse de W-prélissité (où de W-prépropreté) pour être sûr que l'image inverse $X \times_S S'$, par $f' : S' \longrightarrow S$, coïncide bien avec f^* sur les $\mathrm{HOT}^{\mathrm{lc}}_W$ - autrement je n'ai aucune chance. 'On sait' (tout est à revoir!) que c'est O.K. dans les trois cas X W-lisse, X W-propre, X une W-fibration (mais en quel sens???). La vérification à faire (quand on travaille avec les W^{d}_S) est celle-ci :

(∗) $X \xrightarrow{i_X} \Phi_S(X) = Y$ est dans W^{d}_S (sans mérite), et le reste par tout changement de base.

Mais pour des $X, Y \in \mathrm{Ob}\,\mathrm{Cat}/S$ qui sont W-prélisse, la W^{d}_S-équivalence coïncide avec W^{f}_S, laquelle est préservée par changement de base, ainsi que l'hypothèse sur X, Y. Donc on est tranquille.

On est ramené à prouver que si X est W-prélisse sur S et une W-pseudofibration, et si $S' \longrightarrow S$ est un homotopisme, alors $X' \longrightarrow X$ est dans W. Par l'argument de tantôt utilisant $X \longrightarrow \Phi_S(X)$, on se ramène au cas où X est fibrée scindée.

p. 36
[page 50]

La flèche $X' = f^*(X) \longrightarrow X$ s'interprète dans Hot_W comme

(∗) $$p'_!(f^*(\xi)) \longrightarrow p_!(\xi)\ , \qquad \text{où } \xi = \mathrm{hot}_{S,W}(X).$$

Je dis que cette flèche est [un] isomorphisme, i.e. que pour tout $\eta \in \mathrm{Hot}_W$, la flèche transposée

(∗∗) $$\mathrm{Hom}_W(p_!(\xi), \eta) \longrightarrow \mathrm{Hom}_W(p'_!(f^*(\xi)), \eta)$$

est [une] bijection. Admettant la formule d'adjonction, la flèche (∗∗) s'interprète comme

$$\mathrm{Hom}_W(\xi, \underbrace{p^*(\eta)}_{\eta_S}) \longrightarrow \mathrm{Hom}_W(f^*(\xi), \underbrace{p'^*(\eta)}_{f^*(\eta_S)}),$$

i.e.

$$\mathrm{Hom}_W(\xi, \eta_S) \longrightarrow \mathrm{Hom}_W(f^*(\xi), f^*(\eta_S)),$$

que ce soit [un] isomorphisme résulte donc de f^* pleinement fidèle sur les $\mathrm{HOT}^{\mathrm{lc}}_W$. Or on a vu que f^* est une équivalence (cor. 2, page 46).

Je vais reprendre les propositions 9 et 8, un peu mal foutues. [page 51]

Théorème 3. *On suppose que W satisfait à* W(1,2,3). *Soit $f : X \longrightarrow S$. Considérons les conditions suivantes.*

a) $\forall$ $S'' \longrightarrow S'$ *sur S, avec S'', S'* contractiles, *$X'' \longrightarrow X'$ est dans W.*

a′) $\forall$ *S' sur S, avec S' contractile, et $s' \in S'$, l'inclusion*

$$X_{s'} \hookrightarrow X' = X \times_S S'$$

est dans W.

a_1) Comme a′), mais en supposant que S' a un objet final (au lieu de S' contractile).

a_2) Comme a′), mais en supposant que S' a un objet initial.

*b_1) f est W-*prépropre *(i.e. a′) est satisfait quand s' est un objet final de S', sans autre condition sur S' dans* Cat$/S$*), et de plus pour toute flèche $s_0 \longrightarrow s_1$ dans S, la flèche induite $X/s_0 \longrightarrow X/s_1$ est dans W (i.e. a′* [plutôt a]*) est satisfait pour $Y/s_0 \longrightarrow Y/s_1$* [plutôt $S/s_0 \longrightarrow S/s_1$]*).* p. 37

*b_2) f est W-*prélisse *(i.e. a′) est satisfait quand s' est un objet initial de S', sans autre condition sur S'), et de plus les flèches $s_0\backslash X \longrightarrow s_1\backslash X$* [plutôt $s_1\backslash X \longrightarrow s_0\backslash X$] *(pour $s_0 \longrightarrow s_1$ dans S) sont dans W, (i.e. a′* [plutôt a]*) satisfait pour $s_1\backslash Y \longrightarrow s_0\backslash Y$* [plutôt $s_1\backslash S \longrightarrow s_0\backslash S$]*).*

c_1) f est W-prépropre et une W-pseudofibration, i.e. la condition a′) est satisfaite dans les deux cas suivants: 1°) s' est un objet final de S', 2°) $S' = \mathbf{\Delta}^1$.

c_2) f est W-prélisse et une W-pseudofibration, i.e. a′) dans les deux cas: 1°) s' est objet initial de S', 2°) $S' = \mathbf{\Delta}^1$.

Toutes ces 8 conditions sont équivalentes. Elles impliquent la suivante :

d) Soit $S'' \xrightarrow{u} S'$ un homotopisme dans Cat$/S$*, et considérons $u_X : X'' \longrightarrow X'$. Alors* $\mathrm{hot}_W(u_X)$ *est* [un] *isomorphisme. (Donc si W est fortement saturé, $u_X \in W$. Donc sous cette condition sur W, d) équivaut aux conditions précédentes.)*

Définition 4. On dit que $f : X \longrightarrow Y$ dans Cat est une *W-fibration*, si elle satisfait les conditions équivalentes a) à c_2) de la proposition 9. [page 52]

Commentary · Exposition [ms. 52]

Reading the eight equivalent conditions

Grothendieck has now isolated a usable fibration notion. Its eight formulations organize two independent requirements: strict fibres must compute comma fibres universally, and the latter must vary by weak equivalences. The reference to "proposition 9" in Definition 4 means the immediately preceding Theorem 3; Proposition 9 did not contain eight labelled conditions.

Here is the logical structure, including the point at which the contractible-base argument is used. Condition *a*) implies *a′*) by taking $S'' = e$. Conversely, for a map $u : T \to U$ between contractible categories over S, choose $t \in T$. The triangle of inclusions of the same strict fibre into X_T and X_U commutes. Both inclusions are in W by *a′*), so $X_T \to X_U \in W$. Contractible categories are nonempty; there is no missing empty-base case.

The implications *a′*) $\Rightarrow$ a_1), a_2) follow because categories with terminal or initial objects admit categorical contractions. Proposition 8 gives $a_1) \iff b_1) \iff c_1)$ and its dual gives $a_2) \iff b_2) \iff c_2)$. Starting with either c_1) or c_2), use the corresponding split replacement and the finite transport zigzag to obtain the fibre inclusion over every contractible base. This proves the reverse implication to *a′*) and therefore all eight equivalences.

For an ordinary Grothendieck fibration, the comma comparisons are automatic and the remaining test is simply that every pullback functor u^* lies in W; the opfibred statement uses u_*. For a family that is both preproper and prelisse, the two interval endpoint inclusions already lie in W, so the pseudofibration test is automatic. These observations prove the three corollaries. They do not identify a W-fibration with a strict Grothendieck fibration, nor with a perfect functor: the first supplies strict Cartesian lifts, and the second supplies stronger asphericity of lift categories.

Corollaire 1. *Si f est W-propre ou W-lisse, pour que f soit une W-fibration, il faut et il suffit que f soit une W-pseudofibration, i.e. que pour $S' = \mathbf{\Delta}^1 \longrightarrow S$, les inclusions des deux fibres*

$$X'_0 \xrightarrow{i_0} X' \xleftarrow{i_1} X'_1$$

de $X' = X \times_S S'$ soient dans W.

Corollaire 2. *Supposons f* Cat*-fibrant. Alors f est une W-fibration si et seulement si pout toute flèche $u : s \longrightarrow s'$ dans S, $u^* : X_{s'} \longrightarrow X_s$ est dans W. Énoncé dual si f est* Cat*-cofibrant.*

Corollaire 3. *Supposons f W-prépropre et W-prélisse (par exemple f W-parfait). Alors f est une W-fibration.*

Proposition 10. *Soit $f : X \longrightarrow Y$ une flèche dans $\underline{\mathrm{Fib}}_W S$ ([59]) (sous-catégorie pleine de* Cat*$/S$ formée des W-fibrés sur S). Si $\forall\ s \in S$, $f_s : X_s \longrightarrow Y_s$ est dans W, alors $f \in W$.*

Commentary · Exposition [ms. 52]

Fibrewise equivalence gives equivalence of total categories

Proposition 10 is a comparison theorem in one direction. It says that equivalent fibres give equivalent totals when the structural maps make those fibres compute the relevant comma categories. It does not yet assert that an equivalence of totals can be detected fibre by fibre; that converse is the separate axiom W(4b).

This argument uses the full relative axiom W(2), as assumed in Theorem 3; the weaker standing definition of section III alone is not the stated justification. Suppose first that X and Y are prelisse over S, and that $h : X \to Y$ is in W on every fibre. For each s the commutative square

$$\begin{array}{ccc} X_s & \xrightarrow{h_s} & Y_s \\ \downarrow & & \downarrow \\ s\backslash X & \longrightarrow & s\backslash Y \end{array}$$

has its upper and vertical arrows in W. Hence its lower arrow is in W. The dual form of W(2) gives $h \in W$. If the structural maps are preproper, use X/s and Y/s instead. This proves exactly the strengthening in footnote 59, without any pseudofibration hypothesis.

The source's replacement proof packages the same argument differently. The maps i_X, i_Y are homotopy equivalences on total categories and are fibrewise equivalences under prelissity. Their split replacements are smooth over S, so the corollary to Proposition 5 applies to the induced map. Referring to that corollary, rather than requiring the map between the replacements itself to be smooth, is the correct reading of the final sentence.

Considérons

$$\begin{array}{ccccc} X & & \xrightarrow{\quad f \quad} & & Y \\ & \searrow^{i_X} & & & \searrow^{i_Y} \\ & & \Phi_S(X) & \xrightarrow[\Phi_S(f)]{} & \Phi_S(Y), \end{array}$$

p. 38

où $i_X, i_Y \in W$, donc $\Phi_S(f) \in W \Rightarrow f \in W$. Or le fait que X `[est]` W-fibrée sur S implique que $i_X \in W_S^{\mathrm{f}}$ (il suffit même que X soit prépropre `[plutôt prélisse]` sur S), itou pour Y, i_Y. Donc l'hypothèse $f \in W_S^{\mathrm{f}}$ implique $\Phi_S(f) \in W_S^{\mathrm{f}}$, donc $\Phi_S(f) \in W$ par `[la]` proposition 5 (page 29).

p. 39

59. X et Y tous deux prépropres ou tous deux prélisses suffit.

[page 53]

IV Sur l'axiome W(4) et ses variantes.

([60]). J'ai passé des jours à essayer de prouver que toutes ces variantes sont équivalentes. Je vais donner une liste de celles, parmi ces variantes, qui avec le recul me paraissent encore avoir une utilité. (Avec des notations différentes de celles des pages 13-14.)

Commentary · Exposition [ms. 53]

The two directions of a fibration axiom

Grothendieck separates the two properties that ordinary homotopy theory makes look inseparable. The first concerns a change of base: a weak equivalence $T \to S$, pulled back along a suitable family $X \to S$, should remain a weak equivalence. The second concerns a map between families over one fixed base: if its total map is a weak equivalence, each fibre map should be one. These are W(4a) and W(4b), respectively. W(4c) is the special case of the second in which the second family is $S \to S$ itself.

The primes restrict the objects on which these properties are tested. In W(4a') and W(4c') the map is perfect for the minimal localizer; in W(4b') the structural families are split and the comparison preserves the splittings; in W(4b") the structural families are W-perfect. These restrictions are not interchangeable merely by renaming a fibration. In particular, the argument of section I used a stronger base-change condition than the eventual definition on p. 52. The editors' objection to the arrow $a' \Rightarrow b$ records a genuine dependence on that change of definition.

There is also a change of lettering. The weak perfect-fibre axiom called W(4b") in section I is now W(4c'). Keeping its content fixed is safer than carrying its old label into a later argument. The subsequent proof establishes one implication through locally constant coefficients; it does not prove every arrow that the surrounding discussion anticipates.

W(4a) Toute W-fibration (cf. th. 3, p. 51, déf. 3, p. 52) est ultraforte, ce qui revient à ceci: pour

$$\begin{array}{ccc} X & \xleftarrow{q} & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ Y & \xleftarrow{p} & Y' \end{array}$$

cartésien dans Cat, si $f \in \underline{\mathrm{Fib}}_W$, $p \in W$, alors $q \in W$.

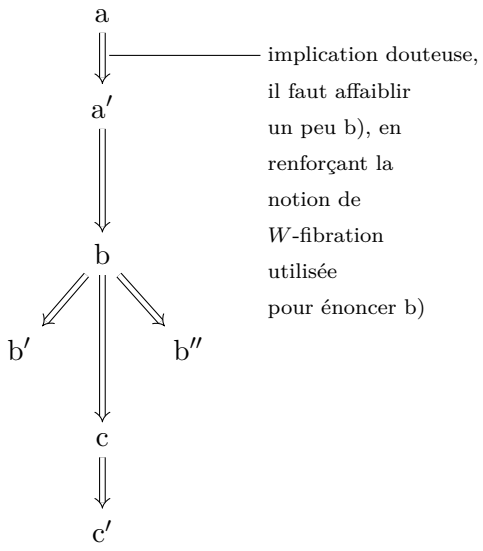
W(4a′) Comme a), en supposant $f \in \mathrm{Parf}_\omega$, i.e. f W_ω-parfait (donc une W_ω-fibration), où $W_\omega \subseteq W$ est la plus petits partie Σ de Fl(Cat) satisfaisant W(1, 2 bis, 3).

W(4b) Soit un diagramme commutatif $\begin{array}{ccc} X & \xrightarrow{f} & Y \\ & {\scriptstyle p}\searrow \quad \swarrow{\scriptstyle q} & \\ & S & \end{array}$ dans Cat, avec $p, q \in \mathrm{Fib}_W$, $f \in W$. Alors $\forall s \in S$, $f_s : X_s \longrightarrow Y_s$ `[est dans W]`.

W(4b′) Comme b), en supposant `[de plus]` X et Y fibrés scindés sur S, f compatible avec `[les]` scindages (donc foncteur cartésien).

W(4b″) Comme b), en supposant p, q *W-parfaits.*

W(4c) Soit $f : X \longrightarrow Y$, avec $f \in \mathrm{Fib}_W \cap W$, alors les fibres de f sont W-asphériques.



W(4c′) Comme c), en supposant $f \in \mathrm{Parf}_\omega \cap W$. (C'est l'ancien W(4b″), dépouillé du W_∞-parasite.)

J'ai cerclé les notions `[encadrées ici]` qui ont été vraiment utiles. Pratiquement, on [page 54]
peut parier que c'est la notion la plus forte, W(4a), qui est la seule importante. Voici les implications tautologiques (à l'exception de W(4a′) $\Longrightarrow$ W(4b), qui est démontré dans la démonstration de la proposition 4 (pages 6-10) ([61])).

p. 40

60. Cf. aussi partie VI (HOT_W), p. 186-196

61. Cette démonstration utilise une notion plus forte de W-fibration que celle du théorème 3, p. 51.

J'ai surtout sué pour montrer que c′) ⟹ c), ou c) ⟹ b), sans y arriver. L'effort m'a permis de me débarrasser de diverses idées fausses, et de les remplacer par des justes, cf. plus bas. Il y a quand même un résultat positif qui surnage :

Proposition 1. *La condition b) (et sans doute même b′) et b″)* ([62])*, mais je ne vais pas le prouver ici …) implique sans doute a) pour $\bar{W}$, le saturé fort de W. En tous cas, si W est fortement saturé, les conditions a), a′), b) (et sûrement aussi b′) et b″)) sont équivalentes.*

Commentary · Present state [ms. 54]

The later resolution of the weakest fibre axiom

Grothendieck's reservations here belong to the search for a proof from a deliberately small list of axioms. The minimal weak-localizer theorem gives $W_\omega = W_\infty$ even with W(2 bis), by Cisinski (2006a, Theorem 6.1.18). The proof in section I, completed by the nondegeneracy argument at p. 20, then shows that W(4c') forces

$$W = W_\infty \quad \text{or} \quad W = \mathrm{Fl}(\mathrm{Cat}).$$

The second possibility must be retained: all the fibration axioms hold vacuously when every functor is a weak equivalence. This argument uses the perfect replacement and iterated homotopy-fibre construction, together with the minimality theorem; it does not require filtered-colimit stability or strong saturation of an arbitrary weak localizer. Those properties follow after the displayed classification. For the nontrivial alternative, ordinary homotopy theory gives the full pullback and fibrewise comparison statements. A related published characterization under the full relative-localization hypothesis is Cisinski (2006a, Theorem 6.4.22 and Remark 6.4.23), formulated using locally constant functors.

The split comparison test b') also detects the weakest perfect-fibre test. If $E \to B$ is W_∞-perfect and belongs to W, compare the split replacements $\Phi_B(E) \to \Phi_B(B)$. Its total map is in W, since both replacement units are. Their transports are weak equivalences, and the comparison is strictly Cartesian. Thus b') makes each $b\backslash E \to b\backslash B$ a W-equivalence. The perfect fibre comparison $E_b \to b\backslash E$ and the initial object of $b\backslash B$ then show that E_b is W-aspherical. The implication from the perfect pullback test a') uses the mapping-path comparison already audited in section I, rather than the disputed reuse of an older fibration definition.

Accordingly the weak perfect test, the split test, and the full tests have the same eventual alternatives. This retrospective conclusion does not turn the unfinished implications in the manuscript into proofs written there. In the claim register their original qualifications remain conjectural or sketched, with the later resolution recorded separately.

62. et en supposant dans le cas de b″, que W satisfait la condition des limites inductives W(6 bis), cf. prop. 5 du 'corollaire' de la, page 14.

Démonstration de b) $\Longrightarrow$ a), quand W est fortement saturé. En fait, moyennant b) (et sans même supposer W fortement saturé), nous allons prouver que si on a

$$\begin{array}{ccc} X & \xleftarrow{q} & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ Y & \xleftarrow{p} & Y' \end{array}$$

cartésien dans Cat, avec f une W-fibration, et $p \in W$, alors $\underline{q \in \bar{W}}$, i.e. $\mathrm{hot}_W(q)$ [est un] isomorphisme. Pour ceci, nous interprétons la flèche q dans Hot_W de la façon suivante. Soit [page 55]

$$\xi = \mathrm{hot}_{Y,W}(X/Y), \qquad \xi' = p^*(\xi),$$

qui dit que q s'identifie à la flèche canonique

$$(*) \qquad H_\bullet^{\mathrm{HOT}_W}(Y', \xi') \longrightarrow H_\bullet^{\mathrm{HOT}_W}(Y, \xi) \qquad \text{dans } \mathrm{Hot}_W = \mathrm{HOT}_W(e), \qquad \text{p. 41}$$

où on note de plus que $\xi \in \mathrm{HOT}_W(Y)$ est un coefficient *localement constant* sur Y.

Établissons d'abord cette interprétation de q. Notons que comme $X \in \underline{\mathrm{Fib}}_W Y$, l'image inverse $\xi' = p^*(\xi)$ n'est autre que $\mathrm{hot}_{Y',W}(X' = X \times_Y Y')$. D'autre part, si $g : Y \longrightarrow e$, $g' : Y' \longrightarrow e$ sont les flèches structurales, les deux membres de $(*)$ s'interprètent resp. comme $g'_!(\xi')$ et $g_!(\xi)$ (les $g'_!$ et $g_!$ au sens du prédérivateur HOT_W). Or le calcul de $g'_!$, $g_!$ nous donne que les deux membres s'identifient resp. à

$$\mathrm{hot}_W(X'), \qquad \mathrm{hot}_W(X),$$

et nous admettons que la flèche

$$\mathrm{hot}_W(X') \longrightarrow \mathrm{hot}_W(X)$$

n'est autre que $\mathrm{hot}_W(q)$. D'ailleurs, comme X est W-fibrée sur S, par définition pratiquement, ξ est dans $\mathrm{HOT}^{\mathrm{lc}}_W(S)$. Donc il nous suffira de prouver le

Corollaire. *Supposons que W satisfait à W(4b), et soit $p : S' \longrightarrow S$ dans W, $\xi \in \mathrm{HOT}^{\mathrm{lc}}_W(S)$, $\xi' = p^*(\xi)$. Alors*

$$H_\bullet(S', \xi') \xrightarrow{\sim} H_\bullet(S, \xi)$$

est un isomorphisme dans Hot_W. [page 56]

Commentary · Exposition [ms. 56]

Why fully faithful restriction controls integration

Grothendieck's proof is driven by the fact that a homotopy colimit is characterized by its maps into constant coefficients. We can state the argument in a form which makes every required comparison visible. Let $p : T \to S$, and suppose that restriction is fully faithful on locally constant coefficients. Let $q : S \to e$ and $r : T \to e$ be the structural maps, and suppose the adjunctions $q_! \dashv q^*$ and $r_! \dashv r^*$ are available. For a locally constant ξ, there is a canonical comparison

$$c : r_! p^* \xi \longrightarrow q_! \xi.$$

For every coefficient A at the point, adjunction identifies precomposition by c with

$$\mathrm{Hom}(\xi, q^* A) \longrightarrow \mathrm{Hom}(p^* \xi, p^* q^* A).$$

Both ξ and q^*A are locally constant, so full faithfulness makes this a bijection. Yoneda implies that c is an isomorphism. Essential surjectivity of restriction is stronger than this argument requires.

The application to a literal pullback $X_T \to X$ needs two further identifications: strict pullback must represent $p^*\xi$, and the chosen integration functors must send these representatives to their total categories, with c represented by the actual projection. Prelissity supplies the first identification; the construction of $q_!$ supplies the second. The source acknowledges these comparisons instead of proving them anew. The same formal Hom argument appears in Cisinski (2009, Proposition 1.10), and its Theorem 1.3 supplies ordinary weak-homotopy invariance for model-category-valued locally constant diagrams. These later results clarify the argument without making W(4b) an unmentioned consequence of W(1,2,3).

Démonstration. Il suffit de prouver que pour tout $\eta \in \mathrm{Ob}\,\mathrm{Hot}_W$ on a une bijection pour les $\mathrm{Hom}(-,\eta)$. Par la formule d'adjonction sur S, S', cette application entre les Hom dans Hot_W s'identifie [à]

$$\mathrm{Hom}_{\mathrm{HOT}_W(S)}(\xi,\eta_S) \longrightarrow \mathrm{Hom}_{\mathrm{HOT}_W(S')}(\xi',\eta_{S'}),$$

où $\eta_S = p^*(\eta)$, $\eta_{S'} = p'^*(\eta)$ [plutôt $\eta_S = g^*(\eta)$, $\eta_{S'} = g'^*(\eta)$, où $g : S \longrightarrow e$, $g' : S' \longrightarrow e$ sont les flèches structurales], donc $\eta_{S'} = p^*(\eta_S)$, et la flèche $(*)$ est la flèche sur les Hom induite par le foncteur

$$p^*_{\mathrm{lc}} : \mathrm{HOT}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(S').$$

Or moyennant l'axiome W(4b) (que nous n'avons pas utilisé jusqu'à présent), ledit foncteur est une *équivalence de catégories* si $p \in W$ (cf. VI, p. 204).

q.e.d.

De peur de les oublier, je vais maintenant faire une liste des petites questions que j'ai élucidées chemin faisant en gribouillant.

Commentary · Examples [ms. 56]

Why preservation of Cartesian arrows matters

Grothendieck's first observation separates fibrewise smoothness from smoothness of the total functor. A small example makes the lost information explicit. Let C be the one-object category with endomorphism monoid $(\mathbf{N},+)$, and put $X = Y = C \times [1]$, both projected to $[1]$. Define an endofunctor $h : X \to Y$ over $[1]$ to be the identity on both fibres and to send a morphism crossing from 0 to 1, labelled $n \in \mathbf{N}$, to the morphism labelled $n+1$.

This is a functor. A composite crosses from 0 to 1 at most once, so adding 1 commutes with precomposition and postcomposition by fibre morphisms. Each fibre functor is the identity and hence is smooth and proper. Both structural projections are products, hence split fibrations. But h does not preserve Cartesian arrows: the Cartesian crossing labelled 0 is sent to the non-Cartesian crossing labelled 1.

To test smoothness of h, take the target object over 1 and the arrow in Y from the object over 0 labelled 0. A lift with this prescribed image would be a crossing morphism labelled n in X with $n+1 = 0$. There is none. Its lifting category is empty, so h is not W_∞-smooth. This is a fully explicit instance of the failure claimed in item 1. If the functor preserves the splitting, an arbitrary arrow over $u : s \to t$ factors through the chosen Cartesian lift, and its lift category is the corresponding lift category of the fibre functor at s. That identification proves the positive assertion in item 1.

1°) Si X, Y sont W-lisses sur S, et $f : X \longrightarrow Y$ un S-morphisme tel que $f_s : X_s \longrightarrow Y_s$ soit W-lisse pour tout $s \in \mathrm{Ob}\,S$, il ne s'ensuit *pas* que f soit W-lisse. Mais c'est pourtant vrai quand X et Y sont fibrées scindées sur S (ce qui implique déjà leur W-lissité sur S), et f compatible avec les scindages et a fortiori cartésien. Énoncé dual pour les catégories cofibrées scindées et les foncteurs strictement cartésiens entre elles qui sont W-propres fibre par fibre : ils sont W-propres. p. 42 [page 57]

2°) J'étais intéressé, dans un cas de catégories fibrées scindées X, Y sur S et d'un foncteur strictement cartésien $f : X \longrightarrow Y$, supposé W-parfait fibre par fibre, de conclure que f soit aussi W-parfait. (C'était un cas où de plus on sait que X, Y sont aussi des W-fibrés sur S, i.e. les fonteurs changement de base $X_{s'} \longrightarrow X_s$, $Y_{s'} \longrightarrow Y_s$ sont dans W. Mais ça n'a pas beaucoup servi …) La question qui restait, en 1°), était celle de la *W-propreté* de f. Mais c'est sans espoir (même pour $Y = S$), en vertu de la brillante

Proposition 2. *Supposons que* $S = 0 \begin{array}{c} \nearrow a \\ \searrow b \end{array}$ *, et soit Z une catégorie sur S. Alors $\Phi(Z)$ est propre sur S si et seulement si $Z = \emptyset$.*

Commentary · Exposition [ms. 57]

The fork obstructs outgoing lifts

The fork is being used for a second purpose here: a free split fibration supplies incoming Cartesian lifts, while properness requires the appropriate outgoing lift categories to be aspherical. The commentary on Chapter VI, manuscript pp. 190–192, gives the full fork calculation and the support obstruction; we refer to it rather than repeat the calculation.

For the present application, one may see the obstruction at an object $(0, z, a)$ of $\Phi_S(Z)$ whose label in S lies on one branch. The arrow from 0 to the other branch has no compatible outgoing lift from that object: it would require a morphism in the fork from the first terminal branch to the other. If Z has an object over either branch, this construction applies. If every object of the nonempty category Z lies over 0, then an outgoing lift towards either terminal branch is again impossible, because no object of Z can label its target. These two cases exhaust the possibilities. In each case the relevant lift category is empty.

Thus the assertion is correct for ordinary properness, and for W-properness whenever W is nontrivial: the empty category is then not W-aspherical. If $W = \mathrm{Fl}(\mathrm{Cat})$, every lift category, including the empty one, is W-aspherical and every functor is W-proper. That degenerate case must be excluded from the relative reading of "if and only if $Z = \varnothing$". Fibrewise perfectness of the structural map to S carries no information about this outgoing obstruction, since every map from a category to the point is perfect.

Prenons alors dans 2°) ci-dessus $X = \Phi(Z)$, $Y = S$, $f : \Phi(Y) \longrightarrow S$ [plutôt $f : \Phi(Z) \longrightarrow S$] le morphisme structural (donc les f_s sont W-parfaits), alors f n'est propre que si $X = \emptyset$. Pourtant, si on prend Z W-fibrée sur S, $\Phi(Z)$ l'est aussi, et on a un contre-exemple à 2°).

Mais on s'est quand même convaincu du résultat suivant :

Proposition 3. *Soient X, Y catégories fibrées scindées sur S, $f : X \longrightarrow Y$ S-foncteur strictement cartésien, tel que pour tout $s \in S$, $f_s : X_s \longrightarrow Y_s$ soit* W-fibrant. *Alors,* si W satisfait W(4a), *f est W-fibrant.* [page 58]

Commentary · Development (commentators') [ms. 58]

A missing hypothesis in the last proposition

Grothendieck is trying to lift a fibrewise fibration statement through the Grothendieck construction. The preceding paragraph mentions an additional assumption that both structural families are W-fibrations over S. That assumption is absent from Proposition 3 as printed. The literal statement is false, even for ordinary weak equivalences.

A strictly Cartesian counterexample. [ours] Take $S = [1]$. Let $F, G : S^{\mathrm{op}} \to \mathrm{Cat}$ be diagrams of discrete categories

$$F(0) = F(1) = e, \qquad G(0) = e, \quad G(1) = \{a, b\},$$

with the unique transition maps. Let η_0 be the identity and let $\eta_1 : e \to \{a, b\}$ select a. These components form a strict natural transformation. Its Grothendieck construction is the inclusion

$$h : \{o \to a\} \longrightarrow \{o \to a,\ o \to b\}.$$

Both source and target are split fibrations over [1], and h preserves the chosen Cartesian lifts: the only nonidentity chosen lift in the source is sent to $o \to a$. Each component of η is perfect. Indeed every functor between discrete categories is both a Grothendieck fibration and an opfibration; the only arrows to lift in its target are identities. It is consequently a W_∞-fibration.

Pull back h along the arrow $o \to b$ in the target. The resulting category has one object, lying over $0 \in [1]$. Its fibres are e at 0 and $\varnothing$ at 1. The second endpoint inclusion is $\varnothing \to e$, which is not a weak equivalence. Thus h is not even a W_∞-pseudofibration. This proves the counterexample. Notice that the target structural family is not a W_∞-fibration: its transport is $\{a, b\} \to e$. This explains exactly how the extra assumption mentioned in the preceding discussion would exclude the example.

Here is a sufficient repair for the fibrewise-perfect situation that motivated the proposition. It states explicitly the two comparison properties used in the proof rather than hiding them in an appeal to ordinary intuition.

A sufficient fibrewise-smooth repair. [ours] Assume W(4a) and W(4b). Let $F, G : S^{\mathrm{op}} \to \mathrm{Cat}$ send every arrow into W, and let $\eta : F \Rightarrow G$ be a strict natural transformation. Suppose every η_s is both W-smooth and a W-fibration; fibrewise perfectness is sufficient. Then $h = \int \eta$ is W-smooth and a W-fibration.

First, an arrow in $\int G$ from (s, y) to the image of (t, x) is given by $u : s \to t$ and $\beta : y \to \eta_s F(u)x$. Its lift category for h is exactly the lift category of β for η_s. This proves smoothness, because the latter category is W-aspherical.

Next fix $u : s \to t$. Form

$$P = G(t) \times_{G(s)} F(s).$$

The projection $P \to F(s)$ belongs to W by W(4a), since it is the pullback of $G(u) \in W$ along the W-fibration η_s. The naturality map $F(t) \to P$ composes with this projection to $F(u) \in W$, so it also belongs to W. Both $F(t) \to G(t)$ and $P \to G(t)$ are W-fibrations. W(4b) therefore shows that for every $z \in G(t)$ the induced relative-fibre transport

$$F(t)_z \longrightarrow F(s)_{G(u)z}$$

belongs to W.

To finish, factor an arbitrary arrow of $\int G$ into an arrow within a fibre followed by a chosen Cartesian arrow. For an arrow within $G(s)$, transport on the under-comma categories of h is in W because η_s is a W-fibration. The comparison with its total under-comma category is a homotopy equivalence: an object above t with base arrow $u : s \to t$ is sent to its Cartesian pullback $F(u)x$ above s, giving a right adjoint to the inclusion of the fibre under-comma category. For a chosen Cartesian arrow, the displayed relative-fibre transport and smoothness identify the corresponding under-comma map as an element of W. Composition now gives the assertion for every arrow of $\int G$. The dual form of Proposition 8, together with smoothness, proves that h is a W-fibration.

This repair covers the preceding discussion when its structural families and fibrewise-perfect hypotheses are retained. It does not claim that adding only the omitted structural-fibration hypothesis proves the entire printed formulation. We checked the later treatments of smooth functors and locally constant families cited in this commentary and did not locate this exact small counterexample or this explicit sufficient repair there. These are deductions given here, without a claim of priority.

(J'espérais avoir que f est W-fibrant 'à l'œil', pour prouver que W(4c) implique W(4b). Mais j'étais obligé de supposer W(4a) …)

Commentary · Later developments [ms. 58]

The coherence condition in a later gluing theorem

The last failed shortcut has a useful later analogue. Rezk (1998, Theorem 7.1) proves that the homotopy colimit of a diagram of sharp maps is sharp when every naturality square is homotopy Cartesian. This square condition is the coherence missing from a bare list of fibrewise fibration assertions. In the counterexample just given, the square of discrete fibres

$$\begin{array}{ccc} e & \longrightarrow & e \\ \downarrow & & \downarrow \\ \{a, b\} & \longrightarrow & e \end{array}$$

is not homotopy Cartesian: the homotopy pullback of the other three corners has two points.

This is a comparison of mathematical mechanisms, not an identification of all the models. Thomason's comparison between the nerve of a Grothendieck construction and a homotopy colimit is a weak equivalence; such a comparison alone does not transport the property that every *strict* pullback is homotopy Cartesian. To deduce a statement about the literal functor of Proposition 3, the comparison must also control the pullbacks that occur in its fibration test. That is why the source's dependence on W(4a), and the omitted control of structural transport, cannot be removed by a slogan about homotopy colimits.

Overview · XI-XIIa

Fibrations, localizers, and the coherence of fibres

The pages assembled here turn a useful geometric intuition into a problem of foundations. A family of categories should behave like a fibration when its strict fibres calculate homotopy fibres and vary coherently over the base. Grothendieck first characterizes that behaviour for ordinary weak homotopy equivalences. He then asks which axioms on an abstract class W of functors permit the same constructions, and discovers that several apparently natural requirements already force the whole ordinary homotopy theory. The resulting revisions are part of the argument: the word "fibration" changes its tests as the desired scope of the theory becomes clearer.

These pages comprise Chapter XI, manuscript pp. 127–136, and Chapter XII, manuscript pp. 1–58, through the end of section IV. These are separate manuscript sequences. The edition explicitly says that Chapter XI has no pp. 1–126; their absence is not a gap in the text. We write $BC = |NC|$ for the classifying space of a category and W_∞ for the functors whose nerves are weak homotopy equivalences.

The geometric theorem and its coefficient proof. Chapter XI begins with a property of the actual pullback functor:

$$f^* : \mathrm{Cat}/Y \longrightarrow \mathrm{Cat}/X \quad \text{preserves } W_\infty.$$

This is a universal condition on changes of base, not a condition merely on the homotopy types of the individual fibres. Theorem 1 identifies it with universal comma-category tests and with base-change and local-constancy statements for direct images of locally constant coefficients. In the terminology later used for model categories, these are sharp maps for the Thomason weak equivalences (Rezk, 1998, §2). Quillen's Theorem B explains the geometry of the comma tests: when their transition functors are weak equivalences, the strict fibre, compared with the appropriate comma category, represents the homotopy fibre (Quillen, 1973, §1).

Most of the coefficient argument is complete as written. The degree-zero comparison and the first-quadrant Leray comparison require no new finiteness hypothesis. The nonabelian passage needs more care. A component of a torsor groupoid has the automorphism group of a representative torsor; this group can be an inner form of the coefficient group, and its direct image is not generally the fixed group printed in the proposed obstruction sequence. We therefore replace that sequence by an argument with the groupoids of torsors on X/y. The universal degree-zero hypothesis gives full faithfulness of their transition functors; the degree-one hypothesis gives essential surjectivity. The same two hypotheses identify their values with the torsor groupoids on strict fibres. Descent reconstructs global torsors from this locally constant diagram, and homotopy invariance of such diagrams proves the required comparison (Cisinski, 2009, Theorem 1.3).

Theorem 2 then detects an equivalence between two such families on one fibre in each connected component of the base. The source's local reduction for torsors becomes precise through the same descent argument. Its converse uses a contractible replacement of the base. We give an independent construction by factoring a point in Thomason's model category (Thomason, 1980, Theorem 4.9), and also check the specific path-category dependency that Chapter XII recalls from Chapter VII. This separates the existence of a suitable replacement from the stronger task of constructing it explicitly with both properness and smoothness.

What the axioms force. Chapter XII starts with identities and cancellation, a theorem-A principle, and the asphericity of categories with a terminal object. Two forms of theorem A occur. W(2) is relative: equivalences on comma categories over every object of a third category imply equivalence of the total functor. W(2 bis) is absolute: aspherical comma

categories imply that a functor is an equivalence. The manuscript deliberately uses the latter in several arguments. Modern "fundamental localizer" normally includes the former. We keep the distinction throughout the audit.

The minimum conjectured in these pages is now known. Cisinski identifies W_∞ as the smallest fundamental localizer (Cisinski, 2004, Theorem 2.2.11), and as the smallest weak fundamental localizer with the absolute theorem-A axiom (Cisinski, 2006a, Theorem 6.1.18). Strong saturation and stability under filtered colimits are also established for full fundamental localizers; those results are not assertions about every class satisfying only the weaker axiom. An inference from "invertible in the localization" to "belongs to W" is justified at the point where its applicable hypothesis is available.

The fibration axioms add a rigidity that the basic localizer axioms do not possess. Their weakest perfect-fibre form, combined with nondegeneracy, makes homotopy fibres of W-maps W-aspherical. Iterating the loop construction then detects all homotopy groups. We repair the source's nondegeneracy argument without its unjustified restriction to a component: a missed component produces an empty homotopy fibre, while two identified components produce a disconnected aspherical fibre, whose diagonal in its square again has an empty homotopy fibre. Asphericity of the empty category collapses the theory. Thus the alternatives are W_∞ and the class of every functor. The second alternative cannot be discarded from the opening assertion about derivators; the terminal derivator realizes it.

The truncation examples explain why a more flexible fibration notion is needed. The class W_n retains homotopy groups only through degree n, and is a genuine localizer. But the based-path family of an $(n+1)$-sphere has an invisible total space and an invisible base while its fibre retains a nonzero n-th homotopy group, or a nontrivial component set when $n = 0$. Hence the strongest fibre axioms fail. In degree zero, the exact sequence must be read in pointed sets and with the appropriate group action: a cokernel of groups does not describe the component set in general.

Lift categories supply the missing structure. Section III develops proper and smooth functors through categories of lifts with prescribed source or target. Those categories turn universal comma comparisons into workable tests, prove stability under base change and composition, and explain why Grothendieck (op)fibrations furnish examples. They also support the passage from fibrewise equivalence to equivalence of total categories. The later formulations by Maltsiniotis describe the corresponding exact squares, while the derivator account explains the associated base-change transformations (Maltsiniotis, 2005, 2012; Groth, 2013).

The proposed weakening to endpoint equivalences over every arrow loses a necessary compatibility. We give a poset with eight objects over [2]. Its fibres have two contractible components, every interval pullback has both endpoint inclusions in W_∞, and transport along $0 \to 1$ and $1 \to 2$ preserves the component labels. Transport along $0 \to 2$ exchanges them. Its total nerve is an eight-cycle. Consequently the edge transports do not compose, and the pseudofibration question raised on manuscript p. 40 has a negative answer. The complete proof is independent of the accompanying finite computation.

The successful replacement uses universal preproperness or prelissity in addition to the interval test. Comma categories then provide actual functorial transport. A split replacement converts this into a diagram of categories whose arrows lie in W. For a categorically contractible base, a finite zigzag of natural transformations gives an explicit finite zigzag of fibrewise and total W-equivalences. This proves the contractible-base portion of Theorem 3 directly, without extracting a zigzag from an abstract isomorphism in a localization. Here "contractible" has the manuscript's categorical meaning; a weakly contractible nerve need not admit such a finite contraction.

The last proposition and the limits of the repair. Section IV returns to the relations among the fibration axioms, then proposes a fibrewise gluing statement. Its final Proposition 3

is false literally as printed. Over [1], take the strictly Cartesian inclusion of the split fibration $\{o \to a\}$ into $\{o \to a, o \to b\}$. Every fibre map is a functor between discrete categories and is perfect. Pulling the total functor back along $o \to b$ gives endpoint fibres e and $\varnothing$; it is not even a pseudofibration. The target structural family is not a W_∞-fibration, precisely the extra condition mentioned in the preceding discussion and omitted from the proposition.

We prove a sufficient repair for that preceding, fibrewise-perfect situation: the structural transports lie in W, the fibre maps are smooth W-fibrations, and W(4a) and W(4b) control the relevant pullback and fibre comparison. We do not claim that adding only the omitted structural condition repairs the full printed statement. Rezk's later gluing theorem has an analogous additional requirement that naturality squares be homotopy Cartesian (Rezk, 1998, Theorem 7.1); passing between models does not by itself remove the need to control strict pullbacks.

The marked developments give these deductions with complete proofs and bounded accounts of the literature examined, without a claim of priority. The registers distinguish what the source proves, sketches, assumes, or conjectures from the status supplied by the commentary. They preserve edition slips in the French text and apply only corrections of the transcription. Questions not decided under their exact weaker hypotheses are identified as limitations of this audit, rather than declared open in the literature.

V Sommes amalgamées et carrés W-cocartésiens dans Cat

1 Généralités sur $U \overset{i}{\hookrightarrow} X \overset{j}{\hookleftarrow} T$, et les sommes amalgamées.

1.1 Données de recollement entre un ouvert et un fermé.

Soit X dans Cat, U un ouvert dans X, T le complémentaire fermé. (**NB** Les ouverts correspondent bien aux ouverts de $\mathrm{Ob}\, X$, topologisé par sa relation de préordre naturelle $x \leq y \iff \mathrm{Hom}_X(x,y) \neq \emptyset$, de même pour les fermés. Les topologies associées aux relations de préordre sont celles où toute intersection d'ouverts est encore ouverte, i.e. toute réunion de fermés est encore fermée. Donc les ouverts d'une telle topologie sont les fermés d'une topologie duale, correspondant à la relation de préordre opposée. La relation de préordre associée à la topologie est

$$x \leq y \qquad \iff \qquad x \in \overline{\{y\}},$$

la topologie associée au préordre sur I est celle pour laquelle les ouverts sont les réunions d'ensembles de la forme I/x (lesquels forment une base d'ouverts), ou encore les *'cribles'* ($x \in U$, $y \leq x \Longrightarrow y \in U$), les fermés sont les réunions d'ensembles $x\backslash I$, c'est-à-dire les cocribles. Pour toute partie A de I, il y a un plus petit ouvert contenant A, qui est aussi son plus petit voisinage, c'est la réunion des I/x pour $x \in A$. Et dualement il y a un plus grand fermé contenu dans A, dont le complémentaire est le plus petit ouvert contenant $B = I\backslash A$, donc $\bigcup_{x\in B} I/x$. L'adhérence de A est la réunion des adhérences $x\backslash I$ de ses points.)

[page 60]

Commentary · Exposition [ms. 59]

An open–closed cut remembers a profunctor

Grothendieck begins with a cut of a category which permits arrows to cross in only one direction. This is the reason that the subsequent pushout calculation is manageable. An open subcategory $U \subset X$ is a full sieve: if an arrow has its target in U, its source belongs to U. The complementary full subcategory T is therefore a cosieve, and there are no arrows from T to U. Once the compositions internal to U and T are known, the remaining information is precisely the action of these compositions on the sets of arrows from U to T.

There is a reversal in the displayed specialization convention on this page. With $x \leq y$ meaning that $\mathrm{Hom}_X(x,y)$ is nonempty and with the opens taken to be downsets, one has

$$\overline{\{x\}} = \{y \mid x \leq y\}, \qquad x \leq y \iff y \in \overline{\{x\}}.$$

The edition really prints $x \in \overline{\{y\}}$. That formula is incompatible with its following description of opens as sieves; it is a source slip, not a transcription error. For the walking arrow $0 \to 1$, the opens are $\varnothing, \{0\}, \{0,1\}$ and the closure of $\{0\}$ is the whole space. All the subsequent formulas for closure and boundary use the downset convention and are correct with it. In particular, the smallest open containing A is its downward closure, while its ordinary closure is its upward closure. No antisymmetry is required: categorically isomorphic objects, and more generally objects connected by arrows in both directions, cannot be distinguished by these opens.

For completeness, the reconstruction in Proposition 1 can be written without a choice of compositions. Given

$$H : U^{\mathrm{op}} \times T \longrightarrow \mathrm{Ens},$$

form a category $\mathrm{Coll}(H)$ whose objects are the tagged disjoint union of those of U and T, whose hom sets within each part are the original ones, whose hom sets from T to U are empty, and whose hom sets from $u \in U$ to $t \in T$ are $H(u,t)$. Define composition with $a : u' \to u$ by $h \mapsto H(a,1)(h)$ and composition with $b : t \to t'$ by $h \mapsto H(1,b)(h)$. The two operations commute by bifunctoriality. Every composable string contains at most one arrow crossing from U to T, so these identities, together with associativity in the two pieces, prove associativity in the collage. The identities follow from the identity laws for H.

A functor preserving the two parts consists of functors f_U, f_T and a natural transformation $H \to H'(f_U^{\mathrm{op}} \times f_T)$. The naturality squares are exactly the equations expressing preservation of composition involving a crossing arrow. This proves full faithfulness of the correspondence of Proposition 1; the collage construction proves essential surjectivity. With tagged objects there is a specified inverse up to canonical isomorphism, which explains the editors' preference for an equivalence over an unqualified isomorphism of categories. Today H is called a profunctor and $\mathrm{Coll}(H)$ its collage. The point of the terminology is that a category can be assembled from its internal categories and a bimodule of arrows between them.

La situation (X, U, T) se reconstitue, à isomorphisme unique près, par la connaissance de

1°) Les deux catégories U, T.

2°) Le bifoncteur $\begin{cases} H : U^\circ \times T \longrightarrow \mathrm{Ens} \\ H(u,t) = \mathrm{Hom}_X(u,t). \end{cases}$

De plus, ces données 1°) 2°) en sont soumises à aucune restriction. On a, plus exactement

Proposition 1. *Un isomorphisme* `[plutôt une équivalence de catégories]` *entre la catégorie $\mathcal{T}$ dont les objets sont les triples (X,U,T), avec $X \in \mathrm{Ob}\,\mathrm{Cat}$, $U \in \mathrm{Ouv}(X)$, $T \in \mathrm{Ferm}(X)$, U et T complémentaires l'un de l'autre, les morphismes de (X,U,T) dans (X',U',T') étant les foncteurs $f : X \longrightarrow X'$ qui induisent $U \longrightarrow U'$, $T \longrightarrow T'$ (d'où $U = f^{-1}(U')$, $T = f^{-1}(T')$), avec la catégorie $\mathcal{T}'$ des triples (U,T,H), de deux catégories U, T et d'un bifoncteur* p. 44

$$H : U^\circ \times T \longrightarrow \mathrm{Ens}$$

(ou encore un préfaiscau $U^\circ \longrightarrow T^\vee$ sur U, donc un objet de $\underline{\mathrm{Hom}}(U^\circ, T^\vee)$)), un morphisme de (U,T,H) dans (U',T',H') étant un triple

$$(f_U, f_T, u) \qquad \begin{cases} \left.\begin{array}{rccc} f_U : & U & \longrightarrow & U' \\ f_T : & T & \longrightarrow & T' \end{array}\right\} \text{des foncteurs} \\ u : H \longrightarrow H' \circ (f_U^\circ \times f_T), \\ \text{i.e. } H(u,t) \longrightarrow H'(f_U(u), f_T(t)) \\ \text{un homomorphisme fonctoriel} \\ \text{(flèche dans } (U \times T^\circ)^\wedge \simeq \underline{\mathrm{Hom}}(U^\circ, T^\vee))), \end{cases}$$

composition des flèches évidente.

Si $U \hookrightarrow X \hookleftarrow T$ est un triple, et

$$f_{U'} : U' \longrightarrow U, \ f_{T'} : T' \longrightarrow T$$

des flèches dans Cat, il y a une façon privilégiée de 'recoller' U' et T', de façon à ce que l'objet (X',U',T') s'envoie dans (X,U,T) en induisant

$f_{U'}$, $f_{T'}$: [page 61]

$$\begin{array}{ccccc} U' & \xhookrightarrow{i'} & X' & \xhookleftarrow{j'} & T' \\ \downarrow{\scriptstyle f_{U'}} & & \downarrow{\scriptstyle f} & & \downarrow{\scriptstyle f_{T'}} \\ U & \xhookrightarrow{i} & X & \xhookleftarrow{j} & T, \end{array}$$

elle s'obtient à l'aide des bifoncteurs

$$\begin{cases} H'(u',t') \overset{\text{déf}}{=} H(f_{U'}(u'), f_{T'}(t')) \\ \text{i.e. } H' = H \circ (f_{U'}^\circ \times f_{T'}). \end{cases}$$

Ce triple, i.e. cet objet de $\mathcal{T}$, représente le foncteur suivant sur $\mathcal{T}$:

$$(X'',U'',T'') \longmapsto \mathrm{Hom}_{\mathrm{Cat}}(U'',U) \times \mathrm{Hom}_{\mathrm{Cat}}(T'',T),$$

i.e. on a pour tout objet (X'', U'', T'') de $\mathcal{T}$ une bijection canonique, fonctorielle en cet objet

$$(*) \qquad \mathrm{Hom}_{\mathcal{T}}((X'', U'', T''), (X', U', T')) \simeq \mathrm{Hom}_{\mathrm{Cat}}(U'', U) \times \mathrm{Hom}_{\mathrm{Cat}}(T'', T).$$

Nul doute qu'on a même p. 45

$$(**) \qquad \underline{\mathrm{Hom}}_{\mathcal{T}}((X'', U'', T''), (X', U', T')) \simeq \underline{\mathrm{Hom}}_{\mathrm{Cat}}(U'', U) \times \underline{\mathrm{Hom}}_{\mathrm{Cat}}(T'', T),$$

tout aussi fonctoriel, dont $(*)$ se déduit en passant aux ensembles d'objets. On dit que le triple (X', U', T') est le triple *induit* par le triple (X, U, T), via les foncteurs $f_{U'}$, $f_{T'}$.

NB Si $f_{U'}$, $f_{T'}$ sont pleinement fidèles, alors il en est de même de $f : X' \longrightarrow X$. Nous utiliserons cette opération de recollement privilégié surtout quand $U' = U$, $f_{U'} = \mathrm{id}_U$, ou inversement $T' = T$, $f_{T'} = \mathrm{id}_T$.

1.2 Relation avec le recollement des topos.

La situation d'un triple

$$(\mathcal{X}, \mathcal{U}, \mathcal{T})$$

d'un topos $\mathcal{X}$, d'un ouvert $\mathcal{U}$ de $\mathcal{X}$, et d'un

[page 62]

Commentary · Exposition [ms. 61]

The induced collage has a relative universal property

The induced triple is meant to express change of the two categories on which the gluing data live. Its universal property has to remember a map to the original triple. Without that map the displayed formulas $(*)$ and $(**)$ are false; both formulas are reproduced faithfully from the edition.

Write $\mathcal{T}$ for the category of triples and $P : \mathcal{T} \to \mathrm{Cat} \times \mathrm{Cat}$ for $(X, U, T) \mapsto (U, T)$. Let $b = (f_{U'}, f_{T'}) : (U', T') \to (U, T)$ and let X' be the collage of b^*H. For any triple $Y = (Y, V, S)$ the correct bijection is

$$\mathrm{Hom}_{\mathcal{T}}(Y, X') \simeq \mathrm{Hom}_{\mathcal{T}}(Y, X) \underset{\mathrm{Hom}(V,U)\times\mathrm{Hom}(S,T)}{\times} \big(\mathrm{Hom}(V, U') \times \mathrm{Hom}(S, T')\big).$$

On the right one chooses a morphism $g : Y \to X$ and functors $a : V \to U'$, $c : S \to T'$ such that $g|_V = f_{U'}a$ and $g|_S = f_{T'}c$. The map on mixed hom sets of g then has type

$$H_Y \longrightarrow H(f_{U'}a-, f_{T'}c-) = (b^*H)(a-, c-).$$

It defines a unique lift $Y \to X'$, and restriction of a lift recovers exactly these data. Thus $X' \to X$ is a cartesian arrow of P, not an object representing arbitrary pairs of functors to U and T.

The same argument works on natural transformations. A transformation between two lifts is a pair of transformations on V, S satisfying the naturality equations for every mixed arrow, and these are precisely the equations in the corresponding strict pullback of functor categories. This is the correctly typed version of $(**)$. One may express the statement in the language of a split fibration of gluing data, using the literal restriction operation on bifunctors; the corresponding assertion for unlabelled collages is invariant under the canonical isomorphisms.

The missing datum cannot be supplied by merely inserting primes on the right of the printed formulas. Take $U = T = U' = T' = e$, both change-of-base functors the identity, and $H = \{a, b\}$. Then $X' = X$ is the category with two parallel arrows from the open object to the closed object. There are two part-preserving functors from the walking arrow to X', whereas there is only one pair of functors from its two singleton parts to U', T'. The choice of crossing arrow is precisely the information lost by the printed right-hand side. The following observation about full faithfulness is unaffected: on the two diagonal sorts of hom sets it follows from $f_{U'}, f_{T'}$, and on mixed hom sets it follows from the defining equality $H' = b^*H$.

sous-topos fermé complémentaire, est toute similaire (**NB** Si $\mathcal{X} = \mathrm{Top}(X)$, avec X dans Cat, alors $\mathrm{Ouv}(\mathcal{X}) \simeq \mathrm{Ouv}(X)$, puisque les ouverts correspondent aux sous-faisceaux du

faisceau final sur $\mathcal{X}$, i.e. du préfaisceau final sur X. Cette bijection est compatible avec le passage aux complémentaires.) La théorie des topos dit que les couples $(\mathcal{X},\mathcal{U},\mathcal{T})$ `[plutôt triples]` se reconstituent, à équivalence définie à isomorphisme unique près, à l'aide d'un triple

$$\begin{cases}\mathcal{U},\ \mathcal{T} \text{ deux topos}\\ \varphi : \mathrm{Fais}\,(\mathcal{U}) \longrightarrow \mathcal{T} \text{ un foncteur exact à gauche ('accessible')},\end{cases}$$

ce foncteur φ étant obtenu, quand on part de

$$\mathcal{U} \xrightarrow{i} \mathcal{X} \xleftarrow{j} \mathcal{T},$$

comme

$$\varphi = j^* i_*.$$

De plus, le triple $(\mathcal{U},\mathcal{T},\varphi)$ peut être choisi arbitrairement, avec la seule restriction (pratiquement anodine, car toujours satisfaite pour tous les foncteurs naturels qu'on rencontre) que φ soit (en plus d'être exact à gauche) 'accessible'.

Dans le cas actuel $\mathcal{X} = \mathrm{Top}(X)$, $\mathcal{U} = \mathrm{Top}(U)$, $\mathcal{T} = \mathrm{Top}(T)$, le foncteur $\varphi = j^* i_*$ est non seulement exact à gauche, mais même il commute aux $\varinjlim$ quelconques, puisqu'il en est ainsi (toujours) de i_*, et aussi (parce que le j topossique est induit par le $j : T \longrightarrow X$ catégorique) de j^*. En fait, on trouve ceci : p. 46 [page 63]

Commentary · Context [ms. 62]

The presheaf case is already present in SGA 4

Grothendieck's comparison with toposes recovers a particularly exact antecedent. In Artin et al. (1972, Exposé IV, Theorem 9.5.4), an open subtopos and its closed complement reconstruct the ambient topos through the accessible left exact gluing functor. Exercise 9.5.10 of the same exposé then treats presheaf toposes: its parts (a)–(c) identify opens with sieves, introduce the cross-hom bifunctor, and characterize the presheaf case by preservation of products by the gluing functor. Thus Proposition 2 is a return to a construction already formulated there, now serving a calculation of categorical pushouts and their homotopy properties. The letters i, j are interchanged between the SGA convention and the present pages.

The category of sheaves in the glued topos is the category of triples

$$(F, G, \theta), \qquad F \in \mathcal{U}, \quad G \in \mathcal{T}, \quad \theta : G \longrightarrow \varphi(F).$$

The comparison arrow records how a section on the closed side approaches the open side. For $X = \mathrm{Coll}(H)$, a presheaf E on X restricts to $F = E|_U$ and $G = E|_T$. Its values on the mixed arrows are maps

$$G(t) \times H(u,t) \longrightarrow F(u)$$

natural in u, t. Transposing in the first variable produces $G(t) \to \mathrm{Hom}_{U^\wedge}(H(-,t), F)$, exactly the required gluing arrow. Conversely these maps reconstruct the restriction maps of E on all arrows; their naturality supplies the mixed composition laws. This directly explains why the ordinary categorical collage and the topos gluing construction agree. The comparison is not an analogy between two shapes of diagrams: both constructions encode the same mixed restriction maps.

Proposition 2 : *Considérons une situation de recollement de deux topos $\mathcal{U}$, $\mathcal{T}$ par $\varphi : \mathrm{Fais}\,\mathcal{U} \longrightarrow \mathrm{Fais}\,\mathcal{T}$, foncteur exact à gauche. Supposons que $\mathcal{U} = \mathrm{Top}(U)$, $\mathcal{T} = \mathrm{Top}(T)$, avec U et T dans* Cat. *Pour que le topos recollé $\mathcal{X}$ soit équivalent à un topos* $\mathrm{Top}(X)$, *avec X dans* Cat, *il faut et il suffit que le foncteur de recollement φ commute aux $\varinjlim$ quelconques, ou ce qui revient au même, qu'il ait un adjoint à gauche :*

$$\psi : \underbrace{\mathrm{Fais}\,\mathcal{T}}_{=T^\wedge} \longrightarrow \underbrace{\mathrm{Fais}\,\mathcal{U}}_{=U^\wedge}.$$

On s'attend dès lors que la donnée de recollement φ, ou ce qui revient au même le foncteur ψ ayant un adjoint à droite, i.e. commutant aux $\varinjlim$ quelconques, revient à celle d'une donnée de recollement H

$$H : U^\circ \times T \longrightarrow \mathrm{Ens}$$

pour U et T. Mais on sait bien que les foncteurs $\psi : T^\wedge \longrightarrow \mathcal{C}$ dans une catégorie $\mathcal{C}$ avec $\varinjlim$ quelconques, qui commutent auxdites $\varinjlim$, forment une catégorie équivalente (par le foncteur $\psi \longmapsto \psi|T(\subseteq T^\wedge)$) à celle des foncteurs

$$\psi_0 : T \longrightarrow \mathcal{C} \quad (= \underbrace{U^\wedge}_{\underline{\mathrm{Hom}}(U^\circ,\mathrm{Ens})} \text{ en l'occurrence}),$$

et la donnée d'un tel foncteur ψ_0 revient bien à celle d'un H. Donc [page 64]

Corollaire. *La catégorie des données de recollement topossique $\varphi : U^\wedge \longrightarrow T^\wedge$ entre* $\mathrm{Top}(U)$, $\mathrm{Top}(T)$*, telles que le topos recollé soit un 'topos* paradisiaque*', i.e. équivalent à un topos de la forme $X^\wedge$ (avec X dans* Cat*), est équivalente à celle des données de recollement $H : U^\circ \times T \longrightarrow$ Ens entre U et T. La donnée topossique φ associée à H est le foncteur adjoint à droite de $T^\wedge \longrightarrow U^\wedge$ déduit de $T \xrightarrow{H} U^\wedge$ par prolongement commutant aux $\varinjlim$, ou encore elle est donnée par*

$$\varphi(\underbrace{F}_{\in U^\wedge})(t) \simeq \mathrm{Hom}_{U^\wedge}(H(t), F),$$

où dans le second membre H est interprété comme un foncteur $T \longrightarrow U^\wedge$. Le topos recollé par φ est canoniquement équivalent à $\mathrm{Top}(X)$*, où X est l'objet de* Cat *obtenu par recollement à l'aide de H.*

Du point de vue de la théorie des faisceaux, cela donne l'interprétation de H, comme exprimant le foncteur

$$\varphi = j^* i_* : U^\wedge \longrightarrow T^\wedge$$

par la formule précédente.

p. 47

Commentary · Exposition [ms. 64] [page 65]

The adjunction which characterizes the presheaf gluing

The extra preservation of limits isolates those gluing functors that come from actual sets of arrows. Let $H_t = H(-, t) \in U^\wedge$. Its colimit-preserving extension from the Yoneda image of T is

$$\psi(G) = \int^{t \in T} G(t) \times H_t, \qquad \varphi(F)(t) = \mathrm{Hom}_{U^\wedge}(H_t, F).$$

Here the coend is an ordinary colimit in $U^\wedge$. A map $\psi(G) \to F$ is a family of maps $G(t) \times H_t \to F$ compatible with the arrows of T. By the ordinary set-valued adjunction between product and hom, this is exactly a natural transformation $G \to \varphi(F)$. This proves $\psi \dashv \varphi$ and the displayed formula of the corollary. It also proves that φ preserves all small limits.

Conversely, suppose that an accessible gluing functor $\varphi : U^\wedge \to T^\wedge$ preserves all small limits. The adjoint functor theorem for locally presentable categories supplies a left adjoint ψ. Set $H_t = \psi(y_T t)$. Every presheaf is the colimit of its representables indexed by its category of elements; since ψ is a left adjoint, this determines ψ from H. The preceding adjunction then identifies its right adjoint with φ. Applying the explicit construction of the preceding block identifies the glued topos with $\mathrm{Coll}(H)^\wedge$. This proves the sufficient direction of Proposition 2 with the size assumption made explicit. The accessibility assumption belongs to the ambient gluing problem; it should not be silently discarded in an abstract claim that every limit-preserving functor has a left adjoint.

For the converse direction of the proposition, let the glued topos be equivalent to $C^\wedge$. Its specified open subtopos corresponds under this equivalence to a subterminal presheaf. Such a presheaf takes the value either $\varnothing$ or a singleton at each object, and its support is a sieve $C_U \subset C$. The complementary full cosieve C_T presents the closed complement. Restriction to C_T preserves all limits, as does the right adjoint to restriction to C_U. Their composite is the transported gluing functor, so φ preserves all limits. The argument uses the specified open and closed pieces but does

not require the given presentations U, T to coincide literally with C_U, C_T. Equivalences of presheaf categories preserve the limiting operations involved. This is precisely the content of the presheaf case of the SGA exercise just cited.

There is a variance convention in the word "category" in the corollary. For fixed U, T, a transformation $H \to K$ induces $\psi_H \to \psi_K$, but it induces a transformation $\varphi_K \to \varphi_H$ on the right adjoints. Thus the asserted equivalence of categories of gluing data uses reversed transformations on the right-adjoint side; with ordinary pointwise transformations it is an antiequivalence. The object classification and every displayed objectwise formula remain unchanged.

A useful test is $U = T = e$ and $H = S$ a set. The collage has two objects and one crossing arrow for each element of S. The functors are $\psi(G) = G \times S$ and $\varphi(F) = F^S$. A presheaf on the collage is a pair of sets F, G with an S-indexed family of maps $G \to F$. If $S = \varnothing$, there is no compatibility datum and the presheaf topos is the product of two copies of Ens. If S is a singleton, it is the category of arrows of sets. These limiting cases also verify the direction $G \to \varphi(F)$ of the gluing arrow.

1.3 Flèches dans Cat, de source ou but un objet recollé (X, U, T).

Quand (X, U, T) est donné par une donnée de recollement

$$U,\ T,\ H : U^\circ \times T \longrightarrow \mathrm{Ens},$$

les flèches

$$f : X' \longrightarrow X$$

dans Cat se décrivent immédiatement ainsi : la donnée de f définit d'abord

$$U' = f^{-1}(U), \qquad T' = f^{-1}(T),$$

couple d'un ouvert de X' et du fermé complémentaire, de sorte que cette donnée équivaut à celle de

1°) un couple (U', T') dans X'

2°) un morphisme (dans $\mathcal{T}$) de (X', U', T') dans (X, U, T), ce qui équivaut par 1.1 à un triple

$$\begin{cases} f_{U'} : & U' & \longrightarrow & U \\ f_{T'} : & T' & \longrightarrow & T \\ u : & H_{U',T'} & \longrightarrow & H \circ (f_{U'}^\circ \times f_{T'}), \end{cases}$$

où on a posé

$$\begin{cases} H_{U',T'} : U'^\circ \times T' \longrightarrow \mathrm{Ens} \\ H_{U',T'}(u', t') = \mathrm{Hom}_{X'}(u', t'), \end{cases}$$

i.e. $H_{U',T'}$ est la donnée de recollement qui conrrespond au triple (X', U', T') dans $\mathcal{T}$.

Nous serons plus intéressés par la situation inverse, i.e. par la question de déterminer les foncteurs [page 66]

$$\underbrace{X}_{=X_{U,T,H}} \longrightarrow X'$$

de X, obtenu par (U, T, H), dans un objet quelconque de Cat. On trouve tautologiquement

Proposition 3. $\mathrm{Hom}_{\mathrm{Cat}}(X, X')$ *est en correspondance bijective canonique, fonctorielle en* X' *dans* Cat*, avec l'ensemble des triples*

p. 48

[(∗)]
$$\begin{cases} \left.\begin{array}{l} f_U : U \longrightarrow X' \\ f_T : T \longrightarrow X' \end{array}\right\} \text{flèches dans Cat} \\ u : H \longrightarrow H_{X'}(f_U^\circ \times f_T),\ \text{flèche dans } \underline{\mathrm{Hom}}(U^\circ \times T, \mathrm{Ens}), \end{cases}$$

où pour tout X' dans Cat*, on a posé*

$$H_{X'} = ((x,y) \longmapsto \mathrm{Hom}_{X'}(x,y)) : X'^{\circ} \times X' \longrightarrow \mathrm{Ens}.$$

Sûrement on aura même un isomorphisme de catégories

$$\underline{\mathrm{Hom}}(X, X') \simeq \text{catégorie des triples } (f_U, f_T, u) \text{ comme dans } (*).$$

1.4 Construction de sommes amalgamées à partir d'une immersion ouverte où fermée.

Pour une construction d'une sorte de somme amalgamée, en termes d'un triple (X, U, T) + …, qui soit symétrique en U, T, j'ai envie de regarder d'abord la situation 'mixte', d'un diagramme en traits pleins [page 67]

$$(*) \qquad \begin{array}{ccccc} U & \xhookrightarrow{i} & X & \xhookleftarrow{j} & T \\ {\scriptstyle f_U}\downarrow & & \vdots\, {\scriptstyle f} & & \downarrow{\scriptstyle f_T} \\ U' & \xhookrightarrow{i'} & X' & \xhookleftarrow{j'} & T', \end{array}$$

qu'on aimerait compléter 'canoniquement', si faire se peut, en un morphisme de triples (i.e. en une flèche dans $\mathcal{T}$). L'idée naturelle, c'est que le X' qui s'y insère serait la limite inductive, dans Cat, du diagramme initial. Si $T' = T$, $f_T = \mathrm{id}_T$, cela signifie donc que X' s'identifie à la somme amalgamée $X \amalg_U U'$, et inversement si $U' = U$, $f_U = \mathrm{id}_U$.

Commentary · Exposition [ms. 66]

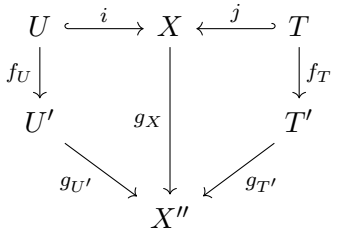
Functors out of a collage include the mixed naturality equation

The next construction will be recognized by mapping out of it. Proposition 3 is therefore the correct place to retain natural transformations, even though its first formulation only mentions sets of functors. A functor $\mathrm{Coll}(H) \to Y$ consists of $a : U \to Y$, $b : T \to Y$ and maps

$$\eta_{u,t} : H(u,t) \longrightarrow \mathrm{Hom}_Y(a(u), b(t))$$

compatible with precomposition in U and postcomposition in T. The argument constructing the collage proves both existence and uniqueness of the functor from these data.

A morphism from (a, b, η) to $(\bar{a}, \bar{b}, \bar{\eta})$ is a pair of natural transformations $r : a \Rightarrow \bar{a}$, $s : b \Rightarrow \bar{b}$ satisfying, for every $h \in H(u,t)$,



$$s_t \, \eta_{u,t}(h) = \bar{\eta}_{u,t}(h) \, r_u.$$

The components r_u and s_t define a natural transformation on the collage because its naturality is already known on arrows within either part, while this equation is its naturality on a crossing arrow. Conversely restriction recovers the pair and the equation. Composition and identities are componentwise. This gives the claimed isomorphism of functor categories, rather than merely an equivalence on their objects.

For a functor into a collage the procedure is different in presentation but just as exact. Pulling back the open part specifies a sieve in the source, and its complement specifies the cosieve; these are forced by the functor. The residual data are then a morphism of profunctors. This is why Proposition 3 does not require the images of a and b to be disjoint: the target is arbitrary, and a functor out of the collage may identify objects from the two parts. The universal property of the forthcoming ordinary pushout must allow precisely these functors.

Désignons par X' la somme amalgamée `[plutôt la limite inductive]`, et explicitons, pour X'' quelconque dans Cat, l'ensemble des flèches g de X' dans X'', comme foncteur en X''. C'est l'ensemble des triples

$$(*) \qquad (g_X, g_{U'}, g_{T'}) \qquad \begin{cases} g_X : X \longrightarrow X'' \\ g_{U'} : U' \longrightarrow X'' \\ g_{T'} : T' \longrightarrow X'' \end{cases} \quad \text{avec} \quad \begin{array}{l} g_X \circ i = g_{U'} f_U \\ g_X \circ j = g_{T'} f_T. \end{array} \qquad \text{p. 49}$$

Notons que pour un tel triple, g_X est partiellement connu déjà en termes de $g_{U'}$, $g_{T'}$, par ses restrictions $g_X \circ i$ et $g_X \circ j$ à U et T respectivement, par les formules

$$g_U = g_{U'} f_U, \qquad g_T = g_{T'} f_T.$$

Donc la donnée d'un triple $(*)$ équivaut à celle d'un triple [page 68]

$$(g_{U'}, g_{T'}, g_X) \qquad \begin{cases} g_X \text{ une flèche } X \longrightarrow X'' \text{ correspondant à} \\ g_U = g_{U'} \circ f_U \text{ et } g_T = g_{T'} \circ f_T \text{ déjà donnés (via } g_{U'},\ g_{T'}), \end{cases}$$

donc en vertu de 1.3. cela correspond à

$$(*) \qquad (g_{U'}, g_{T'}, u) \qquad \begin{cases} g_{U'} : U' \longrightarrow X'' \\ g_{T'} : T' \longrightarrow X'' \\ u : H \longrightarrow \underbrace{H_{X''}\left((g_{U'} \circ f_U)^\circ \times (g_{T'} \circ f_T)\right)}_{(u,t) \longmapsto \mathrm{Hom}_{X''}(g_{U'} f_U(u), g_{T'} f_T(t))}. \end{cases}$$

On va interpréter la donnée de u, en termes d'un foncteur

$$(**) \qquad F^* = (H' \longmapsto H' \circ F) : \underline{\mathrm{Hom}}(U'^\circ \times T', \mathrm{Ens}) \longrightarrow \underline{\mathrm{Hom}}(U^\circ \times T, \mathrm{Ens})$$

où

$$F : U^\circ \times T \longrightarrow U'^\circ \times T' \qquad \text{est donné par } F = f_U^\circ \times f_T.$$

On a un objet $H'' = H''_{g_{U'}, g_{T'}}$ de la catégorie source de $(**)$ déterminé en termes du couple $(g_{U'}, g_{T'})$, par

$$H''(u', t') = \mathrm{Hom}_{X''}(g_{U'}(u'), g_{T'}(t')),$$

et le bifoncteur but de la flèche u dans $(*)$ s'interprète comme

$$F^*(H'') = H'' \circ F : (u,t) \longmapsto \underbrace{H''(f_U(u), f_T(t))}_{= \mathrm{Hom}(g_{U'} f_U(u), g_{T'} f_T(t))}.$$

Ainsi, u s'interprète comme une flèche

$$u : H \longrightarrow F^*(H'').$$

Or le foncteur F^* a un adjoint à gauche $F_!$, i.e. on a

$$(***) \qquad \mathrm{Hom}(H, F^*(H'')) \simeq \mathrm{Hom}(F_!(H), H'').$$

avec

$$F_! : \underline{\mathrm{Hom}}(U^\circ \times T, \mathrm{Ens}) \longrightarrow \underline{\mathrm{Hom}}(U'^\circ \times T', \mathrm{Ens}).$$

Posons

$$H' = F_!(H) : U'^\circ \times T' \longrightarrow \mathrm{Ens},$$

c'est un bifoncteur bien déterminée par la seule donnée du diagramme initial $(*)$ p. 67, ou ce qui revient au même, en termes de [p. 50] [page 69]

$$(U, T, H, f_U : U \longrightarrow U', f_T : T \longrightarrow T').$$

Commentary · Exposition [ms. 68]

Transporting the crossing arrows by a Kan extension

The two categories U, T can now be changed independently. Their new internal arrows are already present in U', T'. What must be supplied are all composites crossing from the first new category to the second, subject to the relations forced by old compositions. This is what the left Kan extension supplies.

Put $F = f_U^{\mathrm{op}} \times f_T$. The ordinary pointwise formula can be written in a form that displays every generator:

$$H'(u', t') = \int^{u \in U,\, t \in T} \mathrm{Hom}_{U'}(u', f_U u) \times H(u, t) \times \mathrm{Hom}_{T'}(f_T t, t').$$

The notation means the quotient of the disjoint union of these products by the relations for composition in U and T. An element is represented by a triple

$$u' \xrightarrow{\alpha} f_U u, \qquad h \in H(u, t), \qquad f_T t \xrightarrow{\beta} t'.$$

For $a : u_0 \to u_1$ in U and $b : t_0 \to t_1$ in T, the defining relations are

$$[f_U(a)\alpha, h, \beta] = [\alpha, H(a, 1)h, \beta], \qquad [\alpha, H(1, b)h, \beta] = [\alpha, h, \beta f_T(b)],$$

whenever the displayed terms are typed. This is the coend formula for $\mathrm{Lan}_F H$; the equivalent comma-category formula is the pointwise Kan-extension theorem (Riehl, n.d., Theorem 6.2.1).

To prove the pushout assertion directly, form $C = \mathrm{Coll}(H')$ and send a crossing arrow h of X to $[1, h, 1]$. The relations make this a functor $X \to C$, and the inclusions of U', T' agree with it on U, T. Now take compatible functors $X \to Y$, $U' \to Y$, $T' \to Y$. On the generator above there is only one possible extension: it must take the value $\beta\, h\, \alpha$, after applying the respective functors. The two relations hold because the original functors preserve composition. Thus there is a unique functor $C \to Y$ inducing all three given functors. This proves the strict colimit universal property, and also identifies its canonical map from X.

Since C was constructed as a collage, U' is a full sieve and T' its full complementary cosieve. Their internal hom sets have not been enlarged by the quotient: no string can leave the open part and subsequently return to it. This supplies the structural content of Theorem 1 beyond existence of a colimit in Cat. It also clarifies the distinction from the earlier induced triple: restriction of H gave a cartesian lift, whereas this left Kan extension gives the universal forward transport. The labels "pullback" and "pushout" refer to these different universal properties, not to a formal substitution of primes in the same formula.

Et on voit que la donnée d'une flèche $X' \longrightarrow X''$, X'' objet variable de Cat, équivaut à celle de

$$g_{U'} : U' \longrightarrow X'',\ g_{T'} : T' \longrightarrow X'',\ u : H' \longrightarrow H'' = H_{X''}(g_{U'}^{\circ} \times g_{T'}),$$

c'est à dire, en vertu de 1.3., à celle d'une flèche

$$X_0' \longrightarrow X'',$$

où X_0' désigne l'objet de Cat déduit de U', T' par recollement au moyen de H'. Cela montre donc que la limite inductive cherchée n'est autre que X_0'. On a ainsi trouvé le

Théorème 1. *La limite inductive X' dans* Cat *du diagramme $(*)$ page 67, défini en termes d'un triple (X, U, T) dans $\mathcal{T}$ et de flèches $f_U : U \longrightarrow U'$, $f_T : T \longrightarrow T'$ dans* Cat*, existe (sans mérite) et les flèches canoniques* [page 70]

$$U' \xhookrightarrow{i'} X' \xhookleftarrow{j'} T'$$

sont des immersions ouvertes et fermées complémentaires l'une de l'autre. La donnée de recollement qui définit X' via U', T' est donnée par

$$H' = (\underbrace{f_U^{\circ} \times f_T}_{F})_!(H) : U'^{\circ} \times T' \longrightarrow \mathrm{Ens},$$

où H est la donnée de recollement qui définit X, i.e. $H : U^\circ \times T \longrightarrow$ Ens est le bifoncteur $(u,t) \longmapsto \mathrm{Hom}_X(u,t)$.

Ainsi on a, pour u' dans U' et t' dans T'

$$\mathrm{Hom}_{X'}(u',t') = F_!(H)(u',t'),$$

et il reste à expliciter $F_!(H)$. Ici $F = f_U^\circ \times f_T$ est un foncteur covariant sur $U^\circ \times T$, on peut l'interpréter comme un préfaisceau sur $U \times T^\circ$, et écrire dès lors

$$(*) \qquad \underbrace{F_!(H)(u',t')}_{\mathrm{Hom}_{X'}(u',t')} = \varinjlim_{(u',t')\backslash U\times T^\circ} \underbrace{\mathrm{Hom}_X(u,t)}_{H(u,t)} .$$

La catégorie $(u',t')\backslash U \times T^\circ$ sur laquelle on prend la $\varinjlim$ s'explicite comme un produit p. 51

$$(u',t')\backslash U \times T^\circ \simeq (u'\backslash U) \times (T/t')^\circ.$$

Les applications

$$\mathrm{Hom}_X(u,t) \longrightarrow \mathrm{Hom}_{X'}(u',t') \qquad (= F_!(H)(u',t'))$$

déduites de cette formule ne sont autres que les suivantes : u, t sont données comme objets [page 71]
de $u'\backslash U$, T/t', i.e. avec des flèches

$$u' \xrightarrow{\alpha} f_U(u), \qquad f_T(t) \xrightarrow{\beta} t',$$

d'où

$$\mathrm{Hom}_X(u,t) \xrightarrow{\text{via } f=f_X:X\to X'} \mathrm{Hom}_{X'}(\underbrace{f(u)}_{f_U(u)}, \underbrace{f(t)}_{f_T(t)}) \xrightarrow{\text{via } \alpha,\ \beta} \mathrm{Hom}_{X'}(u',t').$$

Notons pour mémoire que pour tout objet Z de Cat, et tout préfaisceau G sur Z, on a la formule

$$\varinjlim_Z G \simeq \pi_0(Z/G),$$

où Z/G s'interprète en termes de l'immersion canonique $Z \longrightarrow Z^\wedge$ ($G \in \mathrm{Ob}\, Z^\wedge$). C'est donc une catégorie fibrée sur Z à fibres discrètes, et on a en fait un isomorphisme entre la sous-catégorie pleine de Cat/Z formée de telles catégories fibrées à fibres discrètes, avec $Z^\wedge$. Dans ce dictionnaire parfait entre préfaisceaux d'ensembles et catégories fibrées à fibres discrètes, le foncteur $\varinjlim$ sur $Z^\wedge$ correspond simplement au foncteur π_0 sur la catégorie des objets au dessus de Z dans Cat, lui-même induit par le foncteur (indépendant de Z)

$$\mathrm{Cat} \xrightarrow{\pi_0} \mathrm{Ens}.$$

On peut donc réécrire la formule fondamentale (∗) p. 70, en termes du foncteur H [page 72]
définissant le recollement X de U et de T, par

$$(*) \qquad \boxed{\underbrace{\mathrm{Hom}_{X'}(u',t')}_{H'(u',t')} \simeq \pi_0(\underbrace{(u',t')\backslash U \times T^\circ/H}_{((u'\backslash U)\times(T/t')^\circ)/H}).}$$

Par la suite, nous n'aurons sans doute qu'à utiliser le cas où on a soit $T' = T$, $f_T = \mathrm{id}_T$, soit l'inverse. Nous travaillerons surtout dans le premier cas, en déduisant ce dont nous aurons besoin pour le cas dual, par principe de dualité (automorphisme $X \longmapsto X^\circ$ de la catégorie p. 52
Cat). Dans ce cas, dans la formule fondamentale (∗) l'élément t' de T' s'écrit comme un élément t de T, et la formule se retranscrit comme

$$(**) \qquad \boxed{\mathrm{Hom}_{X'}(u',t) \simeq \pi_0(\ \underbrace{u'\backslash U/t}_{\text{catégorie des triples } (u,\alpha,\beta'),\ \begin{cases} u \in \mathrm{Ob}\, U \\ \alpha : u \longrightarrow t \\ \beta' : u' \longrightarrow f_U(u) \end{cases}}\ ).}$$

C'est la formule que j'avais trouvée directement dans ce cas, sans me soucier encore de faire varier T en même temps que U. Je voudrais faire le lien entre les deux formules $(*)$ et $(**)$, par voie topologique, donc établir une bijection canonique, fonctorielle etc.

$$\pi_0(u'\backslash U/t) \xrightarrow{\sim} \pi_0(((u'\backslash U) \times (T/t)^\circ)/H).$$

On a sûrement un foncteur [page 73]

$$u'\backslash U/t \longrightarrow ((u'\backslash U) \times (T/t)^\circ)/H$$

qui associe à un triple

$$(u, \alpha, \beta') : u \in \mathrm{Ob}\, U,\ \alpha : u \longrightarrow t,\ \beta' : u' \longrightarrow f_U(u)$$

le triple $(\bar{u}, \bar{t}, \xi)$ $(\xi \in H(\bar{u}, \bar{t}))$ dans le second membre, avec $\bar{u}$ dans $u'\backslash U$, $\bar{t}$ dans T/t, défini ainsi :

$$\bar{u} = (u, \beta'),\ \bar{t} = (t, \mathrm{id}_t), \underbrace{\xi}_{=\alpha} \in H(\bar{u}, \bar{t}) = \mathrm{Hom}(u, t).$$

En somme

$$u'\backslash U/t = \text{fibre de } ((u'\backslash U) \times (T/t)^\circ)/H \text{ en l'objet initial } \bar{t} \text{ de } (T/t)^\circ$$

par la projection naturelle, flèche composée

$$\begin{array}{c} ((u'\backslash U) \times (T/t)^\circ)/H \\ \big\downarrow \\ (u'\backslash U) \times (T/t)^\circ \\ \big\downarrow \pi \\ (T/t)^\circ. \end{array}$$

Commentary · Exposition [ms. 72]

Why connected components give the ordinary hom set

Grothendieck wants a topological description of a purely ordinary quotient. For a presheaf $G : Z^{\mathrm{op}} \to \mathrm{Ens}$, the category of elements Z/G has objects (z, g) and arrows

$$(z, g) \longrightarrow (z', g') \quad \text{given by} \quad a : z \longrightarrow z', \qquad G(a)(g') = g.$$

The colimit of G is the disjoint union of its values modulo the identifications $G(a)(g') \sim g'$. These are exactly the identifications imposed on objects when one passes to connected components of Z/G. Hence

$$\operatorname*{colim}_{Z^{\mathrm{op}}} G \simeq \pi_0(Z/G).$$

The source writes $\varinjlim_Z G$ for this presheaf colimit. The opposite belongs in the modern indexing category; it is not a correction to the numerical value of the formula.

The same convention explains the indexing category in the preceding page. If H is regarded as a covariant functor on $U^{\mathrm{op}} \times T$, its ordinary left Kan extension is indexed by

$$F/(u', t') \simeq (u'\backslash f_U)^{\mathrm{op}} \times (f_T/t').$$

Equivalently, regard H as a presheaf on $U \times T^{\mathrm{op}}$ and take its presheaf colimit over the opposite category

$$(u'\backslash f_U) \times (f_T/t')^{\mathrm{op}}.$$

This is the convention used in the edition. Its sentence "Ici $F = \cdots$ ... on peut l'interpréter comme un préfaisceau" contains a harmless but real letter slip: it is H, not the indexing functor F, that is the set-valued presheaf.

When $T' = T$, the resulting objects can be compressed to factorizations

$$(u, \alpha : u' \to p(u), \gamma : u \to t).$$

An arrow from (u, α, γ) to (v, α', γ') is $a : u \to v$ with $p(a)\alpha = \alpha'$ and $\gamma' a = \gamma$. Its connected component is the crossing arrow of the pushout represented by $\gamma\alpha$. Thus the factorization category keeps track of all presentations of a new arrow and all relations between those presentations. Taking π_0 intentionally forgets its higher homotopy. The later asphericity conditions ask precisely when this forgetting is harmless for the homotopy problem, and do not follow from the existence of the ordinary colimit alone.

Il faut voir que l'inclusion de la fibre donne une bijection sur les π_0, ou ce qui revient au même, que l'inclusion de la fibre $u'\backslash U$ *de* π en l'objet initial (t, id_t) de $(T/t)^\circ$ donne une bijection sur les $\varinjlim$ du foncteur H. Donc l'inclusion a intérêt à être asphérique, ou du moins co-cofinalle.

Mais l'inclusion d'un objet initial est toujours asphérique, et le reste par produit avec un objet quelconque (i.e. $u'\backslash U$) de Cat (et même par tout changement de base lisse …), d'où la conclusion. p. 53 [page 74]

Dans la suite, nous nous intéressons surtout à la situation de sommes amalgamées (où on change de notation un peu, à présent)

$$(*) \qquad \begin{array}{ccccc} U & \xhookrightarrow{i} & X & \xleftarrow{j} & T \\ {\scriptstyle p}\downarrow & & {\scriptstyle q}\downarrow & & \vdots \\ U' & \xhookrightarrow{i'} & X' & \leftarrow & T' \simeq T. \end{array}$$

Le fermé T' complémentaire de U' dans X' est alors canoniquement isomorphe au fermé T complémentaire de U dans X, l'isomorphisme étant induit par q. Souvent nous identifierons T' et T, ce qui est licite en regardant X' comme déduit du recollement de U' et de t `[plutôt T]`, par le bifoncteur $U'^{\circ} \times T \longrightarrow$ Ens explicité dans la formule $(**)$ p. 72. Nous nous intéressons surtout à dégager des conditions qui assurent les deux implications suivantes

a) $i \in W \Longrightarrow i' \in W$ (et même $\Longleftrightarrow$).

b) $p \in W \Longrightarrow q \in W$ (et même $\Longleftrightarrow$).

Proposition 4. *Soit $t \in \mathrm{Ob}\, T$. Pour que $t \in \mathrm{Ob}\, \bar{U}$, il faut et il suffit que $q(t) \in \mathrm{Ob}\, \overline{U'}$. En d'autres termes, le 'bord' $\dot{T} = T \cap \bar{U}$ de T dans X est 'le même' que son bord dans X'.* [page 75]

Commentary · Exposition [ms. 74]

The one-sided formula has an explicit deformation retraction

The comparison of the two factorization formulas admits a direct argument which also verifies Grothendieck's cofinality claim with its variance intact. Write E for the category of elements occurring in the general formula when $T' = T$. Its objects are

$$(u, \alpha : u' \to p(u), v, \beta : v \to t, h : u \to v).$$

An arrow to $(u_1, \alpha_1, v_1, \beta_1, h_1)$ consists of

$$a : u \to u_1, \quad b : v_1 \to v, \qquad p(a)\alpha = \alpha_1, \quad \beta b = \beta_1, \quad h = bh_1 a.$$

Let $D = u'\backslash U/t$ be the category in the boxed one-sided formula. Define

$$R : E \longrightarrow D, \qquad R(u, \alpha, v, \beta, h) = (u, \alpha, \beta h).$$

On arrows R takes (a, b) to a; the equality $\beta_1 h_1 a = \beta b h_1 a = \beta h$ proves that this is an arrow of D. The inclusion $J : D \to E$ takes (u, α, γ) to $(u, \alpha, t, 1_t, \gamma)$, and $RJ = 1_D$.

For each object of E, the pair $(1_u, \beta)$ gives an arrow

$$JR(u, \alpha, v, \beta, h) \longrightarrow (u, \alpha, v, \beta, h).$$

The equations above verify naturality, so $JR \Rightarrow 1_E$. Consequently J and R induce inverse homotopy equivalences on nerves, and in particular inverse bijections on π_0. This proves more than the displayed comparison requires. The construction is natural in u' and t, because precomposition of α and postcomposition of β commute with βh.

The reference to the initial object $(t, 1_t)$ of $(T/t)^{\mathrm{op}}$ is therefore sound. An initial object is cofinal for the colimit of a *presheaf*; in covariant colimit notation one has passed to the opposite and it becomes terminal. The proof does not assert that an initial object computes arbitrary covariant colimits. This is the same variance discipline needed in the commentary on Chapter I, manuscript p. 47 ("Cofinality retains an orientation"), but here the explicit retraction identifies the whole category of presentations rather than only invoking the abstract cofinality criterion.

Démonstration. Dire que $t \in \mathrm{Ob}\,\bar{U}$ signifie aussi

$$U/t \neq \emptyset$$

et implique, par continuité, que $q(t) \in \overline{q(U)} \subseteq \overline{U'}$. Inversement, si $q(t) \in \overline{U'}$, i.e. s'il existe $u' \in U'$ tel que

$$\mathrm{Hom}(u', q(t))(= \pi_0(u'\backslash U/t)) \neq \emptyset,$$

il en résulte que $u'\backslash U/t \neq \emptyset$, a fortiori U/t (qui reçoit $u'\backslash U/t) \neq \emptyset$, q.e.d.

Proposition 5. *Soit*

$$\begin{array}{ccc} Y & \xrightarrow{i} & X \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ Y' & \xrightarrow{i'} & X' \end{array}$$

un carré cocartésien dans Cat. *Si i est une immersion ouverte (resp. fermée), alors i' aussi, et le carré est aussi cartésien. Idem pour p et q. Si i et p sont des immersions ouvertes ([1])* p. 54 *(resp. …), alors la situation est isomorphe à celle d'un objet X' de* Cat, *de deux ouverts (resp. fermés) X, Y' de X ayant pour réunion X', pour intersection Y. Inversement, dans une telle situationm le carré correspondant est cocartésien, i.e. X* `[plutôt $X'$]` *s'identifie à la somme amalgamée*

$$X' \simeq X \amalg_Y Y'.$$

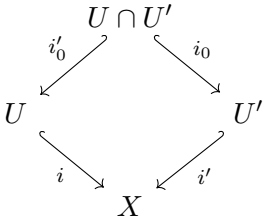
Donc aussi on a la proposition 15, page 158, et ses corollaires.

p. 55

2 Sommes amalgamées et W-équivalences.

2.1 Axiome du carré cocartésien et axiome du cube (ou 'Lemme des cinq').

Nous supposons à présent donné un localiseur fondamental



$$W \subseteq \mathrm{Fl}(\mathrm{Cat}),$$

donc W satisfait à W(1, 2 bis, 3). Nous ne supposons pas pour le moment pour les autres axiomes standard W(4) (axiome de fibration), W(5) (axiome de connexité), W(6) (axiome des limites inductives). Mais nous allons introduire à présent deux axiomes de stabilité supplémentaire, de nature différente, concernant les sommes amalgamées.

W(7 bis) (Axiome du carré cocartésien.) Soient X un objet de Cat, U, U' deux ouverts de X tels que $U \cup U' = X$, considérons le diagramme cocartésien correspondant (cf. prop. 5 en marge de la page `[ci-dessus]`) :

1. **NB** Nous utilisons *'immersion ouverte'*, *'immersion fermée'* au *sens strict* : c'est un *monomorphisme* pleinement fidèle dont l'image est une sous-catégorie *pleine,* soit ouverte, soit fermée. [page 76]

(∗)

Commentary · Examples [ms. 75]

Orbits of crossing arrows and the information discarded

The pushout formula can be seen in a small calculation before it is used homotopically. Let U be the discrete category on u_0, u_1, let $T = e$ with object t, and let $H(u_i, t)$ be a singleton. Thus X is the span $u_0 \to t \leftarrow u_1$. Collapse U to $U' = e$ by p. The category $u'\backslash U/t$ has exactly two objects and no nonidentity arrows, so the pushout $X' = X \amalg_U e$ has two objects and *two* distinct parallel arrows $u' \rightrightarrows t$. Identifying the two objects of U does not identify arrows which have no relation between them. Its nerve realizes to a circle, whereas the nerve of X is contractible. Here p is not a weak homotopy equivalence, so this is an illustration of the formula, not a counterexample to any asserted stability under a weak equivalence.

A group action makes the quotient and its lost homotopy particularly explicit. Put $U = BG$, let $T = e$, and take a right G-set S as the presheaf $H(-, t)$. On pushing BG to e, the mixed hom set becomes

$$\mathrm{Hom}_{X'}(u', t) = S/G.$$

Indeed the category of elements has objects $s \in S$ and an arrow labelled g from s to s' when $s = s'g$. All arrows are invertible, and two objects lie in the same connected component exactly when they lie in the same orbit. If $S = K\backslash G$ is a transitive right action, the automorphism group of the object K is K. Inclusion of that object is fully faithful and essentially surjective, hence the category of elements is equivalent to BK.

Thus a single crossing arrow in the quotient may stand for a factorization category with homotopy type BK. Choosing K nontrivial shows that a singleton ordinary colimit says nothing about the contractibility of its category of presentations. If $S = G$ with the free right action, the stabilizer is trivial and the category of elements is contractible. If S is the singleton with trivial action, it is BG. Both have the same orbit set. The distinction is exactly the one that motivates the total asphericity conditions later in this section.

Alors

$$i_0 \in W \qquad \Longleftrightarrow \qquad i \in W$$

(et symétriquement

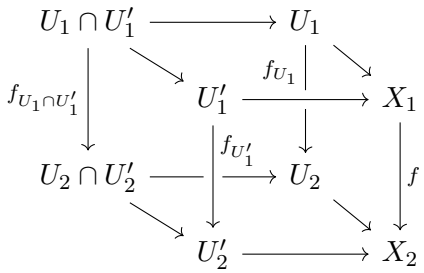
$$i_0' \in W \qquad \Longleftrightarrow \qquad i' \in W).$$

NB Par dualité, cet axiome est équivalent à l'axiome similaire, avec des *fermés* T, T' de X de réunion X.

Corollaire. *Supposons* W(7 bis). *Considérons les conditions suivantes sur le carré précédent.*

a) $U \cap U'$ W-asphérique.

b) U, U' W-asphériques.



c) X W-asphérique.

Alors (a et b) implique c, et (b et c) implique a.

NB Moralement, il faudrait aussi que (c et a) implique b, i.e. si $U \cap U'$ et X sont W-asphériques, il en est de même de U et de U'. Mais il ne semble pas que l'axiome du carré cocartésien permette de le prouver. Par contre, l'axiome qui suit impliquera le corollaire précédent sous sa forme complète.

p. 56

W(7) ('Axiome du cube', ou 'Lemme des cinq'.) Soit un diagramme commutatif cubique

représentant un morphisme (flèches verticales) d'un

[page 77]

carré cocartésien $\begin{array}{ccc} U_1 \cap U_1' & \longrightarrow & U_1 \\ \downarrow & & \downarrow \\ U_1' & \longrightarrow & X_1 \end{array}$ du type envisagé dans W(7 bis) (X_1 réunion de deux ouverts U_1, U_1') dans un autre (à indices 2). Considérons les conditions suivantes.

Commentary · Exposition [ms. 76]

Ordinary covers yield homotopy pushouts, with one direction of excision

Grothendieck's new axioms try to turn a cover by two categorical opens into an excision principle. The underlying geometric fact is especially clean. Suppose $X = U \cup V$ with U, V full sieves and $A = U \cap V$. A simplex of NX is a composable chain $x_0 \to \cdots \to x_n$. Its last vertex lies in U or in V; since these are sieves, all earlier vertices then lie in the same one. Hence

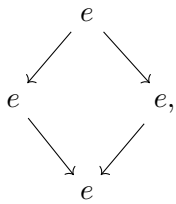
$$NX = NU \cup_{NA} NV$$

is an actual pushout of simplicial sets. The two maps out of NA are monomorphisms. On geometric realization they are inclusions of CW subcomplexes, so this pushout also computes the homotopy pushout. For cosieves the same proof uses the first vertex of the chain.

This proves the direct implication of W(7 bis) for W_∞: if $A \to V$ is a weak equivalence then $U \to X$ is a weak equivalence. It also proves the direct cube assertion (a and b) $\Rightarrow c$: an objectwise weak equivalence of the two spans induces a weak equivalence of their homotopy pushouts. This invariance is the property of a derived colimit. It may be checked using the double mapping-cylinder model, or by mapping into a fibrant space, where the universal mapping space is the homotopy pullback of the three mapping spaces of the span.

The reverse implication requested in W(7 bis), and the two additional implications requested in W(7), are strictly stronger assertions. The formal corollaries drawn here from the proposed axioms are valid as conditional statements, as is Proposition 6's implication W(7)⇒W(7 bis). However, Theorem 2 on manuscript page 78 is false for the full printed axiom. A homotopy pushout can destroy the fundamental group of its intersection. The next block gives a finite categorical counterexample, with the ordinary and homotopy pushouts agreeing throughout. This is not a failure of the nerve to preserve the relevant pushout, and is not repaired by using a derived pushout instead.

a) $f_{U_1 \cap U_1'} \in W$.
b) f_{U_1} et $f_{U_1'}$ sont `[dans]` W.



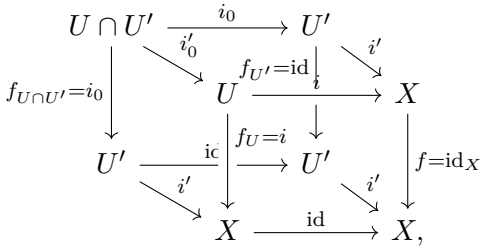
c) $f \in W$.

Alors deux parmi ces conditions impliquent la troisième. En d'autres termes, quand l'une de ces conditions est satisfaite, les deux autres sont équivalentes entre elles.

NB Cet axiome est équivalent à l'axiome dual, en termes d'objets X_1, X_2 représentés chacun comme réunion de deux fermés.

Corollaire. *Supposons* W(7) *satisfait. Alors le corollaire à* W(7 bis) *(axiome qu'on n'a pas à utiliser ici), sous sa forme complétée (cf. le NB qui le suit) est valable : deux parmi les conditions a), b), c) impliquent la troisième.*

Il suffit de regarder l'unique morphisme du diagramme (∗), p. 76, dans le diagramme trivial



correspondant au cas où X est la catégorie finale e, et U, U' égaux à X. Alors le corollaire n'est autre que W(7) appliqué à ce cas particulier.

Cet argument fait sentir que W(7) est sans doute plus fort que W(7 bis). Incité par ce sentiment, je m'aperçois avec plaisir qu'il est fondé :

Proposition 6. *L'axiome* W(7) *(lemme des cinq) implique* W(7 bis) *(axiome du carré cocartésien).* p. 57 [page 78]

On regarde le diagramme cubique suivant

du carré cocartésien donné dans le carré cocartésien déduit de X et de ses deux ouverts X, U', d'intersection U'. Ici les deux flèches verticales f et $f_{U'}$ sont des isomorphismes, donc [dans] W. Avec les notations de W(7), on a donc c) ($f \in W$), donc a) et b) sont équivalentes, i.e. $i_0 \in W$ et $i \in W$ sont équivalentes.

q.e.d.

Théorème 2. *Le localiseur fondamental W_∞ satisfait à l'axiome* W(7).

C'est sûrement une conséquence du critère cohomologique d'Artin-Mazur, compte tenu de la suite exacte de Mayer-Vietoris pour l'un et l'autre des deux carrés cocartésiens, et les variantes non commutatives de Mayer-Vietoris. Je n'ai pas écrit la vérification en forme, et devrais sans doute réparer cette omission.

Commentary · Development (commentators') [ms. 78]

A finite counterexample to the asserted reverse excision

Grothendieck hopes that a five-lemma argument will recover the homotopy type of an intersection from the two pieces and their union. The obstruction can be isolated using the familiar acyclic noncontractible complex of Hatcher (2002, Example 2.38). We give the categorical consequence in full; the input space and its properties are classical. We checked that example, the finite simplicial replacement theorem, the subsequent distinction between the direct and reverse axioms in Chapter XVI, and the model-independent homotopy-pushout argument. We did not find this exact finite-poset formulation attached to Theorem 2 in the sources checked; no priority is claimed.

Proposition (finite failure of W(7 bis) and W(7)). [ours] *There is a finite poset X, covered by two full sieves U, V, such that NU, NV, NX are contractible but $N(U \cap V)$ is not weakly contractible. Consequently W_∞ does not satisfy either printed axiom.*

Proof. Start with a connected CW complex K_0 with one vertex, two oriented edges a, b, and two two-cells attached along

$$a^5 b^{-3}, \qquad b^3 (ab)^{-2}.$$

Its cellular differential from dimension two to dimension one is

$$d_2 = \begin{pmatrix} 5 & -2 \\ -3 & 1 \end{pmatrix}.$$

Its determinant is -1, so d_2 is an isomorphism. The differential d_1 is zero and there are no higher cells. It follows that $\widetilde{H}_*(K_0; \mathbb{Z}) = 0$.

Here is an explicit verification that its fundamental group is nontrivial. With permutations composed from right to left, send

$$a \longmapsto (1\ 4\ 3\ 2\ 5), \qquad b \longmapsto (1\ 2\ 3).$$

The product ab is $(1\ 5)(3\ 4)$, so the images satisfy $a^5 = b^3 = (ab)^2 = 1$ and define a homomorphism from the presented group to A_5. The image of a is nonidentity, proving nontriviality. We need neither a computation of the full group nor asphericity of the presentation complex.

By the finite case of Hatcher (2002, Theorem 2C.5), choose a finite simplicial complex K homotopy equivalent to K_0. Let A be the poset of its nonempty simplices ordered by inclusion. Its nerve is the barycentric subdivision of K, so $|NA|$ is connected and acyclic, and has nontrivial fundamental group. Adjoin two incomparable elements u, v above every element of A, and call the resulting finite poset X. Put

$$U = A \cup \{u\}, \qquad V = A \cup \{v\}.$$

Both are downsets of X, hence full sieves, and $U \cap V = A$. They have terminal objects u and v, respectively. Their nerves are the two cones on NA. A chain in X cannot contain both u and v, and therefore $|NX|$ is the unreduced suspension of $|NA|$.

The suspension of a connected space is simply connected, by van Kampen applied to its two thickened cones. Mayer–Vietoris gives

$$\widetilde{H}_n(|NX|; \mathbb{Z}) \cong \widetilde{H}_{n-1}(|NA|; \mathbb{Z}) = 0.$$

Thus $|NX|$ is a simply connected acyclic CW complex. It is contractible by the homological Whitehead theorem (Hatcher, 2002, Corollary 4.33). The inclusion $U \to X$ is consequently a weak homotopy equivalence. The inclusion $A \to V$ is not, since its source has nontrivial fundamental group and its target is contractible. This contradicts the reverse implication of W(7 bis). The map from the cover square of X to the constant square on e satisfies conditions b, c of W(7) but not a. It therefore contradicts W(7) as well. □

The proposed cohomological proof fails at a specific point. Local systems on the intersection need not extend to either piece or to the union. In the example, the nontrivial representation of $\pi_1(NA)$ in A_5 cannot extend across either cone. Mayer–Vietoris for coefficients restricted from the ambient contractible space only sees constant coefficients on the intersection, for which its acyclicity suppresses the obstruction. The nonabelian comparison required by a weak-equivalence criterion cannot be recovered from that restricted coefficient class. This is the same general difficulty as in the commentary on Chapter I, manuscript p. 81 (“The coefficient lost in the attempted proof”), now realized in a finite categorical cover.

[page 79]

Remarque. La version duale (au sens de Quillen) de l'axiome W(7 bis) du carré cocartésien, i.e. l'axiome correspondant pour les carrés cartésiens, n'est pas valable pour W_∞. L'énoncé pertinent serait le suivant : soit

$$\begin{array}{ccc} X & \xleftarrow{q} & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ S & \xleftarrow{p} & S' \end{array}$$

un carré cartésien, avec f une *W-fibration.* Alors $f \in W \iff f' \in W$. Si W satisfait à W(4c) (ce qui est le cas pour W_∞), alors $f \in W$ implique bien que ses fibres sont W-asphériques, donc

que c'est une W-équivalence universelle, i.e. $f' \in W\ \forall p : S' \longrightarrow S$. Mais pour l'implication inverse $f' \in W \Longrightarrow f \in W$, il faut supposer visiblement que

$$\pi_0(p) : \pi_0(S') \longrightarrow \pi_0(S)$$

est *surjectif*. (P. ex. si $S' = \emptyset$, on a $X' = \emptyset$, donc $f' \in W$, sans que ça implique $f \in W$!) p. 58
Le fait que dans le cas cocartésien de W(7 bis), $i_0 \in W \Longrightarrow i \in W$ doit être considéré comme 'allant de soi' - autrement le carré ne mérite pas, du point de vue W-homotopique, le nom de 'cocartésien'. Par contre, l'implication inverse $i \in W \Longrightarrow i_0 \in W$ m'apparaît comme un trait très particulier du dérivatuer HOT_W (quand il le possède), et notamment de $\mathrm{HOT} = \mathrm{HOT}_{W_\infty}$. Le début de la remarque signifie simplement que le dérivateur dual HOT° ne possède [page 80]
pas cette même propriété. Je dois renvoyer à ce sujet aux deux axiomes pour les dérivateurs correspondants à W(7 bis), W(7), ce que je ferai sans doute sous peu, de façon à donner un sens plus précis aux présents commentaires.

Commentary · Present state [ms. 79]

What survives of the cube principle

The distinction between direct and reverse excision is already visible in Grothendieck's later reorganization. Chapter XVI separates the cube conditions into Loc(6a), Loc(6b), and Loc(6c); its Commentary 3.4 distinguishes the direct theory of homotopy cofibres from the extra reversibility property (Grothendieck, 1991c, §3, manuscript pp. 16–27). For the pages at hand the reliable assertion for ordinary homotopy types is the direct one: weak equivalences of all three entries of a span give a weak equivalence of its homotopy pushout. A reverse five lemma cannot be added without hypotheses that exclude the preceding example. Theorem 2 has no repair with its stated hypotheses; its direct part is a theorem.

The pullback remark makes a different, correct observation. Base change need not meet every connected component of the base. Take $S = \{0, 1\}$ discrete, and the discrete fibration $X \to S$ with one point over 0 and two points over 1. Pulling back along $\{0\} \to S$ gives an isomorphism, while $X \to S$ is not even bijective on connected components. This is a nonempty version of the empty-base example printed in the source.

Under the intended fibration hypothesis, contractibility of homotopy fibres is the correct test. If base change meets every component and the pullback is a weak equivalence, its homotopy fibres are contractible. Fibre transport along paths then shows that every homotopy fibre of the original fibration is contractible, so the original map is a weak equivalence. This argument explains the appearance of surjectivity on π_0; it must be applied where the source's W-fibration axioms really identify categorical fibres with homotopy fibres. Merely calling an arbitrary functor a fibration does not supply that identification. The corresponding discussion of categorical fibres was developed in the commentary on Chapter VI, manuscript p. 45 ("Why the new fibration axiom selects full homotopy theory").

The final contrast with the dual derivator should therefore be read in two parts. Its warning about detection after pullback is justified. Its attribution of unrestricted reverse excision to HOT depends on the false Theorem 2. Both qualifications are needed before applying the proposed axioms to the less special pushouts that follow.

Commentary · Development (commentators') [ms. 79]

What the symmetric cube rule can detect

The failed implication in Theorem 2 has a structural source. A homotopy pushout can erase information in its intersection. It is useful to determine whether passing to a bounded homotopy theory removes that obstruction, and to compare the answer with the homological argument suggested in the manuscript. The following finite family gives a uniform negative answer to the first question. We did not locate this precise family of tests in the source, its Appendix, or the later papers checked; the observation is elementary and is offered without a priority claim.

Finite truncation obstruction. [ours] For an integer $n \geq 0$, let $W_{\leq n}$ consist of functors whose nerves induce a bijection on components and isomorphisms on all homotopy groups in degrees

$1, \dots, n$, at every basepoint. There is a finite poset covered by two sieves for which the reverse implication of W(7 bis) fails for $W_{\le n}$.

Proof. Let A_n be the poset of nonempty proper subsets of a set with $n+2$ elements, ordered by inclusion. A nondegenerate simplex of NA_n is a strictly increasing chain of such subsets. Thus NA_n is the barycentric subdivision of the boundary of the $(n+1)$-simplex, and $|NA_n|$ is homeomorphic to S^n. Adjoin two distinct elements $+$ and $-$, each greater than every element of A_n, with no order relation between them. Call the resulting poset D_n, and put $U_+ = A_n \cup \{+\}$ and $U_- = A_n \cup \{-\}$. These are sieves, their intersection is A_n, and each has a greatest element. Their nerves are cones on NA_n. Since a chain of D_n can contain at most one of $+$ and $-$, their union is exactly ND_n, whose realization is the suspension of $|NA_n|$, hence S^{n+1}.

It follows that $U_+ \hookrightarrow D_n$ belongs to $W_{\le n}$: both spaces are connected, and all their homotopy groups in degrees at most n vanish. On the other hand, $A_n \hookrightarrow U_-$ does not belong to $W_{\le n}$. For $n = 0$ it identifies two components. For $n \ge 1$ it kills the nonzero group $\pi_n(S^n) \simeq \mathbb{Z}$. This is precisely the forbidden reverse implication in the cover square. □

The example for $n = 1$ has eight objects in the union: six objects forming the barycentric subdivision of a triangle boundary and the two cone points. These tests do not replace the acyclic example at p. 78, since the latter is needed for untruncated weak equivalences. Together they show that the issue is not repaired by merely stopping the homotopy groups at some finite degree.

For comparison, consider the class of functors inducing isomorphisms on nerve homology with coefficients in a fixed ring R. The full symmetric cube rule *does* hold for that class. Here is the complete chain-level reason. If $X = U \cup U'$ is a union of two sieves and $A = U \cap U'$, every chain of composable arrows in X belongs to one of the two subcategories: choose a subcategory containing its last vertex and use the sieve condition. The same statement holds for nondegenerate chains. Consequently the normalized chain complexes have the natural short exact sequence

$$0 \longrightarrow C_*(NA; R) \xrightarrow{(\iota, -\iota')} C_*(NU; R) \oplus C_*(NU'; R) \xrightarrow{\jmath + \jmath'} C_*(NX; R) \longrightarrow 0.$$

Injectivity, exactness in the middle, and surjectivity can each be checked on the basis of chains: those in the intersection occur twice, all others once. For a morphism between two such covers, take the mapping cones of the three vertical chain maps. The result is again a short exact sequence of complexes. Its long exact homology sequence implies that if any two of these cones are acyclic, then so is the third. The middle cone is the direct sum of the cones for the maps on U and U', so its acyclicity is equivalent to the acyclicity of both summands. This proves all three implications requested in W(7). For cosieve covers, the first vertex supplies the same proof.

The manuscript's proposed Mayer–Vietoris justification therefore has an exact domain of validity: it works for fixed-coefficient homology equivalences. The passage from those equivalences to weak homotopy equivalences is the step that cannot be supplied. The acyclic intersection in the preceding counterexample makes that distinction visible without any ambiguity about the existence or computation of the pushout.

2.2 Application aux carrés cocartésiens déduits d'une immersion ouverte ou fermée.

Les axiomes W(7), W(7 bis) (du cube, et du carré cocartésien) concernent des carrés cocartésiens de nature très particulière. Nous allons voir à présent comment en déduire des énoncés du même type pour des carrés cocartésiens beaucoup plus généraux, y compris pour des carrés qui n'ont rien de cocartésien (dans Cat) - et que nous appelerons 'homotopiquement cocartésiens' (relativement à W), ou simplement W-cocartésiens. (Il y aura également des carrés W-cartésiens un jour …) Dans le cas où $W = W_\infty$, je les appelerai aussi Hot-cocartésiens.

Je commencerai par le cas particulier d'un carré cocartésien associé à une immersion ouverte (diagramme (∗), p. 74) :

$$(*) \qquad \begin{array}{ccccc} U & \xrightarrow{\ i\ } & X & \xleftarrow{\ j\ } & T \\ {\scriptstyle p}\downarrow & & {\scriptstyle q}\downarrow & & \vdots \\ U' & \xrightarrow{\ i'\ } & X' & \xleftarrow{\ j'\ } & T' \simeq T. \end{array}$$

[page 81]

Le grand traquenard ici qu'il faut arriver à exorciser, c'est qu'il peut arriver que $i \in W$, sans qu'on ait $i' \in W$, et aussi $p \in W$ sans qu'on ait $q \in W$. Je m'en étais convaincu en 1983 en écrivant Pursuing Stacks (durant les semaines de 'scratchwork'), et n'ai pas envie de rechercher un contre-exemple ici, s'il ne se présente de lui-même (ce qu'il fera sans doute).

Je vais donner un cas important où ces ennuis disparaissent :

Commentary · Exposition [ms. 81]

Separating the boundary from the ambient category

Grothendieck wants to isolate the part of a pushout which can change its homotopy type. The complement T is carried isomorphically to T', whereas the arrows entering it from U are changed by a Kan extension. The useful intermediate category is therefore the closure $\bar{U}$, which consists of U and the objects of T reached by at least one arrow from U. Write $A = \bar{U} \cap T$. We then have a square

$$\begin{array}{ccc} A & \longrightarrow & T \\ \downarrow & & \downarrow \\ \bar{U} & \longrightarrow & X \end{array}$$

of cosieve inclusions. It is both Cartesian and cocartesian. Every arrow of X lies in one of these two full subcategories: if its source lies in $\bar{U}$, its target does too; otherwise its source lies in T, and its target lies in T. The same assertion for composable strings shows that the nerve is the union of the two corresponding simplicial subsets. Its realization is consequently a homotopy pushout, since inclusions of simplicial subsets realize as cofibrations.

The formula for the pushed-out gluing presheaf shows that an object $t \in T$ receives an arrow from U' after pushout exactly when it received an arrow from U before pushout. Indeed, a nonempty Kan-extension value is represented by an original arrow and a morphism in U'; conversely, an original arrow supplies such a value at the image of its source. Thus $A \to A'$ is an isomorphism. All the movement has been confined to $\bar{U} \to \overline{U'}$.

This explains the architecture of Proposition 6. If $U \to \bar{U}$ and $U' \to \overline{U'}$ are weak equivalences, two-out-of-three replaces the question about p by the question about $\bar{p}$. The resulting map of closed-cover squares is the identity on A and T. The ordinary homotopy gluing lemma therefore proves, for W_∞, the useful implication

$$p \in W_\infty \quad \Longrightarrow \quad q \in W_\infty.$$

This argument requires only the usual forward gluing statement.

The biconditionals in the printed proposition have stronger hypotheses. They explicitly invoke W(7 bis) and W(7), with their reverse implications as formulated on pp. 76–77. The counterexample discussed at p. 78 prevents us from treating those axioms as properties of W_∞. Proposition 6 remains a valid formal deduction under its stated axioms; its proof is not a proof that ordinary weak homotopy equivalences can be detected backwards from every such pushout. This distinction will matter when the one-point test is proposed on p. 85.

Proposition 6 : *Considérons les adhérences $\bar{U}$ et $\overline{U'}$ de U et U' dans X, X' respectivement, et supposons que les inclusions*

$$U \xrightarrow{i_0} \bar{U}, \qquad U' \xrightarrow{i'_0} \overline{U'}$$

soient dans W ([64]). Alors

p. 59

$$\begin{cases} \text{ⓐ } i \in W & \Longleftrightarrow \quad i' \in W \quad \textit{si on a } \text{W(7 bis)} \\ \text{ⓑ } p \in W & \Longleftrightarrow \quad q \in W \quad \textit{si on a } \text{W(7)}. \end{cases}$$

Démonstration. Considérons d'abord le cas ⓐ de i, i'. Soit

$$k : \bar{U} \hookrightarrow X$$

64. cf. th. 3 p. 107 pour des conditions générales assurant que cette hypothèse est satisfaite.

l'inclusion. Le triangle $U \xrightarrow{i_0} \bar{U} \xrightarrow{k} X$ $\quad\Big(\text{où } i = k \circ i_0\Big)$, où $i_0 \in W$, montre que

$$i \in W \iff k \in W.$$

D'autre part, X est la réunion des fermés $\bar{U}$, T, donc on a un carré cocartésien dans Cat

$$(*) \qquad \begin{array}{ccc} \bar{U} \cap T = \dot{T} & \xrightarrow{k_0} & T \\ {\scriptstyle j_0}\downarrow & & \downarrow{\scriptstyle j} \\ \bar{U} & \xrightarrow{k} & X. \end{array}$$

L'axiome W(7 bis) (sous sa forme duale (i.e. appliqué au carré formé par les catégories opposées …)) implique que [page 82]

$$k \in W \iff k_0 \in W,$$

d'où

$$i \in W \iff (k_0 : \dot{T} \longrightarrow T) \in W.$$

De même on trouve, en appliqunt ceci à (X', U') au lieu de (X, U)

$$i' \in W \iff (k'_0 : \dot{T}' \longrightarrow T') \in W.$$

Or on a $T \xrightarrow{\sim} T'$ (isomorphisme), et par la proposition 4 cet isomorphisme transforme $\dot{T}$ en $\dot{T}'$. Donc

$$k_0 \in W \iff k'_0 \in W \qquad \text{(trivialement)},$$

d'où a).

Prouvons b). Le carré commutatif induit par $(*)$, p. 80, p. 60

$$\begin{array}{ccc} U & \xrightarrow{i_0} & \bar{U} \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle \bar{p}} \\ U' & \xrightarrow{i'_0} & \overline{U'}, \end{array}$$

où $i_0, i'_0 \in W$ par hypothèse, montre que

$$p \in W \iff \bar{p} \in W,$$

donc tout revient à prouver que

$$\bar{p} \in W \overset{?}{\iff} q \in W.$$

Mais q induit un homomorphisme du carré $(*)$ déduit de $(X, \bar{U}, T)$ (avec $X = \bar{U} \cup T$), dans le carré similaire pour X'

$$\begin{array}{ccc} \overline{U'} \cap T' = \dot{T}' & \xrightarrow{k'_0} & T \\ {\scriptstyle j'_0}\downarrow & & \downarrow{\scriptstyle j'} \\ \overline{U'} & \xrightarrow{k'} & X', \end{array}$$

les flèches verticales étant notées $q_{\dot{T}}$, q_T, $\bar{p}$, q. On sait que $q_{\dot{T}}$, q_T sont des isomorphismes, [page 83] donc dans W, donc le 'lemme des cinq' W(7) nous assure que $\bar{p} \in W \iff q \in W$, q.e.d.

Commentaire. Cette proposition nous amène à chercher des conditions sur un ouvert U d'un X, qui assurent que l'inclusion $i_0 : U \longrightarrow \bar{U}$ soit `[dans]` W, et *que cette propriété soit conservée par tout cochangement de base* $U \longrightarrow U'$. De plus, nous recherchons des conditions qui soient de nature locale sur $\bar{U}$, plus exactement sur $\bar{U} \cap T = \dot{U} = \dot{T}$. Nous pouvons motiver

ce souci (a posteriori) en disant que nous voudrions que la propriété $i_0 \in W$ soit conservée, non seulement par cochangement de base quelconque $U \longrightarrow U'$, mais aussi, de plus, par passage de X à toute sous-catégorie pleine X_1 contenant U, donnant donc naissance à une situation

$$U \overset{i_Y}{\hookrightarrow} X_1, \qquad U \xrightarrow{(i_Y)_0} \bar{U}^{X_1} = \bar{U} \cap X_1$$

[$Y = X_1$?], similaire à la situation de départ. Plus généralement encore, nous voudrions qu'elle soit conservée en passant du triple (X, U, T) à un triple "induit" (X_1, U, T_1), par une flèche quelconque $g : T_1 \longrightarrow T$ de but T dans Cat, donnant naissance au couple de flèches

$$U \overset{\mathrm{id}}{\to} U,\ g : T_1 \longrightarrow T$$

(cf. pages 60, 61). Le cas précédent est celui où T_1 est une sous-catégorie pleine de T, g la flèche d'inclusion, Notons à ce sujet la proposition soritale p. 61 [page 84]

Proposition 7. *Conditions équivalentes sur l'ouvert U d'un objet X de* Cat (moyennant W(7 bis)) :

a) L'inclusion $i_0 : U \longrightarrow \bar{U}$ est W-asphérique, i.e. pour tout $t \in \dot{U} = \bar{U} \backslash U$, la catégorie U/t est W-asphérique.

b) L'inclusion $i_0 : U \longrightarrow \bar{U}$ est dans W, et cette condition reste satisfaite, quand on remplace (X, U) par (X_1, U), où (X_1, U) est déduit de (X, U) au moyen d'une flèche $T_1 \longrightarrow T (= X \backslash U)$ dans Cat*, comme rappelé ci-dessus.*

b′) Comme b), dans le cas où T_1 est la catégorie ponctuelle e, et où de plus son image est dans $\dot{U}$.

Démonstration. Il est évident que si dans b), b′) on remplace la condition "$i_0 \in W$" par la condition plus forte 'i_0 est W-asphérique', les quatre [plutôt trois] conditions a) à b′) sont équivalentes. Il reste à prouver que la condition que les U/t soient W-asphériques ($t \in \bar{U}$ - mais c'est trivial pour $t \in U$, donc il suffit de l'exprimer pour $t \in \bar{U} \backslash U = \dot{U}$) est déjà impliquée par la plus faible b′ et on devine qu'on a ceci :

Corollaire. (Moyennant W(7 bis).) *Soit X dans* Cat*, U un ouvert de X tel que $X \backslash U = \overline{\{t\}}$ soit la catégorie finale. Alors l'inclusion $U \overset{i}{\to} X$ est dans W si et seulement si elle est W-asphérique, i.e. si et seulement si U/t est W-asphérique (où t est l'unique élément de T).* [page 85]

Nous démontrons ultérieurement ce corollaire ([65]). La proposition 7 ne nous servira pas d'ici là - elle n'aura qu'un rôle purement esthétique à jouer, pour justifier notre propos délibéré de chercher des conditions sur $i : U \longrightarrow X$ (pour assurer que $U \longrightarrow \bar{U}$ est dans W et le reste, quand on remplace (X, U) par d'autres couples (X_1, U_1) qui s'en déduisent par certaines opérations …) qui soient de *nature locale* sur $\bar{U}$ (en fait, en les points de $\dot{U}$), et qui en tout état de cause entrainent la *W-asphéricité* de $U \longrightarrow \bar{U}$. [page 86]

Commentary · Exposition [ms. 85]

The one-point test and the direction of Theorem A

The purpose of Proposition 7 is to turn a condition on the whole inclusion into a condition at each new point. For a sieve $i : U \hookrightarrow X$, the comma category U/u has final object (u, id_u) whenever $u \in U$. All possible failures of asphericity are therefore concentrated at the complementary objects. Replacing T by the point selecting t preserves precisely the presheaf $u \mapsto \mathrm{Hom}_X(u, t)$, and hence precisely the category U/t. This proves the equivalence of the three versions in which every occurrence of "belongs to W" is replaced by "is W-aspherical." The remaining implication is exactly the deferred corollary, not a consequence of the definition.

For ordinary weak homotopy equivalences, the corollary's reverse implication is false. To see its geometry without altering the source, take a connected acyclic category A whose nerve is not weakly contractible, as in the counterexample at p. 78. Form U by adjoining a final object u_+ to A.

65. cf. cor. 4 de la proposition 15, page 149.

Form X by adjoining instead two distinct final cone points u_+ and t, with no morphisms between them. Then $U \hookrightarrow X$ is a sieve and its complement is the one-object category $\{t\}$. Every object of A has its unique arrow to t, while u_+ has none, so

$$U/t \simeq A.$$

On the other hand, BU is contractible and $BX \simeq \Sigma BA$. The suspension of a connected acyclic CW complex is simply connected and acyclic, hence weakly contractible by the Hurewicz and Whitehead theorems. Thus $U \to X$ is a weak homotopy equivalence although it is not aspherical.

The missing distinction is between the homotopy type of an attachment and the homotopy type of its attaching category. A cone attachment can erase a nontrivial perfect fundamental group without leaving any homology behind. Theorem A supplies the implication from contractible comma categories to weak equivalence; it does not supply the converse. In modern language this is also the distinction between a weak equivalence of classifying spaces and a homotopy initial functor: the comma categories here are $U/t = (i \downarrow t)$. Compare the dual of Lurie (2009, Theorem 4.1.3.1 and Corollary 4.1.3.3), applied to i^{op}. The source has retained W(7 bis) in the corollary, and the audit retains it too. Its subsequent use for W_∞ needs an independent argument in each application.

J'avais espéré que cette condition d'asphéricité (suggérée par la notion 'd'immersion de Dwyer') serait stable par cochangement de base quelconque $U \longrightarrow U'$, ce qui aurait assuré en même temps qu'après une telle opération, l'immersion ouverte $i' : U' \longrightarrow X'$ obtenue satisfait encore à la condition que $i'_0 : U' \longrightarrow \overline{U'}$ est dans W. Nous verrons que cette attente n'est pas fondée - la condition de W-asphéricité n'est *pas* stable par cochangement de base, et elle ne suffit *pas* même à assurer qu'après un cochangement de base, $i'_0 : U' \longrightarrow \overline{U'}$ soit dans W. Il faudra une notion plus forte, qui est suggérée par le cas où $T = \{t\}$ est la catégorie finale et contenue dans $\bar{U}$ (cas auquel nous avons essayé de nous ramener dans la proposition 7). Dans ce cas, on l'a dit (corollaire précédent), la condition que $i : U \longrightarrow \bar{U} = X$ soit dans W, équivaut à la W-asphéricité de i, i.e. à la W-asphéricité de U/t, et de même pour $i' : U' \longrightarrow \overline{U'} = X'$: elle est dans W si et seulement si U'/t' est W-asphérique, où t' est l'unique élément de $T'(\simeq T) = X' \backslash U'$. Donc il faut des conditions sur U/t qui assurent que non seulement U/t, mais aussi toutes les catégories similaires U'/t `[plutôt` U'/t'`]`, soient W-asphériques. Dans le cas général où T est quelconque, c'est cette condition-là que nous allons imposer aux U/t ($t \in \mathrm{Ob}\, T$), et il s'avérera que cette fois-ci, elles sont stables `[plutôt elle est stable]` par tout cochangement de base $U \xrightarrow{p} U'$, i.e. que les U'/t' ($t' \in \mathrm{Ob}\, T'$) satisferont alors à la même condition. C'est cette condition que nous allons à présent reformuler.

p. 62

[page 87]

Commentary · Exposition [ms. 87]

A boundary presheaf and all its direct images

Grothendieck now strengthens the boundary condition in the way dictated by the actual pushout formula. The extra quantifier is the essential feature. Given $H : U^{\mathrm{op}} \to \mathbf{Set}$, let $\int_U H = U/H$ denote its category of elements. Its objects are pairs (u, h) with $h \in H(u)$, and a morphism $(u, h) \to (v, k)$ is an arrow $a : u \to v$ satisfying $H(a)(k) = h$. If X is obtained by adjoining a complementary point t with $\mathrm{Hom}_X(u, t) = H(u)$, then $U/t = \int_U H$ literally records all ways to enter that point.

For $p : U \to U'$, the new boundary is $p_! H$, where $p_!$ is the ordinary left Kan extension along p^{op}. It is useful to calculate it through the category of elements, rather than to lose the variance in an informal colimit. With $\alpha : \int_U H \to U$ the projection,

$$(p_! H)(u') \cong \pi_0\big(u' \downarrow p\alpha\big).$$

An object on the right is $(u, h, \beta : u' \to p(u))$. Its connected component is the generator of the Kan extension represented by that triple. A map $a : u \to v$ with $H(a)(k) = h$ identifies the generator (u, h, β) with $(v, k, p(a)\beta)$; these are exactly the relations in the pointwise colimit. This gives both the formula and its functoriality in u'.

The ordinary asphericity of H only tests $p = \mathrm{id}_U$. Total asphericity requires the entire category of elements of every $p_! H$ to be aspherical. The operation takes connected components before the resulting presheaf is assembled over U'. It can therefore destroy homotopy information inside each

comma category while creating nontrivial topology in the assembled category. The finite example at p. 100 will make this effect visible in degree two.

The definition has a deliberate stability property. If H is totally W-aspherical and $p : U \to U'$ is any functor, then $p_!H$ is totally W-aspherical: for every $q : U' \to U''$ there is a canonical isomorphism $q_!p_!H \cong (qp)_!H$. Thus the strengthened condition is preserved by the very operation against which it was designed to protect the boundary. This is the formal reason the later definition of a W-Dwyer immersion uses these presheaves.

The editors' warning about terminology is necessary. The earlier test-category usage of "totally aspherical" concerns products or diagonal functors. Here the quantifier runs over all outgoing functors and their set-valued left Kan extensions. The commentary on Chapter II, manuscript p. 36 ("The quantifier in total asphericity") already treats this quantifier; the present pages apply it to a concrete gluing problem. Likewise the filtered examples should be read together with the commentary on Chapter II, manuscript pp. 32–35, rather than as a new assertion that contractibility alone controls all direct images.

2.3 Objets totalement W-asphériques de Cat, et morphismes totalement W-asphériques.

Reprenons la situation

$$U \overset{i}{\hookrightarrow} X \overset{j}{\hookleftarrow} T, \qquad \text{avec } T = \{t\}, \text{ catégorie finale, } t \in \bar{U}, \text{ i.e. } X = \bar{U},$$

et celle d'un cochangement de base $U \longrightarrow U'$, donnant naissance à un carré cocartésien dans Cat

$$(*) \qquad \begin{array}{ccccc} U & \overset{i}{\hookrightarrow} & X & \overset{j}{\dashleftarrow} & T = \{t\} \\ {\scriptstyle p}\downarrow & & {\scriptstyle q}\downarrow & & \vdots\,{\scriptstyle \text{iso}} \\ U' & \overset{i'}{\hookrightarrow} & X' & \overset{j'}{\dashleftarrow} & T' = \{t'\}. \end{array}$$

La donnée de recollement H entre U et T, $H : \underbrace{U^\circ \times T}_{\simeq U^\circ} \longrightarrow \mathrm{Ens}$, peut s'interpréter comme un préfaisceau sur U, $H \in \mathrm{Ob}\, U^\wedge : U^\circ \longrightarrow \mathrm{Ens}$, et on a [page 88]

$$U/t \simeq U/H,$$

où U/H est interprété en termes du plongement canonique

$$U \hookrightarrow U^\wedge.$$

De même, le recollement entre U' et T' sera donné par un préfaisceau

$$H' \in \mathrm{Ob}\, U'^\wedge : U'^\circ \longrightarrow \mathrm{Ens},$$

et on aura p. 63

$$U'/t' \simeq U/H'.$$

La relation entre H' et H a été explicitée au §1, comme

$$H' = p_!H, \qquad \text{où } p_! : U^\wedge \longrightarrow U'^\wedge$$

est l'adjoint à gauche de $p^* : U'^\wedge \longrightarrow U^\wedge$, donné par

$$p^*F' = F' \circ p.$$

On a

$$p_!(H)(u') \simeq \pi_0(u'\backslash U/H). \qquad [\text{page 89}]$$

Définition 1. ⓐ Soit U un objet de Cat, $H \in \mathrm{Ob}\, U^\wedge$ un préfaisceau sur U. On dit que H est *totalement W-asphérique* si pour toute flèche $p : U \longrightarrow U'$ de Cat, $p_!(H)$ dans $U'^\wedge$ est un objet W-asphérique, i.e. $U'/p_!H$ est W-asphérique. ⓑ On dit qu'un objet V de Cat est *totalement W-asphérique,* si le foncteur final e_V sur V ($v \longmapsto \{\emptyset\}$) est totalement W-asphérique, i.e. si pour toute flèche $f : V \longrightarrow V'$ dans Cat, le préfaisceau

$$\pi_0(f) \overset{\text{déf}}{=} f_!(e_V) \overset{\text{déf}}{=} (v' \longmapsto \pi_0(v'\backslash V))$$

sur V' est W-asphérique, i.e. si la catégorie

$$\underline{\pi}_0(f) \quad \text{ou} \quad \underline{\pi}_0(V/V') \overset{\text{déf}}{=} V'/\pi_0(f)$$

est W-asphérique. [Cette notion est différente de la notion de totale asphéricité de Pursuing Stacks.]

Notons que la définition des foncteurs $p_!$ (ou $f_!$) comme adjoints, et leur 'calcul' en termes de π_0 de certaines catégories, ne dépend pas du localiseur W. Donnons quelques précisions à ce sujet. On a un morphisme d'adjonction dans $V^\wedge$

$$f^* f_!(F) \longleftarrow F,$$

d'où

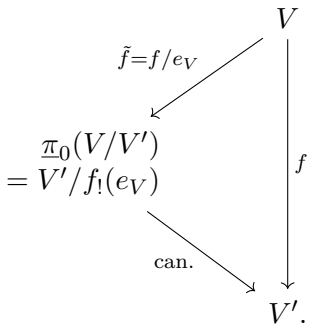
$$(*) \qquad V/F \longrightarrow V/f^* f_!(F) \simeq V \times_{V'} (V'/f_!(F)),$$

le dernier isomorphisme provenant du fait que l'on a commutativité, à isomorphisme canonique près, dans le diagramme de foncteurs

$$\begin{array}{ccc} V'^\wedge & \xrightarrow{f^*=(F' \longmapsto F' \circ f)} & V^\wedge \\ {\scriptstyle F' \longmapsto V'/F'}\downarrow & & \downarrow{\scriptstyle F \longmapsto F/V} \\ \mathrm{Cat}/V' & \xrightarrow{f^*_{\mathrm{Cat}}=(W' \longmapsto W' \times_{V'} V)} & \mathrm{Cat}/V, \end{array}$$

en d'autres termes, l'opérateur f^* sur les préfaisceaux s'interprète, en termes géométriques, comme l'opération $W' \longmapsto W' \times_{V'} V$ de changement de base par $V \longrightarrow V'$, sur les catégories au dessus de V' qui sont fibrées à fibres discrètes (propriété qui se conserve par changement de base). p. 64 [page 90]

Ceci dit, la donnée d'une flèche $(*)$ équivaut, par la propriété universelle du changement de base, à celle d'une flèche (canonique en l'occurrence)



$$f/F : V/F \longrightarrow V'/f_!(F)$$

rendant commutatif le carré

$$(*) \qquad \begin{array}{ccc} V/F & \xrightarrow[\text{ou foncteur source}]{\text{oubli de } F} & V \\ {\scriptstyle f/F}\downarrow & & \downarrow{\scriptstyle f} \\ V'/(F' = f_!(F)) & \xrightarrow{\text{oubli de } F'} & V'. \end{array}$$

Dans le cas qui nous intéresse surtout ici, $F = e_V$, $V/F \longrightarrow V$ est un isomorphisme, et on obtient une factorisation canonique de foncteurs [page 91]

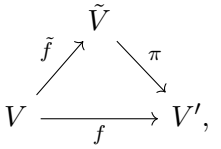
(∗∗)

Explicitons le V'-morphisme $\tilde{f}$ sur les fibres,

$$(***) \qquad \tilde{f}_{v'} : V_{v'} \longrightarrow \underline{\pi}_0(V/V')_{v'} \overset{\text{déf}}{=} \pi_0(v'\backslash V),$$

où dans le dernier membre, on a identifié l'ensemble $\pi_0(v'\backslash V)$ à la catégorie discrète qu'il définit. Pour expliciter cette flèche $(***)$, notons qu'on a une inclusion canonique

$$V_{v'} \longrightarrow v'\backslash V$$



et pour toute catégorie W, un morphisme canonique (d'adjonction) $W \longrightarrow \pi_0(W)$, d'où un composé

$$V_{v'} \longrightarrow v'\backslash V \longrightarrow \pi_0(v'\backslash V),$$

qui n'est autre que $\tilde{f}_{v'}$ dans $(***)$.

Il doit être facile de montrer que la factorisation $(**)$ de f est caractérisée, à isomorphisme unique près, en tant que factorisation dans Cat/V'

p. 65
[page 92]

par les propriétés suivantes :

a) π est fibrée à fibres discrètes, i.e. un isomorphisme local (i.e. $\tilde{V}$ est isomorphe dans Cat/V' à une catégorie V/F', avec F' dans $V'^{\wedge}$).

b) $\tilde{f}_!(e_V) = e_{\tilde{V}}$, i.e. pout tout $\tilde{v} \in \mathrm{Ob}\,\tilde{V}$, la catégorie $\tilde{v}\backslash V$ est 0-connexe : les colocalisés de V au dessus de $\tilde{V}$ sont 0-connexes.

Notons ici, en passant, que pour *tout* morphisme $\pi : W' \longrightarrow W$ dans Cat qui soit fibré à fibres discrètes, i.e. tel que W' soit isomorphe dans Cat/W à une catégorie de la forme W/F ($F \in \mathrm{Ob}\, W^{\wedge}$), on a

$$(*) \qquad \pi_!(e_{W'}) = F, \qquad \text{i.e. } W' \underbrace{\simeq}_{\text{dans Cat}/W} W/\pi_!(e_{W'}).$$

Il faut vérifier que le foncteur

$$w \longmapsto \pi_0(\underbrace{w\backslash(W/F)}_{\overset{\text{déf}}{=} w\backslash W/F})$$

est canoniquement isomorphe à F. Mais l'inclusion

$$\underbrace{W'_w}_{=F(w)\ \text{(catégorie discrète)}} \longrightarrow w\backslash W'$$

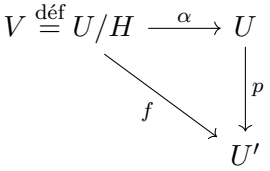
définit bien comme tantôt [page 93]

$$F(w) = W'_w \longrightarrow \pi_0(w\backslash W'),$$

il faut prouver que c'est bijectif. Or, W' étant W_∞-lisse sur W, on sait que l'inclusion $W'_w \hookrightarrow w\backslash W'$ est dans W_∞, a fortiori induit un isomorphisme pour les π_0.

Ceci posé, si on a une factorisation de $f : V \longrightarrow V'$ en $f = \pi\tilde{f}$ ayant les propriétés a) b) de la page précédente, on voit déjà que l'on a

$$f_!(e_V) \simeq \pi_!(\underbrace{\tilde{f}_!(e_V)}_{\simeq e_{\tilde{V}} \text{ par b)}}) \simeq \pi_!(e_{\tilde{V}}),$$



ce qui déjà détermine $\tilde{V}$ à isomorphisme canonique près (grâce à a) comme

$$\tilde{V} \simeq V'/f_!(e_V) \overset{\text{déf}}{=} \underline{\pi}_0(V'/V),$$

et il ne doit pas être bien dur de se convaincre que $\tilde{f}$ n'est autre que la flèche canonique de la page 91. p. 66

Proposition 8. *Pour qu'un objet H de $U^\wedge$ soit totalement W-asphérique, il suffit que l'objet U/H de* Cat *soit totalement W-asphérique.*

Supposons en effet cette dernière condition satisfaite et prouvons que H est totalement W-asphérique, i.e. que pour tout $p : U \longrightarrow U'$, $U'/p_!(H)$ soit W-asphérique. [page 94]

Soit f le foncteur composé du diagramme ci-contre `[ci-dessus]`, on a $H \simeq \alpha_!(e_V)$ (par $(*)$ p. 92), d'où

$$p_!(H) \simeq p_!\alpha_!(e_V) \simeq (p\alpha)_!(e_V) \simeq f_!(e_V),$$

qui est W-asphérique par hypothèse sur $V = U/H$.

Commentary · Exposition [ms. 93]

The connected-component factorization, with its proof

Grothendieck's relative $\underline{\pi}_0$ turns a map of categories into a genuine family of sets over its target. This is the right construction for understanding what ordinary Kan extension forgets. Let $f : A \to B$, put

$$F(b) = \pi_0(b \downarrow f), \qquad E = B/F,$$

and let $\pi : E \to B$ be the projection. Precomposition with a morphism $b' \to b$ gives the restriction map $F(b) \to F(b')$, so F is a presheaf. The factorization map

$$j : A \longrightarrow E, \qquad j(a) = \big(f(a), [(a, \mathrm{id}_{f(a)})]\big)$$

is functorial: a morphism $a \to a'$ identifies the evident two objects in $f(a) \downarrow f$. We have $f = \pi j$.

To prove the missing connectedness assertion, fix $e = (b, c) \in E$. An object of $e \downarrow j$ is an $a \in A$ together with $\beta : b \to f(a)$ such that the component of (a, β) is c. Its morphisms are exactly the morphisms of $b \downarrow f$ between those objects. Thus

$$e \downarrow j \;\cong\; (b \downarrow f)_c,$$

the component indexed by c. It is nonempty and connected by definition. In the usual ordinary-category terminology, j is a *final functor*. No higher contractibility is being asserted.

We also need to recover a discrete fibration from this procedure. Suppose $\pi : E \to B$ is the category of elements of a presheaf F. For $(e, \beta : b \to \pi e)$ in $b \downarrow \pi$, the unique lift of β into e has source $(b, F(\beta)(e))$. This assignment gives a functor to the discrete fibre E_b. Its composite with the

fibre inclusion is naturally connected to the identity by the lifted arrows, and its restriction to the fibre is the identity. Consequently

$$\pi_0(b \downarrow \pi) \cong F(b), \qquad \pi_! 1_E \cong F.$$

The same argument proves a homotopy equivalence between the comma category and the discrete fibre, which explains the appeal to smoothness on p. 93 without requiring that theory here.

Finally, suppose $f = \rho k$ is another factorization with $\rho : D \to B$ discrete and $k : A \to D$ final. By the Kan-extension formula $k_! 1_A = 1_D$, and hence

$$f_! 1_A \cong \rho_! k_! 1_A \cong \rho_! 1_D.$$

The preceding recovery calculation identifies D over B with $B/F = E$. This identification also respects the first factor. Indeed, for any presheaf G on B, a functor $A \to B/G$ over B is the same as a natural transformation $1_A \to f^*G$, and adjunction identifies these with natural transformations $f_! 1_A \to G$. For $G = F$, the canonical first factor corresponds to id_F; the identification obtained from $\rho_! 1_D \cong F$ carries k to that same map. This proves uniqueness with its compatibility, rather than only determining the middle category as an abstract object.

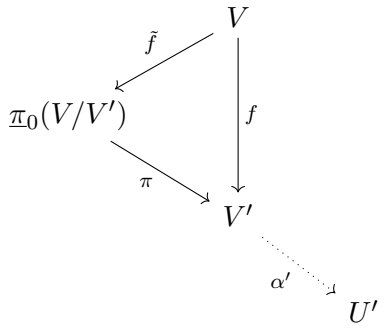
The result is the discrete-fibration form of the comprehensive factorization of Street and Walters (1973). A complete direct proof in the opposite variance is in Kelly (1982, §4.7, pp. 73–75, especially (4.77)–(4.79)); Kelly also identifies an invalid Kan-extension inference in the original proof and replaces it by the component calculation used above. The theorem predates these manuscript pages. Its role here is to distinguish the final first factor from a homotopy final map, whose comma categories would have to be weakly contractible.

Commentary · Later developments [ms. 93]

From comprehensive factorization to homotopy families

The geometric interpretation of $\underline{\pi}_0$ has continued to be useful independently of derivators. Berger and Kaufmann (2017, §1.3, Lemma 1.6, and Theorem 1.7) place the two ordinary comprehensive factorizations in a general theory of comprehension schemes: presheaves supply discrete fibrations, and the unit of comprehension supplies their universal approximation. Their Proposition 1.10 and Remark 1.11 explain the associated base-change and Frobenius properties. These are structural statements about the factorization, not claims that its first factor is a weak homotopy equivalence.

For the comparison with higher categories, the decisive change is to keep the homotopy type of each comma category instead of only its set of components. The homotopy-finality criterion requires $B(b \downarrow f)$ to be contractible for every b, as in Lurie (2009, Theorem 4.1.3.1). Here j only makes these spaces connected. Thus comprehensive factorization is a useful discrete approximation, but it cannot replace a construction of a homotopy Kan extension. The examples below measure precisely what is lost when this approximation is used before forming a total category.



La réciproque de `[la]` prop. 8 est-elle valable, i.e. si H est totalement W-asphérique, en est-il de même de $V = U/H$? La difficulté provient du fait que cela signifie que pour *toute* flèche $f : V \longrightarrow V'$ dans Cat de source V, on ait $f_!(e_V)$ W-asphérique, alors que l'hypothèse équivaut à le postuler seulement pour les flèches qui se factorisent par U. Notons que si on ne fait pas cette hypothèse sur f, mais qu'on suppose au lieu de cela que f s'insère dans un carré commutatif [page 95]

$$\begin{array}{ccc} V & \xrightarrow{\alpha} & U \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle p} \\ V' & \xrightarrow{\alpha'} & U', \end{array}$$

avec α' lui aussi un isomorphisme local, alors on peut conclure que $\underline{\pi}_0(f) = \underline{\pi}_0(V/V')$ est bien asphérique. En effet, on a un isomorphisme canonique dans Cat/U',

$$\underline{\pi}_0(\alpha' f) \simeq \underline{\pi}_0(f), \qquad \text{i.e. } \underline{\pi}_0(V/V') \simeq \underline{\pi}_0(V/U'), \qquad \text{p. 67}$$

du fait p. ex. que la factorisation canonique de f

fournit une factorisation du même type pour $\alpha' f$, en

$$\alpha' f = (\alpha' \pi) \circ \tilde{f}.$$

Ceci dit, on peut appliquer l'hypothèse à p et on trouve bien la W-asphéricité de $\underline{\pi}_0(f) \simeq \underline{\pi}_0(\alpha' f) = \underline{\pi}_0(p\alpha)$.

L'idée naturelle, pour une réciproque à `[1a]` prop. 8, serait de prendre pour U' la somme amalgamée de U et V' sur V, ce qui marchera pourvu qu'on sache que α' est bel et bien un isomorphisme local tout comme α. C'est bien le cas p. ex. si $V \longrightarrow U$ est une immersion ouverte, i.e. H un sous-préfaisceau du préfaisceau final. Mais je crains que ce ne soit pas vrai en général - ça a l'air un peu trop beau pour être vrai! C'est en effet déjà faux dans le cas [page 96]

$$\begin{array}{ccc} V = E_G & \xrightarrow{\alpha \text{ can}} & B_G = U \\ \Big\downarrow{\scriptstyle f} & & \\ V' = B_{G'}, & & \end{array}$$

dans le cas p. ex. où $G = \{\pm 1\}$, groupe à deux éléments, et où l'élément α de G', image par f de l'une des deux flèches non identiques de E_G est $\neq 1$ `[plutôt de carré` $\neq 1$`]`. Si H' est le sous-groupe invariant engendré par α `[plutôt par` α^2`]` dans G', la somme amalgamée s'identifie à $B_{G'/H'}$, or $B_{G'} \longrightarrow B_{G'/H'}$ n'est *pas* un isomorphisme local (car $(B_{G'})/t_0 \longrightarrow (B_{G'/H'})/t'_0$ n'est pas bijectif sur les objets, s'identifiant à $G' \xrightarrow{q} G'/H' \ \ldots$).

Mais d'autre part la condition de totale W-asphéricité sur un objet H de $U^\wedge$ paraît déjà à tel point exigeante, que je me vois mal construire un exemple où elle est satisfaite, sans que U/H elle-même ne soit totalement W-asphérique. [page 97]

Commentary · Exposition [ms. 96]

The converse for subterminal presheaves and its obstruction

Proposition 8 compares two quantifiers. Write $V = U/H$ and $\alpha : V \to U$. Total asphericity of V tests every outgoing functor $f : V \to C$. Total asphericity of H tests the special family $p\alpha$, with $p : U \to B$. The proposition follows because $\alpha_! 1_V = H$, but reversing it requires a way of placing an arbitrary f in that special family without changing its comprehensive middle category.

The square criterion on p. 95 does this whenever one can complete

$$\begin{array}{ccc} V & \xrightarrow{\alpha} & U \\ {\scriptstyle f}\big\downarrow & & \big\downarrow{\scriptstyle p} \\ C & \xrightarrow[\beta]{} & B \end{array}$$

with β a discrete fibration. To justify the assertion completely, factor f as a final functor $V \to E$ followed by a discrete fibration $E \to C$. Since discrete fibrations compose, the same E is the

comprehensive middle category of $\beta f = p\alpha$. Its category is therefore W-aspherical when H is totally W-aspherical.

If H is subterminal, α is a sieve inclusion. Form the ordinary categorical pushout $B = U \amalg_V C$. Theorem 1 preserves the sieve inclusion on the other side, so $\beta : C \to B$ is again a sieve, in particular a discrete fibration. The preceding argument applies to every $f : V \to C$. This supplies the full proof of the source's subterminal case: for such H, the total asphericity of H and of U/H are equivalent.

The groupoid example identifies why the same proof cannot be extended merely by replacing "sieve" with "discrete fibration." Let $G = C_2$ and let E_G be the indiscrete groupoid on two objects. Its projection to BG sends both nonidentity arrows to the unique nontrivial element g. A functor $E_G \to BG'$ sends one of these arrows to an element $a \in G'$ and the inverse arrow to a^{-1}. In a cocone on this span, the two objects must become equal, and compatibility with the projection to BG forces

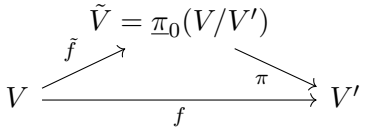
$$a = a^{-1}, \quad \text{equivalently } a^2 = 1.$$

There are no additional relations. The pushout is therefore

$$B\big(G'/\langle\!\langle a^2 \rangle\!\rangle\big).$$

For example, with $G' = \mathbb{Z}$ and a its generator, the induced map is $B\mathbb{Z} \to BC_2$. A discrete fibration between one-object groupoids must lift every arrow uniquely into the sole object, so its map of morphism sets must be bijective. This quotient map is not. The bracketed corrections in the edition, replacing a by a^2, are thus mathematically necessary.

This counterexample defeats the proposed pushout method; it does not by itself refute the general converse of Proposition 8. That converse is false: a presheaf with three elements on a monoid with two elements is given in the commentary at ms. 97. The subterminal case is proved, and the obstruction to the broader argument is explicit.



L'existence d'objets totalement W-asphériques dans Cat n'est pas tellement évidente a priori. Qu'il y en ait un bon paquet est assuré par la

Proposition 9. p. 68

a) Tout objet V de Cat *ayant un objet final est totalement W-asphérique - donc tout préfaisceau d'ensembles H* représentable *sur une catégorie U (la représentabilité signifiant justement que U/H a un objet final) est totalement W-asphérique.*

b) ([66]) (Supposons W(7 bis) *satisfait.) Soient V dans* Cat, *V', V'' deux ouverts de réunion V. Si V', V'', $V' \cap V''$ sont totalement W-asphériques, il en est de même de V.*

Démonstration de a). Soit V avec objet final et $f : V \longrightarrow V'$, d'où la factorisation

de f. On démontre sans mal ([67]) (histoire de cofinalité) ceci :

Corollaire. *L'image par $\tilde{f}$ d'un objet final de V est un objet final de $\tilde{V} = \underline{\pi}_0(V/V')$.*

Comme un objet de Cat avec objet final est W-asphérique par W(3), cela établit a).

Prouvons b). J'ai envie de dire que si on a $f : V \longrightarrow W$ dans Cat, alors $\underline{\pi}_0(V/W)$ est réunion de deux ouverts isomorphes à $\underline{\pi}_0(V'/W)$, $\underline{\pi}_0(V''/W)$, dont l'intersection est isomorphe à $\underline{\pi}_0(V' \cap V''/W)$. Cela signifierait ni plus ni moins que ceci : $f_!$ transforme les monomorphismes [page 98]

66. !! Sans doute *faux* tel quel, cf. rectification page suivante.

67. Voici une démonstration simple : On a pour toute V dans Cat $e_V = \varinjlim_{v \text{ dans } V} v$ (limite inductive du foncteur d'inclusion de V dans $V^\wedge$), car $\forall\, x$ dans V

$$\varinjlim_{v \text{ dans } V} \mathrm{Hom}(x, v) \simeq \pi_0(x\backslash V) = e.$$

Comme $f_!$ commute aux $\varinjlim$, on a donc $f_!(e_V) = \varinjlim_{v \text{ dans } V} f(v)$. Si v_0 est un objet final de V, cela montre que $f_!(e_V) = f(v_0)$, q.e.d.

$V' \longrightarrow V$, $V'' \longrightarrow V$ (interprétés comme flèches dans $V^\wedge$, de but e_V) en monomorphismes, et le produit fibré $V' \cap V'' = V' \times_V V''$ en le produit fibré correspondant dans $W^\wedge$. Mais le foncteur $f_!$ commute aux $\varinjlim$ quelconques (étant un adjoint à gauche), et je ne vois aucune raison a priori pour qu'il commute (disons) aux produits fibrés (ce qui impliquerait aussi qu'il transforme monomorphismes en itou). Si je me rappelle bien, c'est ultrafaux en général. Donc je doute fort à présent que l'énoncé b) soit vrai, sans hypothèse supplémentaire. Pour assurer la monomorphie, on songe à imposer l'existence de *rétractions* de V sur V', V'' et de V' ou V'' sur $V' \cap V''$.

Commentary · Development (commentators') [ms. 97]

Total asphericity tested on final images

Grothendieck's search becomes more transparent if we express the quantifier through the first half of comprehensive factorization. The following elementary consequence is our formulation of what the construction already permits; it is not a claim of priority. We checked the factorization accounts of Street–Walters, Kelly, and Berger–Kaufmann, which establish the factorization but do not state this characterization of the manuscript's total-asphericity class.

Final-image criterion. [ours] For any localizer W for which asphericity is invariant under isomorphism, a small category A is totally W-aspherical if and only if every ordinary final functor $A \to C$ has W-aspherical target. Moreover, the class of totally W-aspherical categories is closed under ordinary final functors.

Proof. If $u : A \to C$ is final, then $u_! 1_A = 1_C$. Hence the category of elements used in the definition of total asphericity is $C/1_C \cong C$, proving the necessity. Conversely, factor an arbitrary $f : A \to B$ comprehensively as

$$A \xrightarrow{j} E = B/(f_! 1_A) \xrightarrow{\pi} B.$$

The first factor is final, so the assumed condition says that E is W-aspherical. This is exactly the required test for f.

For the closure assertion, suppose A is totally W-aspherical and $u : A \to C$ is final. For every $g : C \to D$,

$$g_! 1_C \cong g_! u_! 1_A \cong (gu)_! 1_A.$$

Its category of elements is W-aspherical by the hypothesis on A. Thus C is totally W-aspherical.□

There is an equivalent extremal description which is sometimes useful for constructing examples. Among subclasses of the W-aspherical categories which are closed under taking targets of ordinary final functors, the totally W-aspherical categories form the largest one. They themselves have that closure property, and they are aspherical by taking $f = \mathrm{id}$. Conversely, if A belongs to any such subclass, every comprehensive middle category of an outgoing map from A belongs to it, hence is aspherical. The criterion just proved applies.

The result also separates two kinds of positive examples. If A has final object a_0, then for every $f : A \to B$,

$$f_! 1_A \cong B(-, f(a_0)), \qquad B/(f_! 1_A) \cong B/f(a_0),$$

whose final object is $(f(a_0), \mathrm{id})$. This is Proposition 9(a) in an explicit form. Filtered categories provide the further examples already explained in the commentary on Chapter II, manuscript pp. 32–35, through filtered colimits of representables. For instance $(\mathbb{N}, \leq)$ has no final object, so the conjecture in footnote 73 cannot survive even in ordinary homotopy theory. The new criterion explains what both examples must control: all final images, not just their own classifying spaces.

Commentary · Development (commentators') [ms. 97]

A total presheaf whose category of elements is not total

Grothendieck expects that Proposition 8 has no converse outside the subterminal case, and proposes to look for a totally W-aspherical presheaf H whose category of elements is not totally W-aspherical. Such a presheaf exists on the smallest category that is not a preorder and not a group. We found no source for the example; it is given without a claim of priority.

Proposition (the converse of Proposition 8 fails). [ours] *Let U be the category with one object $*$ and $\mathrm{End}(*) = \{1, e\}$, $e^2 = e$. Let H be the presheaf on U with $H(*) = \{i, h_1, h_2\}$, on which e acts*

by the constant map with value i. Then H is totally W-aspherical for every fundamental localizer W. The category U/H is not totally W-aspherical for $W = W_\infty$, for the homology equivalences W_R with coefficients in a nonzero commutative ring R, and for the n-equivalences with $n \geq 2$.

Proof. Let $R = U(-, *)$ be the representable presheaf. Its elements are 1 and e, and e acts on them by $x \mapsto xe$, the constant map with value e. The endomorphism $\varepsilon : x \mapsto ex$ of R is idempotent with image the subpresheaf $Q = \{e\}$. The presheaf H is the pushout $R \amalg_Q R$ of two copies of R along Q: the element e is i, and the two copies of 1 are h_1, h_2.

Let $p : U \to C$ be any functor to a small category, and put $c = p(*)$, $d = p(e)$, so that $d^2 = d$. The functor $p_!$ preserves colimits, sends R to $C(-, c)$, and sends ε to the endomorphism $\alpha \mapsto d\alpha$. Every functor preserves the splitting of an idempotent. Hence $p_!Q$ is the subpresheaf

$$Q_d(v) = \{\alpha : v \to c \mid d\alpha = \alpha\} \subseteq C(v, c),$$

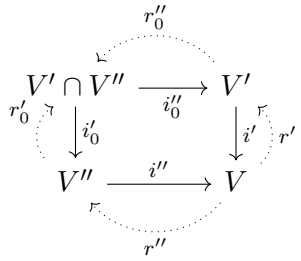
with its inclusion, and

$$p_!H \cong C(-, c) \amalg_{Q_d} C(-, c).$$

This pushout is formed objectwise along injections. The category of elements $E' = C/p_!H$ is therefore the union of two full sieves S_1, S_2, each isomorphic to C/c, with $S_1 \cap S_2 = C/Q_d$. A chain of arrows of E' lies in the sieve that contains its last object, so $NE' = NS_1 \cup NS_2$ and $NS_1 \cap NS_2 = N(C/Q_d)$. Each S_j has the terminal object (c, id_c). The category C/Q_d has the object (c, d), and the arrows $\alpha : (v, \alpha) \to (c, d)$ are the components of a natural transformation from the identity functor to the constant functor at (c, d): for an arrow $g : (v, \alpha) \to (w, \beta)$ one has $\beta g = \alpha$. Thus BS_1, BS_2 and their intersection are contractible, and so is BE'. Since p was arbitrary, H is totally W_∞-aspherical. Every fundamental localizer contains W_∞ (Cisinski, 2004, Théorème 2.2.11), which gives the first assertion.

The category $E = U/H$ has the three objects i, h_1, h_2 and, besides identities, the arrows

$$e_i : i \to i, \qquad u_1 : i \to h_1, \qquad u_2 : i \to h_2, \qquad e_i^2 = e_i, \quad u_j e_i = u_j.$$



Let $q : E \to \Psi$ be the functor to the outgoing fork $\Psi = (a \leftarrow z \to b)$ of the commentary at ms. 100 which sends i, h_1, h_2 to z, a, b and e_i to the identity. It is bijective on objects and full. For an object y of Ψ with preimage $\tilde{y}$, every object $(x,\ y \to q(x))$ of $y\backslash E$ receives an arrow from $(\tilde{y}, \mathrm{id}_y)$, obtained by lifting $y \to q(x)$. So q is final. The inclusion $f : \Psi \to C$ into the four-object category of the same commentary is final and $BC \simeq S^2$. The composite $fq : E \to C$ is a final functor whose target is not aspherical for any of the localizers named. By the final-image criterion above, U/H is not totally aspherical for them. □

The objects h_1, h_2 of U/H have no common successor; this is the property that fails, and it cannot be seen by functors that factor through U. For the localizers W_0 and W_1 (bijections on π_0; bijections on π_0 and isomorphisms on all π_1) the converse of Proposition 8 does hold. A final functor induces a bijection on connected components, and a final image of a 1-connected category is 1-connected (the argument with coverings at ms. 101). If H is totally W_0-aspherical, the test $p = \mathrm{id}$ shows that U/H is nonempty and connected, and then so is every final image of U/H; for W_1 the same reasoning applies with 1-connectedness.

Je viens de vérifier la chose, et donne le **Corollaire 1** (rectification de `[1a]` prop. 9, partie b) ([68]) : *L'énoncé est valable si on suppose qu'il existe une* rétraction r'_0 *de* V'' *sur* $V' \cap V''$, p. 69

68. NB Il y a un énoncé légèrement plus général, en partant d'une catégorie U et d'un diagramme
$$\begin{array}{ccc} V' \cap V'' & \longrightarrow & V' \\ \downarrow & & \downarrow \\ V'' & \longrightarrow & V \end{array}$$
dans $U^\wedge$: si V', V'', $V' \cap V''$ sont totalement W-asphériques, il en est de même de V.

et de même une rétraction r''_0 de V' sur $V' \cap V''$. ([69])

(**NB** Nous verrons plus tard qu'il suffit de l'existence d'*une* de ces rétractions pour assurer la conclusion.)

Démonstration. Comme V est somme amalgamée de V' et V'', il existe une rétraction r' de V sur V' (donnée par $\mathrm{id}_{V'}$ sur V', par $i''_0 r'_0$ sur V'') qui induit r'_0 sur V'', et de même il existe une rétraction r'' de V sur V'', induisant r''_0 sur V'. L'existence de ces rétractions [page 99] assure déjà que pour tout foncteur $f : V \longrightarrow W$, le diagramme transformé de

$$\begin{array}{ccc} V' \cap V'' & \longrightarrow & V' \\ \downarrow & & \downarrow \\ V'' & \longrightarrow & V \end{array}$$

(intérprété comme diagramme dans $V^\wedge$) est formé de monomorphismes ([70])

$$\begin{array}{ccc} f_!(V' \cap V'') & \hookrightarrow & f_!(V') \\ \downarrow & & \downarrow \\ f_!(V'') & \hookrightarrow & f_!(V), \end{array}$$

et de plus que $f_!(V') \cap f_!(V'')$ (qui contient $f_!(V' \cap V'')$) lui est en fait *égal.* Il en résulte que l'on a un diagramme à la fois cartésien et cocartésien d'immersions ouvertes dans Cat p. 70

$$\begin{array}{ccc} W/f_!(V' \cap V'') & \hookrightarrow & W/f_!(V') \\ \downarrow & & \downarrow \\ W/f_!(V'') & \hookrightarrow & W/\Big(f_!(V) \overset{\text{déf}}{=} f_!(e_V)\Big), \end{array}$$

lequel s'identifie aussi à

$$\begin{array}{ccc} \underline{\pi}_0(V' \cap V''/W) & \hookrightarrow & \underline{\pi}_0(V'/W) \\ \downarrow & & \downarrow \\ \underline{\pi}_0(V''/W) & \hookrightarrow & \underline{\pi}_0(V/W). \end{array}$$

Commentary · Exposition [ms. 98]

Why a categorical retraction cannot be sent through this Kan extension

Grothendieck tries to protect a union from collapsing under $f_!$ by splitting its inclusions. Splitting is indeed preserved by every functor, but the retraction must be a morphism in the category on

69. Corollaire rectifié faux également - les rétractions ne sont pas des flèches de $V^\wedge$, et ne passent dans $p_!$.
70. **faux,** déjà dans le cas où $V = \Phi$, V', V'' ses deux ouverts canoniques isomorphes à $\mathbf{\Delta}^1$, et $V' \cap V'' = e$.

which that functor acts. Here $f_!$ acts on $V^\wedge$, whereas the retractions just constructed are functors between full subcategories of V.

For a sieve $S \subseteq V$, the associated subterminal presheaf $1_S \subseteq 1_V$ takes the value one on objects of S and the empty set elsewhere. If S omits an object of V, there cannot be a map $1_V \to 1_S$: at that object it would have to be a function from a singleton to the empty set. Thus a proper sieve, even if it admits a categorical retraction, does not define a split subobject of the terminal presheaf. A functor $r : V \to S$ moves the base object; a morphism in $V^\wedge$ must stay over it. This is exactly the defect identified by the source's corrective footnote.

What would suffice is a genuinely different hypothesis. Given a union $H = H_1 \cup H_2$ in a presheaf category, suppose that for every p the images of its three inclusion maps remain monomorphisms and the square remains Cartesian. Since $p_!$ preserves the pushout, the resulting categories of elements then form a union of two sieves with the expected intersection. The ordinary forward homotopy gluing lemma proves total W_∞-asphericity of H when the other three presheaves are totally W_∞-aspherical. This is the precise exactness condition the proposed proof needs. Categorical retractions provide none of it.

L'hypothèse sur V', V'', $V' \cap V''$ implique que les trois sommets du carré autres que [page 100]
$\underline{\pi}_0(V/W)$ sont W-asphériques, donc par W(7 bis) il en est de même de ce dernier, q.e.d.

Corollaire 2 ([71]). *Moyennant* W(7 bis)*, la catégorie* $\Psi = \begin{array}{ccc} & & a \\ & \nearrow & \\ 0 & & \\ & \searrow & \\ & & b \end{array}$ *(ou* $0 \longleftarrow 1 \longrightarrow 2$*)*

est totalement W-asphérique ([72]).

On applique le corollaire 1 à Ψ et à ses deux sous-catégories ouvertes, Ψ/a, Ψ/b (isomorphes à $\mathbf{\Delta}^1$), et à leur intersection $\{0\} \simeq \mathbf{\Delta}^0 = e$. Comme ces trois catégories ont un objet final (contrairement à Ψ elle-même, qui n'a qu'un objet initial …), elles sont totalement W-asphériques. Le corollaire s'applique, l'existence des rétractions r'_0, r''_0 étant ici évidente.

C'est surtout la partie b) (rectifiée) de la page 9 qui assure l'existence de catégories totalement W-asphériques autres que celles ayant un objet final ([73]). Il est vrai qu'en sens inverse il faudrait quand même s'assurer qu'un objet X W-asphérique de Cat n'est pas *toujours* totalement W-asphérique! Le contre-exemple n'est pas tellement évident finalement - j'ai [page 101]
passé des heures avant d'en trouver un et d'y voir un peu clair! Il suffit en somme d'exhiber un exemple d'une flèche dans Cat

$$f : X \longrightarrow Y$$

telle que

p. 71

a) $\underline{\pi_0}(f) \overset{\text{déf}}{=} \underline{\pi}_0(X/Y) \xrightarrow{\sim} Y$, i.e. les $\pi_0(y\backslash X)$ `[plutôt les` $y\backslash X$`]` sont 0-connexes (pour $y \in \operatorname{Ob} Y$),

Commentary · Examples [ms. 100]

The finite fork counterexample, computed completely

Grothendieck eventually finds a very small witness to the failure of the preceding gluing claims. The construction is in his Appendix to Chapter XII, manuscript pp. 10–12, where the final corrective footnote identifies the homotopy type as S^2 (Grothendieck, 1990–1991p). We work it out here because it explains at once the failure of total asphericity and the failed use of retractions.

Let C have four objects x, z, a, b and the nonidentity morphisms generated by

$$\begin{array}{ccccc} x & \underset{\beta}{\overset{\alpha}{\rightrightarrows}} & z & \xrightarrow{\ r\ } & a \\ & & \downarrow{\scriptstyle s} & & \\ & & b & & \end{array} \qquad r\alpha = r\beta, \quad s\alpha = s\beta.$$

71. Plus généralement, si I est une catégorie *ordonnée finie,* ayant un objet initial, alors
72. **Faux,** Ψ n'est *pas* totalement W-asphérique.
73. Je conjecture à présent que ce sont les seules! ([74])
74. Faux, il y a les catégories filtrantes (si W satisfait l'axiome des limites).

Besides the four displayed arrows there are just the two composites $x \to a$ and $x \to b$. Let A be its full subcategory on z, a, b, the outgoing fork Ψ, and let $f : A \hookrightarrow C$ be the inclusion. The category A has initial object z, so BA is contractible.

We first compute $f_!1_A$. At a and b the outgoing comma category is a point. At z it has initial object (z, id). At x it has four objects

$$(z, \alpha),\ (z, \beta),\ (a, r\alpha),\ (b, s\alpha),$$

and one arrow from each of the first two to each of the last two. Its nerve is a four-edge circle. In particular it is nonempty and connected. Thus every $c \downarrow f$ is connected, and

$$f_!1_A = 1_C, \qquad \underline{\pi}_0(A/C) = C.$$

The map f is final in the ordinary sense, although its comma category at x is not contractible.

The homotopy type of C can be read without a spectral sequence. Let K be the full subcategory on x, z, with its two parallel arrows. Its nerve realizes as a circle. The full subcategories C_a on x, z, a and C_b on x, z, b each adjoin a final object to K. Their nerves are therefore cones on NK. They cover NC, with intersection NK, because there are no arrows between a and b. Consequently

$$BC = BC_a \cup_{BK} BC_b \cong \Sigma BK \simeq S^2.$$

Here the union description is literal at the level of nerves. Hence A is not totally W_∞-aspherical: its direct image along f has category of elements C, with $H_2(BC; \mathbb{Z}) \cong \mathbb{Z}$.

Now return to the proposed retraction repair. Inside A, put $A_a = \{z \to a\}$ and $A_b = \{z \to b\}$. Both have final objects, their intersection is $\{z\}$, and both admit retractions to that intersection. Proposition 9(a) therefore gives total asphericity of all three pieces. Nevertheless their union is A, which we have just shown is not total. The false step can be inspected at a single value. Write $y_c = C(-, c)$. Since left Kan extension carries a representable to the corresponding representable,

$$f_!(1_{\{z\}}) = y_z, \quad f_!(1_{A_a}) = y_a, \quad f_!(1_{A_b}) = y_b.$$

The equality $1_{A_a} = A(-, a)$ follows because a receives exactly one arrow from z and none from b, and similarly for b. Evaluating the first inclusion after Kan extension at x yields

$$\{\alpha, \beta\} = C(x, z) \longrightarrow C(x, a) = \{r\alpha = r\beta\}.$$

It is not injective. The other leg has the same defect. Their pushout is the singleton $1_C(x)$, exactly as preservation of colimits predicts. The putative intersection square has failed before any homotopy argument is applied.

The same finite construction also explains the two kinds of pushout failure announced on p. 81. Adjoin a final object to A, giving $A^\triangleright$. Pushing out $A \subset A^\triangleright$ along f adjoins a final object to C, because $f_!1_A = 1_C$. The upper inclusion is an aspherical weak equivalence; the lower inclusion $C \to C^\triangleright$ is not, since $BC \simeq S^2$.

To make the other leg a weak equivalence as well, replace the target of f by $C^\triangleright$, with final point c_+. The composite $p : A \to C^\triangleright$ is a weak equivalence between contractible categories. Its direct image of 1_A is the subterminal presheaf supported on C: it is one on every object of C and empty at c_+. The resulting pushout P is C with two distinct final cone points, c_+ and the newly attached point. Hence

$$BP \simeq \Sigma BC \simeq S^3.$$

Both $A \to A^\triangleright$ and p are weak equivalences, while neither map from $C^\triangleright$ or $A^\triangleright$ to P is. This proof uses the explicit nerve, so it does not depend on the invalid reverse implication of the one-point corollary on p. 85.

Commentary · Development (commentators') [ms. 100]

Testing the retracted assertions under their stated axiom

The fork example proves that ordinary weak contractibility is insufficient for total asphericity. There is a logical point still to check: several of the source's retracted conclusions explicitly assume W(7 bis), whereas W_∞ does not satisfy that axiom. To refute those conditional conclusions

themselves, rather than only their proposed proof, we need an example in a weak equivalence class for which the axiom holds. Fixed-coefficient homology provides such a test. The homological tools are standard; the application below is our explicit check of these conditional assertions, with no claim of priority.

A homological counterexample with W(7). [ours] Let R be a nonzero commutative ring, and let W_R consist of functors inducing isomorphisms on all homology groups of their nerves with coefficients in R. Then W_R is a fundamental localizer satisfying the full W(7). Nevertheless a union of two totally W_R-aspherical sieves with totally W_R-aspherical intersection need not be totally W_R-aspherical, even when both pieces retract onto their intersection.

Verification of the test class. Identities, two-out-of-three, and closure under retracts follow by applying homology. A category with a terminal object has contractible nerve and hence maps to the terminal category by an arrow in W_R. We spell out the relative Theorem A axiom, since that is the remaining condition needed here. Suppose $A \xrightarrow{u} B \to C$ is a triangle and every induced map $A/c \to B/c$ is an R-homology equivalence. For the composite $f : A \to C$, form the bisimplicial set with (p, q)-simplices

$$\big(a_0 \to \cdots \to a_p, \quad f(a_p) \to c_0 \to \cdots \to c_q\big).$$

Deleting the last a-vertex composes the crossing arrow with the image of that last arrow under f; deleting the first c-vertex composes on its other side. These rules, with the ordinary remaining faces and identity degeneracies, make the two simplicial directions commute. Take free R-modules, normalize in each direction, and use the usual sign in the total differential.

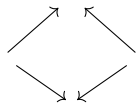
For each fixed a-chain, the second direction is the nerve of $f(a_p)\backslash C$, a category with initial object $\mathrm{id}_{f(a_p)}$. Its positive homology vanishes and its degree-zero homology is R. The spectral sequence that first takes this homology therefore identifies the homology of the total complex with $H_*(NA; R)$. In the other direction, for each fixed chain $c_0 \to \cdots \to c_q$, the first simplicial direction is $N(A/c_0)$. Consequently the map induced by u gives an isomorphism on that first homology page by the hypothesis on the comma categories. The comparison of the first-quadrant spectral sequences gives an isomorphism of total homology, and thus $H_*(NA; R) \cong H_*(NB; R)$. Convergence is sufficient here without any finiteness assumption: there are only finitely many bidegrees in any given total degree. This proves the relative localizer axiom. Finally the normalized-chain argument after ms. 79 proves W(7) for precisely this class W_R.

The counterexample. Use the finite functor $f : \Psi \to C$ computed in the preceding block, with $\Psi = (z \to a, z \to b)$. It is ordinary final, so $f_! e_\Psi = e_C$. But $BC \simeq S^2$, and

$$H_2(BC; R) = R \neq 0.$$

Hence Ψ is not totally W_R-aspherical. Its two full sieves $\{z \to a\}$ and $\{z \to b\}$, and their intersection $\{z\}$, each have a terminal object. Proposition 9(a), whose proof does not use W(7), makes all three totally W_R-aspherical. The constant functors from the two arrows to $\{z\}$ are retractions of the inclusions of the intersection. Thus both the union assertion and its proposed retraction repair fail, and the conclusion asserting totality of the outgoing fork fails as well. All this occurs in a fundamental localizer satisfying W(7), so the conditional qualifications in those statements do not save them. □

The same calculation keeps two different defects apart. The proof's use of left Kan extension to preserve a monomorphism is invalid before any weak equivalence class is chosen. The example above additionally shows that the resulting total-asphericity conclusion can be false after all its stated homotopical axioms have been imposed.



et telle que de plus

b) X est W-asphérique, et Y non.

La difficulté est la suivante, quand on cherche des contre-exemples 'idiots' : c'est que l'hypothèse a) implique déjà, quand X est W_∞-asphérique (ou seulement 1-connexe) que Y est 1-connexe : le foncteur

$$Y' \longmapsto X' = X \times_Y Y'$$

de la catégorie des revêtements étales Y' de Y vers celle des revêtements étales X' de X est pleinement fidèle (vérification immédiate), d'où le résultat annoncé. Donc un contre-exemple [page 102]

doit faire appel à l'existence d'un $\pi_i(Y,y)$ non nul, avec $i \geq 2$. Cela implique qu'il n'y a pas de contre-exemple avec des catégories de la forme $Y = Z/F$ (déduites d'un foncteur $q : X \longrightarrow Z$ en prenant $F = q_!(e_X) = \pi_0(X/Z)$), où Z est une catégorie telle que $\mathbf{\Delta}^1$ (?), Φ, Ψ, ou  (ayant le type d'homotopie du cercle) etc., car les composantes connexes de telles catégories Y sont des $K(\pi,1)$ - les π_i supérieures ($i \geq 2$) sont nuls.

Commentary · Exposition [ms. 101]

Why the first obstruction occurs above the fundamental group

Grothendieck's assertion about coverings explains why a counterexample with a circle as target cannot work. Let $f : A \to B$ be final, so every $b \downarrow f$ is nonempty and connected. Let $L, M : B \to \mathbf{Set}$ be local systems, meaning that every arrow is sent to a bijection. Given a natural transformation $\theta : Lf \to Mf$, choose any object $(a, \beta : b \to f(a))$ of $b \downarrow f$ and define

$$\bar{\theta}_b = M(\beta)^{-1}\theta_a L(\beta).$$

If $h : a \to a'$ is a morphism in that comma category, then $f(h)\beta = \beta'$ and the naturality of θ identifies the expressions obtained from (a,β) and (a',β'). Connectedness makes the expression independent of all choices. For $\gamma : b' \to b$, the object $(a, \beta\gamma)$ computes $\bar{\theta}_{b'}$, proving naturality in b. Its restriction to A is θ, using (a, id), and the same formula proves uniqueness. Thus restriction along f is fully faithful on local systems.

Finality also preserves the set of connected components: it preserves the colimit of the constant singleton diagram, which is π_0. Suppose now that BA is simply connected. Then BB is connected, and every pulled-back local system on A is constant. Fix a fibre of a local system L on B. Each element of that fibre determines a section of the pulled-back system; full faithfulness, applied to maps from the singleton local system, makes it descend uniquely to a global section of L. Every monodromy action is therefore trivial. Applying this to the regular action of $\pi_1(BB)$ shows that the group itself is trivial. This supplies the omitted verification on p. 101.

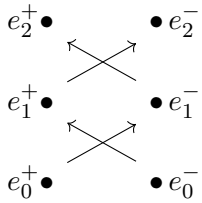
The four-object example above is consistent with this restriction: $BC \simeq S^2$ is simply connected but not contractible. Its critical comma category is a circle, and taking π_0 discards exactly that loop before rebuilding the total category. By contrast, if the target category is a discrete fibration over one of the height-one categories drawn on p. 102, it has no composable nonidentity arrows. Its nerve is a graph. Each connected component is a $K(\pi,1)$, so simple connectivity would force it to be contractible. The source's exclusion of these examples is thus correct for the displayed bases; it is not a statement about arbitrary categories merely sharing their homotopy type.

In the modern cofinality theorem, connectedness of the comma categories is strengthened to their weak contractibility (Lurie, 2009, Theorem 4.1.3.1). That stronger condition controls all homotopy colimits and implies weak equivalence of classifying spaces. The ordinary finality used here controls ordinary colimits and already constrains coverings, but it leaves the higher homotopy obstruction exposed.

Cette difficulté vue, le contre-exemple devient évident. Je pars d'un objet 1-connexe *quelconque* Y de X `[plutôt de` Cat`]`, et je prends $y_0 \in \mathrm{Ob}\, Y$,

$$X = \underline{\mathrm{Ch}}(Y; y_0, -) \xrightarrow{f} Y.$$

On sait que X est W_∞-asphérique, et que f est W_∞-parfait, donc les inclusions



$$X_y \longrightarrow y\backslash X$$

sont des W_∞-équivalences. L'hypothèse a) que les $y\backslash X$ soient 0-connexes équivaut donc à la même hypothèse sur les fibres X_y, ou encore sur une seule fibre (f étant parfait, donc une W_∞-fibration, et Y 0-connexe), soit [page 103]

$$X_{y_0} \simeq \Omega(Y, y_0).$$

Sa 0-connexité équivaut à l'hypothèse de 1-connexité de Y (on n'a utilisé encore que celle de 0-connexité). Donc pour un contre-exemple, il suffit de prendre Y 1-connexe et non ∞-connexe. Le cas le plus simple est celui où Y a le type d'homotopie de la sphère S^2, réalisé p. ex. par la catégorie ordonnée ci-contre `[ci-dessous]` à 6 sommets.

p. 72

`[de plus,` $e_0^+ \leq e_1^+ \leq e_2^+$`,` $e_0^- \leq e_1^- \leq e_2^-$`]` ([75]). Je résume le résultat obtenu.

Proposition 10. *Soit Y une petite catégorie 1-connexe ($y_0 \in \mathrm{Ob}\, Y$). Alors $\underline{\mathrm{Ch}}(Y; y_0, -)$ est W_∞-asphérique, mais n'est pas totalement W_∞-asphérique si Y elle-même n'est ∞-connexe, i.e. W_∞-asphérique.* ([76]).

On peut se demander si Y W_∞-asphérique implique que $\underline{\mathrm{Ch}}(Y; y_0, -)$ est totalement W_∞-asphérique. J'en doute fort!

Revenons maintenant à la situation du début de la section, diagramme $(*)$, p. 87, [page 104]

$$(*) \qquad \begin{array}{ccccc} U & \xhookrightarrow{i} & X & \xleftarrow{j} & T = \{t\} \\ {\scriptstyle p}\downarrow & & {\scriptstyle q}\downarrow & & \vdots\ \text{iso} \\ U' & \xhookrightarrow{i'} & X' & \xleftarrow{j'} & T' = \{t'\}. \end{array}$$

Nous pouvons donner maintenant un exemple où i est dans W (et même W-asphérique) sans que i' le soit :

$$(**) \qquad i \in W, \qquad i' \notin W.$$

On peut même supposer que t soit objet final de X (ce qui signifie que l'objet H de $U^\wedge$ est isomorphe à e_U, l'objet final), et t' objet final de X' (i.e. $p_!(e_U) = e_{U'}$, i.e. les $u'\backslash U$ sont 0-asphériques). Dans ce cas, comme X, X' sont W-asphériques, les relations $(**)$ équivalent à

$$(***) \qquad U \text{ est } W\text{-asphérique, et } U' \text{ non,}$$

ce qui est justement la situation que nous venons de construire (p. 101-103).

Commentary · Exposition [ms. 103]

The information lost by taking components

Grothendieck has found the obstruction that the preceding attempts were missing: an ordinary direct image of a set-valued presheaf remembers connected components of comma categories, whereas a weak equivalence of nerves must preserve all homotopy groups. The path construction makes the difference particularly visible. Put $P = \underline{\mathrm{Ch}}(Y; y_0, -)$ and let $f : P \to Y$ be its endpoint functor. The earlier path theory supplies the two facts used here: BP is contractible and the homotopy fibre of Bf over y is a based path space from y_0 to y. We write $BA = |NA|$ for the classifying space of a category. The comparison of strict fibres with comma categories is the additional consequence of the perfectness hypothesis; contractibility of BP alone would not supply that comparison.

75. C'est en somme cet exemple (à homotopie topologique près) que je réalise (sans d'abord m'en apercevoir dans l'Appendice p. 10-12, mais avec des catégories finies).

76. Mais un exemple plus percutant est $\Psi = \begin{array}{ccc} & & b \\ a & \nearrow & \\ & \searrow & \\ & & c \end{array}$, qui est W_∞-asphérique, mais pas totalement!

For connected Y, the components of each such path space form a torsor for $\pi_1(BY, y_0)$. Thus simple connectivity gives

$$(f_!e_P)(y) = \pi_0(y\backslash P) = \{*\}.$$

Consequently $f_!e_P = e_Y$, and the category of elements of this direct image is Y itself. If BY is not contractible, this single functor f disproves total W_∞-asphericity of P. This argument uses precisely the universal quantifier in Definition 1: the homotopy type of P cannot determine how all its ordinary direct images behave.

The six-element ordered set displayed in the text is a useful finite model of the required target. Its elements occur in three levels $\{e_k^+, e_k^-\}$, $k = 0, 1, 2$, and every element of a lower level precedes every element of a higher level. Its order complex is therefore

$$S^0 * S^0 * S^0 \cong S^2.$$

There are six vertices, twelve edges, and eight triangular faces. Each simplex chooses at most one vertex in each level, so these are exactly the faces of the boundary of an octahedron. The two chains supplied in the editors' brackets are essential: the diagonal arrows alone would not specify this ordered set.

The finite fork construction in the commentary at ms. 100 supplies the same failure without a path category: a contractible Ψ admits a functor $\Psi \to C$ with connected undercategories and $BC \simeq S^2$. We shall use it below. The question about $\underline{\mathrm{Ch}}(Y; y_0, -)$ when BY is contractible is a different question. Proposition 10 gives no implication in that case, and a replacement of the path category by some equivalent contractible category would not answer it. The next commentary answers it, negatively, with this same fork.

Commentary · Development (commentators') [ms. 103]

The path category over a contractible base need not be total

The question that closes this page, whether $\underline{\mathrm{Ch}}(Y; y_0, -)$ is totally W_∞-aspherical when Y is W_∞-aspherical, has a negative answer, and the witness is the category that Grothendieck names in the footnote to Proposition 10.

Proposition. [ours] *Let $Y = \Psi$ be the outgoing fork $a \leftarrow z \rightarrow b$ and $y_0 = z$. Then BY is contractible, and $P = \underline{\mathrm{Ch}}(Y; z, -)$ is W_∞-aspherical and not totally W_∞-aspherical. It is not totally W_R-aspherical for any nonzero commutative ring R either.*

Proof. The object z is initial, so BY is contractible; in particular Y is 1-connected. Proposition 10 applies: P is W_∞-aspherical, and, as recalled in the preceding commentary, the endpoint functor $f : P \to Y$ satisfies $f_!e_P = e_Y$, that is, every $y\backslash P$ is nonempty and connected. So f is final. The inclusion $g : \Psi \to C$ of the commentary at ms. 100 is final, and $BC \simeq S^2$. Final functors compose, because $(gf)_!e_P = g_!f_!e_P = g_!e_Y = e_C$. The category of elements of $(gf)_!e_P$ is C, which is neither W_∞-aspherical nor W_R-aspherical. □

The proof uses only two facts: the endpoint functor of the path category over a 1-connected base is final, and total asphericity passes to final images. Hence $\underline{\mathrm{Ch}}(Y; y_0, -)$ is totally W_∞-aspherical only if Y is. Since total asphericity of Y is far stronger than asphericity (for a category with finitely many objects it means that Y is filtered; see the commentary on Chapter II, ms. 36), the path construction does not produce totally aspherical categories from aspherical ones.

On aimerait aussi trouver un exemple où dans (∗) on ait $p \in W$, $q \notin W$.

Je prendrai encore $(X, U, \{t\})$ tel que t soit objet final de X, mais si on veut $q \notin W$, on ne peut supposer t' élément final de X'. Au lieu de cela, je vais supposer p. 73 [page 105]

a) U, U' (et aussi X, ayant objet final t) W-asphériques, donc $i \in W$ (et même i W-asphérique), $p \in W$, mais

b) X' non W-asphérique, donc $i', q \notin W$.

Pour ceci, notons que

$$U'/t' \simeq U'/p_!(e_U) \overset{\text{déf}}{=} \underline{\pi}_0(U/U').$$

Le corollaire de la proposition 7 (cf. p. 85), non encore démontré, nous dit que $i' \in W$ (i.e. ici, X' W-asphérique) si et seulement si i' est W-asphérique, i.e. U'/t' est W-asphérique. Nous allons l'admettre ici. Tout revient donc à trouver une flèche

$$p : U \longrightarrow U'$$

dans Cat avec les propriétés suivantes.

a) U et U' sont W-asphériques,

b) $\underline{\pi}_0(U/U')$ n'est pas W-asphérique.

Nous allons reprendre l'exemple précédent

$$f : X \longrightarrow Y$$

(p. 101-103), en prenant

$$U = X, \qquad \underline{\pi}_0(U/U') = Y,$$

donc tout revient, à partir de l'exemple donné $X \xrightarrow{f} Y$, à construire une flèche [page 106]

$$(*) \qquad \pi : Y \longrightarrow U'$$

dans Cat qui satisfasse les conditions

a) π est un isomorphisme local,

b) U' est W-asphérique.

On prendra alors

$$p = \pi f.$$

Mais par la façon dont X a été construit à partir d'un Y 1-connexe et non ∞-connexe, par ailleurs quelconque, on est ramené finalement à trouver $(*)$ satisfaisant a), b), et de plus

c) Y est 1-connexe, mais non ∞-connexe. p. 74

(NB On suppose maintenant $W = W_\infty$.) Il revient au même de trouver

U' objet *asphérique* de Cat, $F \in \mathrm{Ob}\, U'^{\wedge}$ tels que U'/F soit 1-connexe et non ∞-connexe.

On songe par exemple à prendre simplement une sous-catégorie ouverte U'_0 de U', qui soit 1-connexe et non ∞-connexe. Partons d'une telle catégorie U'_0 - par exemple une réalisation homotopique dans Cat, de la sphère S^2. On l'immerge comme ouvert dans un U' asphérique, en lui ajoutant un objet final. On a gagné.

Faisons un énoncé en forme. [page 107]

Proposition 11. *On peut trouver une situation* $(*)$ (p. 124 `[plutôt 104]`) *avec*

a) t objet final de X.

b) U, U' (et X) W_∞-asphériques, donc $i, p \in W_\infty$ (et même i W_∞-asphérique).

c) X' non W_∞-asphérique, donc $i', q \notin W_\infty$.

Il suffit pour cela de partir d'un objet 1-connexe Y de Cat, de lui adjoindre un objet final u'_0, ce qui donne U', de prendre $U = \underline{\mathrm{Ch}}(Y; y_0, -)$, $p : U \longrightarrow U'$ le composé $U \xrightarrow{\text{but}} Y \xhookrightarrow[\text{can.}]{\text{incl.}} U'$, et X déduit de U en lui ajoutant un objet final t. On a alors $U'/t' \simeq Y$, d'où

$$X' \ W_\infty\text{-asphérique (i.e. } i' \in W_\infty) \Longleftrightarrow Y \ W_\infty\text{-asphérique.}$$

On a le contre-exemple cherché en prenant Y (1-connexe mais) non ∞-connexe.

Commentary · Examples [ms. 107]

Two cones and the two failures of pushout invariance

Grothendieck now converts the failure of total asphericity into failures of ordinary categorical pushouts. The two constructions deserve to be separated because they test different edges of the square. We can make both finite by using the functor $f : \Psi \to C$ constructed at ms. 100. Here $\Psi = (z \to a, z \to b)$ has an initial object, $BC \simeq S^2$, and every category $c\backslash\Psi$ is connected and nonempty. Hence

$$f_! e_\Psi = e_C.$$

The crucial point is that this is an equality of ordinary presheaves; f is not a weak equivalence.

For the first square take $U = \Psi$, $U' = C$, and let $X = \Psi^\triangleright$ be obtained by adjoining a new terminal object t. The gluing weight for $U \subset X$ is e_Ψ. The pushout formula proved in §1 says that $X' = X \amalg_\Psi C$ has gluing weight $f_! e_\Psi = e_C$. Thus $X' = C^\triangleright$, with its new terminal object t'. Both X and X' are contractible. The inclusion $i : \Psi \to \Psi^\triangleright$ is a weak equivalence and is even W_∞-aspherical: its slices over old objects have terminal objects and its slice over t is Ψ. But $i' : C \to C^\triangleright$ is not a weak equivalence, because its source has the homotopy type of S^2. This proves the assertion at ms. 104 without any converse to the gluing lemma.

For the second square first adjoin a terminal object s to C, and write $U' = C^\triangleright$. Let $j : C \hookrightarrow U'$ be the resulting sieve and put $p = jf$. Now U, U' and $X = U^\triangleright$ are all contractible, so both i and p are weak equivalences. Since j is a sieve, extension by $j_!$ sends e_C to the subterminal presheaf which is a singleton on C and empty at s. Indeed, $c\backslash C$ has an initial object for $c \in C$, whereas $s\backslash C$ is empty. Therefore

$$p_! e_U = j_! e_C, \qquad (p_! e_U)(c) = \{*\}, \quad (p_! e_U)(s) = \varnothing.$$

The pushout $X' = X \amalg_U U'$ is consequently obtained from C by adjoining two distinct objects s, t' above every object of C, with no arrow between s and t'. It is the union of two terminal cones on C.

This description computes the homotopy type directly. Every composable string in X' lies in one of the two cones, because a string cannot contain both of their incomparable apexes. Hence

$$NX' = N(C^\triangleright_s) \amalg_{NC} N(C^\triangleright_{t'}).$$

The two inclusions of NC are simplicial monomorphisms, so this ordinary union is a homotopy pushout. Its realization is the unreduced suspension of BC, and therefore

$$BX' \simeq \Sigma BC \simeq S^3.$$

Neither $i' : U' \to X'$ nor $q : X \to X'$ is a weak equivalence. This proves Proposition 11 at ms. 107 and shows exactly how an arbitrary sieve can destroy pushout invariance even when the other three categories are contractible.

The text invokes the converse in Proposition 7 to justify the second construction. That converse depends on the stronger gluing axiom discussed at ms. 78–85 and cannot be used as an unconditional theorem for W_∞. The suspension computation repairs this use of it. More generally, for the simply connected Y of the manuscript, ΣBY is contractible exactly when BY is contractible: suspension shifts reduced integral homology, and a simply connected acyclic CW complex is contractible by the Hurewicz and Whitehead theorems. The hypothesis of simple connectivity is doing real work in this last equivalence.

2.4 Application aux immersions ouvertes dwyériennes.

Donnons quand même l'enoncé *positif* auquel nous en avions.

Théorème 3. *Soient (X, U, T) un triple $\in \mathcal{T}$ (U ouvert de X dans* Cat*, $T = X\backslash U$), et pour toute flèche $p : U \longrightarrow U'$ flèche de* Cat*, le carré cocartésien dans* Cat

$$\begin{array}{ccccc} U & \xhookrightarrow{i} & X & \dashleftarrow & T \\ {\scriptstyle p}\downarrow & & {\scriptstyle q}\downarrow & & \vdots\,\text{iso} \\ U' & \xhookrightarrow{i'} & X' & \dashleftarrow & T'. \end{array}$$

p. 75
[page 108]

Supposons que pour tout $t \in \dot{T} = \dot{U}$, le préfaisceau d'ensembles

$$i^*(t) = (u \longmapsto \mathrm{Hom}(u,t)) \in U^\wedge$$

soit totalement W-asphérique (déf. 1, p. 88) ([77]) - p. ex. que la catégorie U/t soit totalement W-asphérique (prop. 8, page 93). (NB le cas où les U/t ont un objet final, cf. prop. 9 a), i.e. celui où l'inclusion $U \longrightarrow \bar{U}$ admet un adjoint à droite, est celui envisagé par Dwyer, celui des immersions ouvertes de Dwyer ([78]).) Alors pour toute $p : U \longrightarrow U'$, l'immersion ouverte

$$i'_0 : U' \longrightarrow \overline{U'}$$

est W-asphérique (et même, tout comme i_0, strictement W-asphérique), et a fortiori elle est [dans] *W. Par suite (prop. 6* [p. 81]*) on a ceci.*

ⓐ $\quad i \in W \iff i' \in W \quad$ *moyennant* W(7 bis).
ⓑ $\quad p \in W \iff q \in W \quad$ *moyennant* W(7). ([79])

Commentary · Exposition [ms. 108]

A condition on weights that survives every direct image

After the counterexamples, Grothendieck seeks a hypothesis expressed in the actual gluing data. For a sieve $i : U \hookrightarrow X$, write $\overline{U}$ for the cosieve generated by U, and put $\dot{T} = \overline{U} \setminus U$. An object t belongs to $\dot{T}$ precisely when at least one arrow $u \to t$ exists with $u \in U$. Its gluing weight is

$$H_t = \mathrm{Hom}_X(i(-), t) \in \widehat{U}.$$

Only these objects need testing. At $u \in U$ the weight is representable and therefore totally aspherical; outside $\overline{U}$ it is empty and no assertion of asphericity is intended.

The hypothesis of Theorem 3 is that every H_t, $t \in \dot{T}$, remains aspherical after every ordinary left Kan extension. A pushout along $p : U \to U'$ replaces this weight by $p_!H_t$. Its total asphericity follows without a gluing axiom: for a second functor $r : U' \to V$,

$$r_!(p_!H_t) \cong (rp)_!H_t,$$

and the right-hand side is aspherical by the original hypothesis. This calculation explains both the terminology "strictly aspherical" for $U \to \overline{U}$ and its stability under arbitrary pushout.

The support is preserved as well. If H_t is nonempty, a representative $h \in H_t(u)$ produces a class at $p(u)$ in $p_!H_t$; a colimit of sets cannot delete that class. If H_t is empty, its direct image is empty. Thus the boundary objects of the two pushouts identify with the same $\dot{T}$, and the preceding test covers exactly the new boundary. It follows that

$$i'_0 : U' \longrightarrow \overline{U'}$$

is strictly W-aspherical and hence W-aspherical. The claim at the start of the proof on ms. 112 that i' itself is aspherical must read i'_0. A W-dwyérienne inclusion need not be a weak equivalence: the empty sieve into a nonempty category already demonstrates the distinction.

The two equivalences printed as (a) and (b) have a different logical status from this weight calculation. They use respectively W(7 bis) and W(7), exactly as stated. Those additional axioms must remain visible; they are not automatic properties of weak homotopy equivalences of nerves. The modern Dwyer pushout theorem gives the useful forward implications in its own hypotheses, as discussed in the later-development block. The intrinsic statement here, valid before imposing either gluing axiom, is preservation of the condition on all the weights.

77. **NB** On dit sous ces conditions que $i_0 : U \longrightarrow \bar{U}$ est *strictement W-asphérique* (cf. déf. 2 page suivante).

78. Je ne connais pas d'autre cas où th. 3 s'applique - faute de connaître de catégorie totalement W-asphérique qui n'ait un objet final, ni d'objet F d'une catégorie $U^\wedge$ qui soit totalement W-asphérique sans être représentable, i.e. U/F a un objet final. À présent, je sais que les catégories *filtrantes* sont totalement W-asphériques si W satisfait l'axiome des limites inductives.

79. Démonstration page 112.

Commentary · Examples [ms. 108]

A boundary with no last object

The footnote about filtered categories points beyond the original adjoint criterion. The commentary on Chapter II, manuscript pp. 35–36 ("Left Kan extension carries the ind-presentation" and "The quantifier in total asphericity"), explains why filtered presentations make this universal condition tractable. Here their role can be seen in one concrete inclusion.

Let U be the ordered set $\mathbb{N}$ with its usual order, and let $X = \mathbb{N} \cup \{\infty\}$ with $n < \infty$ for every n. The inclusion $i : U \hookrightarrow X$ is a sieve and $\overline{U} = X$. For an old object n, the slice U/n has terminal object n. For the new object ∞, the slice is U itself. For any $p : \mathbb{N} \to B$, one has

$$F := p_! e_{\mathbb{N}} \cong \varinjlim_{n} \mathrm{Hom}_B(-, p(n)).$$

Write $p_{nm} : p(n) \to p(m)$ for the transition map when $n \leq m$, and let $E = B/F$. This category is nonempty, since it contains $(p(0), [\mathrm{id}_{p(0)}])$. Given finitely many objects (b_j, x_j) of E, choose representatives $g_j : b_j \to p(n_j)$ of their elements. For $m \geq n_j$ for every j, the arrows $p_{n_j m} g_j$ give morphisms from all these objects to $(p(m), [\mathrm{id}_{p(m)}])$.

For parallel morphisms $h, k : (b, x) \rightrightarrows (c, y)$ in E, choose a representative $g : c \to p(n)$ of y. The defining condition on these morphisms gives $[gh] = x = [gk]$ in $F(b)$. Equality in this filtered colimit means that, for some $m \geq n$,

$$p_{nm} gh = p_{nm} gk.$$

Thus $p_{nm} g : (c, y) \to (p(m), [\mathrm{id}_{p(m)}])$ equalizes h and k. These are exactly the nonemptiness, finite-cocone, and parallel-arrow tests for a filtered category. A filtered category has weakly contractible nerve: a cocone on the finite data of a simplicial sphere map contracts that map. Thus every such E is W_∞-aspherical.

It follows that i is totally W_∞-dwyérienne. It is also a couniversal weak equivalence, without using either additional gluing axiom. After any pushout its slice over the new object is the filtered category of elements just computed, while its slices over the old objects have terminal objects. Quillen's Theorem A therefore applies to every pushout inclusion. It is not a Dwyer immersion in the original adjoint sense. A right adjoint $r : X \to U$ to i would require

$$n \leq r(\infty) \quad \text{for every } n \in \mathbb{N},$$

which is impossible. This distinguishes the two classes even though both $\mathbb{N}$ and $\mathbb{N}^{\triangleright}$ are contractible.

The negative answer also holds within the full gluing framework assumed in the source's question. Let $W_{\mathbb{Z}}$ denote integral-homology equivalences of nerves. Every pushout just considered is a weak homotopy equivalence and therefore an integral-homology equivalence, so i is couniversally a $W_{\mathbb{Z}}$-equivalence. Every tested category of elements is already weakly contractible, so i is also totally $W_{\mathbb{Z}}$-dwyérienne. The development at ms. 100, *Testing the retracted assertions under their stated axiom*, verifies that $W_{\mathbb{Z}}$ is a fundamental localizer satisfying full W(7). The failure of the right-adjoint condition is independent of the choice of weak equivalences. Thus the proposed recovery of an original Dwyer immersion fails even with W(7) imposed. The distinct converse from an arbitrary homotopical cofibration to Grothendieck's condition on every boundary weight is not established by this example.

Corollaire 1. *Supposons* W(7). *Si $i : U \hookrightarrow X$ est une immersion ouverte telle que $i_0 : U \hookrightarrow \bar{U}$ soit totalement* `[il suffit strictement]` *W-asphérique, alors $i : U \longrightarrow X$ est une W-cofibration ('ultraforte'), par quoi j'entends ceci : pour toute flèche $U' \xrightarrow{f} U''$ dans $U\backslash\mathrm{Cat}$,*

telle que $f \in W$, la flèche $g : X' \longrightarrow X''$ qui s'en déduit par cochangement de base à partir de l'objet X de $U\backslash\mathrm{Cat}$, est aussi dans W. [page 109]

Démonstration du corollaire : on applique le théorème 3 à l'immersion ouverte $U' \xhookrightarrow{i'} X'$ déduite de $U \xhookrightarrow{i} X$ par le cochangement de base $U \xrightarrow{f} U'$, en notant de plus que l'hypothèse du théorème 3 sur i est préservée en passant de i à i'.

Il faut quand même introduire une terminologie adéquate :

Définition 2 :

a) Une flèche $f : X \longrightarrow Y$ est dite *strictement W-asphérique* si pour toute $y \in \mathrm{Ob}\, Y$, $f^*(y) = (x \longmapsto \mathrm{Hom}_Y(f(x), y))$ est un objet totalement W-asphérique de $X^\wedge$ (cf. déf. 1, page 88). Elle est dite *totalement W-asphérique* si pour tout $y \in \mathrm{Ob}\, Y$, X/y ($\simeq X/f^*(y)$) est un objet totalement W-asphérique de Cat.

b) Une immersion ouverte $i : U \longrightarrow X$ est dite *W-dwyérienne* (resp. *totalement* `[W-]` *dwyérienne*) si l'immersion induite $i_0 : U \longrightarrow \bar{U}$ est strictement (resp. totalement) W-asphérique. Une immersion fermée $j : T \longrightarrow X$ est dite *W-dwyérienne* (resp. *totalement W-dwyérienne*) si et seulement si $j^\circ : T^\circ \longrightarrow X^\circ$ est une immersion ouverte W-dwyérienne (resp totalement W-dwyérienne). p. 76

c) Une flèche $i : U \longrightarrow X$ de Cat (pas nécessairement une immersion) est appelée une *W-cofibration,* si pour toute flèche $f : U' \longrightarrow U''$ dans $U\backslash$Cat, la flèche $g : X' \longrightarrow X''$ qui s'en déduit par le cochangement de base par X (objet de $U\backslash$Cat) est dans W quand f l'est. [page 110]

NB Cette notion de W-cofibration est stable par composition et par cochangement de base, et les isomorphismes de Cat sont des W-cofibrations. Si f est une W-cofibration, f° l'est et inversement.

(Le corollaire s'énonce en disant qu'une immersion ouverte ou fermée qui est W-dwyérienne est une W-cofibration.)

d) Une flèche $i : U \longrightarrow X$ dans Cat est appelée une *W-cofibration triviale*, ou une *W-équivalence couniverselle,* si pour toute U' dans $U\backslash$Cat, i.e. toute flèche $p : U \longrightarrow U'$ dans Cat, la flèche déduite de i,

$$i' : U' \longrightarrow X' = U' \amalg_U X' \quad \texttt{[plutôt } U' \amalg_U X\texttt{]} \quad ,$$

est dans W. (NB Il est immédiat que cela implique bien que i est une W-cofibration.)

(Cette notion de W-cofibration triviale est elle aussi stable par composition et par cochangement de base, et les isomorphismes dans Cat en sont.)

Commentary · Exposition [ms. 110] [page 111]

What the cofibration condition quantifies over

Grothendieck's definition concerns the entire undercategory, and this is why he calls the condition "ultraforte". For $i : U \to X$, let

$$i_! : U\backslash\mathrm{Cat} \longrightarrow X\backslash\mathrm{Cat}, \qquad (U \to A) \longmapsto (X \to X \amalg_U A).$$

The condition is that this functor preserve the weak equivalences of underlying categories. In particular it tests a weak equivalence $A \to B$ after an arbitrary preliminary change of base $U \to A$. Merely requiring preservation of weak equivalences whose source is U would be weaker. The modern terminology and its relation to model-category cofibrations are treated in the later-development block.

The elementary closure assertions follow from the universal properties of pushouts. If $U \to X \to Z$ are two such maps, pushout along the composite is the composite of their pushout functors, up to the canonical isomorphism, so it preserves weak equivalences. If $U \to V$ is arbitrary and $i' : V \to X \amalg_U V$ is the pushout of i, then for $A \to B$ under V its two pushouts along i' are canonically the pushouts along i of the same map considered under U. This proves stability under change of base. Isomorphisms give equivalences of the undercategories. Passage to opposite categories proves the duality assertion provided that W is invariant under opposites, as in the standing localizer framework.

The adjective "trivial" is defined by a separate universal property: every pushout $A \to X \amalg_U A$ of i belongs to W. This implies the preceding preservation condition by two-out-of-three. Indeed the natural square

$$\begin{array}{ccc} A & \longrightarrow & X \amalg_U A \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle g} \\ B & \longrightarrow & X \amalg_U B \end{array}$$

has both horizontal maps in W; when $f \in W$, commutativity and two-out-of-three give $g \in W$. Stability of these universal weak equivalences under composition and pushout follows by factoring each new pushout into two pushouts of the original maps.

Without an additional hypothesis one should not replace this definition by "a W-cofibration which belongs to W". Corollary 2 establishes that implication for the W-dwyérienne sieves considered there, using Theorem 3 and the stated gluing assumptions. This is the reason for retaining the full definition even though its name resembles the terminology of a model category.

Commentary · Later developments [ms. 110]

The later theory of homotopy cofibrations

Grothendieck wants a property of an attachment that is visible from weak equivalences alone. This is exactly the property now called an *h-cofibration*: the functor of cobase change on undercategories preserves weak equivalences. The terminology and a general model-categorical treatment appear in Batanin and Berger (2017, Definition 1.1), who explicitly acknowledge the antecedent in Grothendieck's manuscripts. In a left proper model category their Proposition 1.6 and Corollary 1.9 identify this condition with the requirement that every pushout along the map compute a homotopy pushout. Their Lemma 1.10 also proves that an h-cofibration which is a weak equivalence is couniversal. These are precise later replacements for the useful direction of the present gluing programme; none requires the reverse implication of W(7 bis). The same undercategory definition is retained as "W-cofibration" by Manetti and Meazzini (2019, Definition 2.1 and Lemma 2.4).

The definition here must be kept distinct from the cofibrations of a chosen Quillen model structure. For example, for every small category C, the map $\varnothing \to C$ is a W_∞-cofibration: its cobase-change functor is $A \mapsto A \amalg C$, and the nerve of a disjoint union is a disjoint union of nerves. A weak equivalence on the first summand and the identity on the second induce a weak equivalence on the union, component by component. Thus every category is cofibrant for Grothendieck's *relative* notion. This statement does not assert that every category is cofibrant in Thomason's model structure. The distinction explains why a satisfactory description of these attachments can be broader than the particular generating cofibrations used to construct a model category.

Corollaire 2. (Moyennant W(7).) *Soit $i : U \longrightarrow X$ une immersion ouverte W-dwyérienne. Pour que i soit une W-cofibration triviale, il faut et il suffit que $i \in W$, ou ce qui revient au même* (cf. page 82), *que $\dot{T} \hookrightarrow T$ soit dans W.*

C'est évidemment nécessaire, et la suffisance résulte du théorème 3 a).

Questions ouvertes.

a) J'ignore si une immersion ouverte i qui est une W-cofibration, voire une W-cofibration triviale, est forcément W-dwyérienne ([80]). Mais par le corollaire de la proposition 7 (p. 85), je sais que c'est le cas si on suppose T isomorphe à la catégorie finale e. Il s'ensuit toute au moins ceci : Pour que non seulement $i : U \longrightarrow X$, mais aussi toutes les immersions ouvertes $i_1 : U \longrightarrow X_1$ qui s'en déduisent par le procédé de prop. 7 b) au moyen de flèches quelconques $T_1 \longrightarrow T$ de but T dans Cat, soient des W-cofibrations, il faut et il suffit que i soit dwyérienne.

b) Y-a-t-il une bonne notion d' immersion dwyérienne, applicable à toutes les immersions p. 77 [page 112]

Commentary · Development (commentators') [ms. 111]

The open questions of this page

Question a) asks whether a sieve that is a W-cofibration, or even a trivial W-cofibration, must be W-dwyérienne, and asserts this when the complement T is the final category. Three small examples separate the notions. In each of them $U = \{u\}$ is a single object, so a functor $p : U \to A$ is the choice of an object $c = p(u)$ of A.

Proposition (a trivial cofibration that is not dwyérienne). [ours] *Let X have objects u, t, s and nonidentity arrows $\alpha, \beta : u \to t$, $\gamma : t \to s$, $\delta : u \to s$, with $\gamma\alpha = \gamma\beta = \delta$. The*

80. et peut-être même une immersion de Dwyer?

sieve $U = \{u\} \hookrightarrow X$ is a trivial W-cofibration for every fundamental localizer W. It is not W-dwyérienne when W is W_∞, a homology localizer W_R with $R \neq 0$, or the class W_n of n-equivalences for some $n \geq 0$.

Proof. The presheaf $v \mapsto \mathrm{Hom}_X(v,t)$ on U has two elements, so U/t is a discrete category with two objects; the test $p = \mathrm{id}$ shows that this presheaf is not totally W-aspherical for the localizers named. Let $p : U \to A$ be arbitrary, $c = p(u)$, and $P = X \amalg_U A$. Its objects are those of A and t, s; for $v \in A$,

$$P(v,t) = A(v,c) \times \{\alpha, \beta\}, \qquad P(v,s) = A(v,c), \qquad P(t,s) = \{\gamma\},$$

composition with γ forgets the second coordinate, and there are no arrows from t or s to A. Let $j : A \to P$ be the inclusion and $r : P \to A$ the functor that is the identity on A, sends t, s to c, projects the two crossing sets to $A(v,c)$ and sends γ to id_c. Let $F : P \to P$ be the identity on A, send t and s to s, each crossing arrow to its composite into s, and γ to id_s. There are natural transformations

$$\mathrm{id}_P \Longrightarrow F \Longleftarrow jr,$$

both the identity on A; the first has components γ at t and id_s at s, the second has at t and at s the arrow $c \to s$ corresponding to id_c. Naturality at a crossing arrow (g, α) or (g, β) is the relation $\gamma\alpha = \gamma\beta = \delta$. Since $rj = \mathrm{id}_A$, the map Bj is a homotopy equivalence. So every cobase change of $U \to X$ is in $W_\infty \subseteq W$. □

This answers the first sentence of question a) negatively; the footnote's stronger hope fails with it, since a Dwyer immersion is dwyérienne.

Proposition (the case $T \simeq e$). [ours] *Let X_0 have objects u, t and exactly two nonidentity arrows $\alpha, \beta : u \to t$, and let $U = \{u\}$, $T = \{t\}$. For $W = W_\infty$ and for $W = W_R$, the sieve $U \hookrightarrow X_0$ and every sieve $U \hookrightarrow X_1$ deduced from it by a change of complement $T_1 \to T$ (Proposition 7 b)) is a W-cofibration, and none of them with $T_1 \neq \varnothing$ is W-dwyérienne.*

Proof. The category X_1 has the objects u and those of T_1, the arrows of T_1, and two arrows $\alpha_x, \beta_x : u \to x$ for every $x \in T_1$, compatible with the arrows of T_1. Each crossing presheaf has two elements, so no U/x is connected. For $p : U \to A$ with $c = p(u)$, the pushout $P_A = X_1 \amalg_U A$ has $P_A(v,x) = A(v,c) \times \{\alpha, \beta\}$ for $v \in A$, $x \in T_1$. A chain of arrows of P_A either lies in A, or lies in T_1, or consists of a chain in A, a crossing arrow (g, λ) with $\lambda \in \{\alpha, \beta\}$, and a chain in T_1; the chain in A together with g is a chain of A/c. Write $J = N(A/c) * NT_1$ for the join, and $J_\alpha \cup J_\beta$ for two copies of J glued along NT_1. Then NP_A is the pushout of simplicial sets

$$NA \longleftarrow N(A/c) \amalg N(A/c) \hookrightarrow J_\alpha \cup J_\beta,$$

in which the left map forgets the arrow to c and the right map is a monomorphism; it is therefore a homotopy pushout. A functor $h : A \to A'$ under U induces a map of these diagrams. The categories A/c and $A'/h(c)$ have terminal objects, so their nerves and the joins J are contractible, and the maps on $N(A/c) \amalg N(A/c)$ and on $J_\alpha \cup J_\beta$ are weak equivalences whatever h is. If $h \in W_\infty$, the map $NP_A \to NP_{A'}$ is then a weak equivalence. For W_R one uses the Mayer–Vietoris sequences of the same pushouts. □

So the assertion "je sais que c'est le cas si on suppose T isomorphe à la catégorie finale e" is false for W-cofibrations, and with it the equivalence stated at the end of question a), also under the axiom W(7), which the localizers W_R satisfy. The corollary of Proposition 7 concerns membership in W of one inclusion, not the cofibration property. What it does give is the statement for *trivial* cofibrations and homology:

Proposition. [ours] *Let $U \hookrightarrow X$ be a sieve whose complement is one object t with only its identity, and suppose that $H = \mathrm{Hom}_X(-,t)|_U$ is not empty. For a nonzero commutative ring R, the inclusion is a trivial W_R-cofibration if and only if H is totally W_R-aspherical, that is, if and only if it is W_R-dwyérienne.*

Proof. After a cobase change $p : U \to A$ the complement is still $\{t\}$ and the crossing presheaf is $p_!H$. A chain of arrows of $X \amalg_U A$ that does not lie in A is a chain of $A/p_!H$ followed by t, so $N(X \amalg_U A)$ is NA with the cone on $N(A/p_!H)$ attached along the forgetful map, and $B(X \amalg_U A)$ is the mapping cone of $B(A/p_!H) \to BA$. The inclusion of BA is an R-homology isomorphism exactly when the reduced R-homology of $A/p_!H$ vanishes, that is, when $A/p_!H$ has the R-homology of a point. Quantifying over p gives the statement. □

For W_∞ the same computation shows that a one-point sieve is a trivial W_∞-cofibration if and only if every $A/p_!H$ is nonempty and integrally acyclic and the cone attachment does not change fundamental groups. Whether this forces H to be totally W_∞-aspherical is not decided here: a counterexample would be a presheaf H all of whose direct images have acyclic categories of elements, one of them with a nontrivial (necessarily perfect) fundamental group.

et incluant le cas des immersions ouvertes et des immersions fermées?

Démonstration du théorème 3 (p. 107). Il suffit de prouver que si i est W-dwyérienne (i.e. i_0 strictement W-asphérique). alors i' l'est également - car il en résultera que i' est W-asphérique et a fortiori $\in W$. Il faut donc vérifier que pour tout $t' \in \dot{U}' = \dot{T}$, l'élément $i^*(t') = (u' \longmapsto \mathrm{Hom}_{X'}(u', t'))$ de $U'^\wedge$ est totalement W-asphérique. Or t' provient d'un unique élément t de $\dot{T}$, et on sait qu'on a

$$i'^*(t) = p_!(i^*(t)) \quad \texttt{[plutôt } i'^*(t') = p_!(i^*(t))\texttt{]}, \qquad \text{où } \; p_! : U^\wedge \longrightarrow U'^\wedge.$$

Par hypothèse, $F = i^*(t)$ est un élément totalement W-asphérique de $U^\wedge$, ce qui signifie que pour toute flèche $p : U \longrightarrow U'$ dans Cat de souce U, $p_!(F)$ est un élément W-asphérique de U'. En fait, on a le lemme immédiat (par transitivité $(p'p)_! \simeq p'_! p_!$).

Lemme. *Soit U dans* Cat*, et F dans $U^\wedge$. Si F est totalement W-asphérique (resp. si U/F est totalement W-asphérique), alors pour toute flèche $p : U \longrightarrow U'$ dans* Cat *de source U, $F' = p_!(F)$ est un objet totalement W-asphérique de $U'^\wedge$ (resp.*

U'/F' est un objet totalement W-asphérique de Cat*.)* [page 113]

Corollaire 3 (du théorème 3). *Si $i : U \longrightarrow X$ est une immersion ouverte ou fermée W-dwyérienne (resp. totalement W-dwyérienne), alors pour toute flèche $p : U \longrightarrow U'$ dans* Cat*, $i' : U' \longrightarrow X' = U' \amalg_U X'$ [plutôt $U' \amalg_U X$] l'est aussi.*

(NB Le cas non respé est essentiellement le théorème 3. Il ne dépend d'aucun axiome supplémentaire sur W, mais n'a d'intérêt qu'en vue des équivalences ⓐ et ⓑ (p. 108) qui en résultent, et qui sont valables moyennant W(7 bis) resp. W(7) seulement.)

Commentary · Exposition [ms. 113]

The stronger clause uses comprehensive factorization

The lemma proves more than stability of a condition on a presheaf. Its parenthesized assertion says that the category of elements after direct image is itself totally aspherical, so that one may test it by arbitrary functors leaving that category. This does not follow merely by repeating the formula for a second direct image on the original base. The canonical comprehensive factorization supplies the missing step.

Write $V = U/F$, let $a : V \to U$ be the projection, and set $b = pa : V \to U'$. The identity $a_! e_V = F$ gives

$$b_! e_V = p_! F = F'.$$

Let $E = U'/F'$. The canonical functor $v : V \to E$ appearing in the comprehensive factorization of b is final in the ordinary sense: for every $e \in E$, the category $e\backslash V$ is connected and nonempty. Equivalently,

$$v_! e_V = e_E.$$

This is the factorization established at ms. 91–93; it involves connectedness, not contractibility.

Now suppose that V is totally W-aspherical, and let $r : E \to Z$ be any functor. Transitivity of ordinary left Kan extension gives

$$r_! e_E \cong r_! v_! e_V \cong (rv)_! e_V.$$

The last presheaf is W-aspherical by totality of V, so E is totally W-aspherical. This proves the parenthesized clause with its full quantifier. The unparenthesized clause is simpler: for $s : U' \to Z$, one has $s_! F' \cong (sp)_! F$, to which the definition applies directly.

The same argument yields a useful formal principle. If $v : V \to E$ is an ordinary final functor and V is totally W-aspherical, then E is totally W-aspherical. The converse is not being asserted.

In particular, an arbitrary final functor need not be a weak homotopy equivalence; the finite example at ms. 100 makes that failure explicit. Here totality of the source is precisely what permits the final functor to be used in every subsequent direct-image calculation.

Corollary 3 follows by applying the two clauses to the gluing weights of each boundary object, with the support calculation already explained after Theorem 3. This proof establishes stability under pushout. It supplies no composition theorem for arbitrary strictly or totally W-aspherical functors: in a composite one pulls back a weight of the second functor, whereas the lemma controls left Kan extension. The distinction identifies the mathematical content of the doubt expressed on ms. 113–114. Composition is treated in the commentary at ms. 114: both classes of functors are stable under it, by a different argument.

Commentaire de motivation : les immersions ouvertes ou fermées W-dwyériennes, ou totalement W-dwyériennes, sont stables par cochangement de base (d'après le corollaire précédent), mais n'ont pas du tout l'air de l'être par composition. À cet égard, les 'immersions de Dwyer' (où on suppose l'existence de l'adjoint à droite de $i_0 : U \longrightarrow \bar{U}$, dans le cas d'une immersion ouverte) se comportent mieux, étant stables par composition. (**NB** Il ne semble pas non plus clair que les flèches strictement W-asphériques, ou les totalement W-asphériques, soient stables par composition - sorry!) Ma motivation pour m'échiner sur la notion W-dwyérienne est double. [page 114]

a) J'aimerais avoir des conditions à la fois compréhensibles, et aussi générales que possible, sur une immersion (ouverte p. ex), pour que ce soit une W-cofibration, propriété visiblement importante (toute comme la notion duale de W-fibration).

p. 78

b) J'ai envie, pour des applications ultérieures, de disposer d'une classe d'immersions ouvertes ayant les propriétés suivantes :

   1°) Ce sont des W-cofibrations, et

   2°) Si $U \overset{i}{\hookrightarrow} X$ est dans la classe, et si $\varepsilon \overset{j}{\to} I$ est l'inclusion 'source-but' de la catégorie discrète $\{0,1\}$ dans l'intervalle

$$\Phi_n = 0 \longrightarrow 1 \longleftarrow 2 \longrightarrow \dots 2n-1 \longleftarrow 2n$$

   ($j(0) = 0$, $j(1) = 2n$), $n \geq 2$, l'inclusion α de $(U \times I) \cup (X \times \varepsilon)$ dans $X \times I$ est dans la classe.

Or cette dernière propriété de stabilité n'est *pas* vérifiée par les immersions de Dwyer. (Prendre $i : \{0\} \longrightarrow \mathbf{\Delta}^1 = \{0,1\}$, l'inclusion α n'est pas immersion de Dwyer.)

[page 115]

Commentary · Examples [ms. 114]

The interval test fails because a slice has two maxima

The interval condition asks for a class of admissible inclusions that can also attach both ends of a homotopy. Its categorical form is a pushout product. The original Dwyer condition is too rigid for this purpose, and the example in the text can be checked at a single object.

Take $X = [1] = (0 < 1)$, $U = \{0\}$, and

$$I = \Phi_n = (0 \to 1 \leftarrow 2 \to \cdots \leftarrow 2n), \qquad n \geq 2.$$

Let $A = (\{0\} \times I) \cup ([1] \times \{0, 2n\})$, considered as a full subposet of $[1] \times I$. The inclusion $A \hookrightarrow [1] \times I$ is a sieve: both end vertices of I are sources, and the entire lower row is already in A. Its generated cosieve is the whole product, since every upper-row object $(1, k)$ receives an arrow from $(0, k)$.

If this were an original Dwyer immersion, the inclusion into that cosieve would admit a right adjoint. For an inclusion of ordered sets, this means that for every object x of the larger poset the lower set A/x has a greatest element. Test $x = (1, 1)$. Its lower set inside A contains exactly

$$(0,0), \quad (0,1), \quad (0,2), \quad (1,0).$$

The strict relations are

$$(0,0) < (0,1), \qquad (0,2) < (0,1), \qquad (0,0) < (1,0).$$

Thus $(0,1)$ and $(1,0)$ are distinct incomparable maximal elements, and neither is above the other. There is no greatest element. This proves the failure of the adjoint condition for every $n \geq 2$.

The calculation also explains why ordinary contractibility of this slice is insufficient to recover the missing adjoint: its nerve is an interval with three edges, hence contractible. An adjoint selects a universal object, a much stronger requirement. Whether another class provides the desired interval stability is a structural question about the interaction of pushout and homotopy, rather than a reason to weaken *terminal object* to *contractible* in this particular criterion. The subsequent use of integration replaces a difficult ordinary pushout by a category designed to retain the homotopy of the entire diagram.

Commentary · Exposition [ms. 114]

A terminal fibre controls all the ordinary direct images

The last subsection returns to a situation in which the apparent loss of higher information can be controlled. For a W-proper functor over a category with a terminal object, the terminal-fibre inclusion is W-coaspherical. Under W(5) it is ordinary final, which is the property needed for total asphericity. Making this explicit shortens the proof and explains the editors' repeated suggestion to replace W-properness by W_0-properness.

Let $f : X \to I$ be W-proper, let i_0 be terminal in I, and write $k : X_{i_0} \hookrightarrow X$. The properness criterion says that k is W-coaspherical: every undercategory $x\backslash X_{i_0}$ is W-aspherical. If W(5) holds, a W-aspherical category is nonempty and connected. Hence k is an ordinary final functor, and the pointwise formula gives

$$(k_! e_{X_{i_0}})(x) = \pi_0(x\backslash X_{i_0}) = \{*\}.$$

For every $p : X \to Y$ it follows that

$$(pk)_! e_{X_{i_0}} \cong p_! k_! e_{X_{i_0}} \cong p_! e_X. \tag{C1}$$

If X_{i_0} is totally W-aspherical, the left side of (C1) is an aspherical presheaf on Y for every p, proving Proposition 11 of ms. 115. This proposition has the same number as the counterexample on ms. 107; the manuscript page is needed to distinguish them. The proof uses no W(7) or W(7 bis).

The general component formula in Proposition 12 explains how (C1) fits into a family. W-properness together with W(5) identifies $\pi_0(X_i)$ with $\pi_0(X/i)$, naturally in i, and therefore supplies the transition maps even when f is not an opfibration. For an arbitrary functor f, there is a canonical bijection

$$\varinjlim_{i \in I} \pi_0(X/i) \;\cong\; \pi_0(X). \tag{C2}$$

One can see it without choosing a cleavage. A representative $(x, \beta : f(x) \to i)$ in X/i has the same image in the colimit as $(x, \mathrm{id}_{f(x)})$, by the transition along β. A morphism $x \to x'$ identifies the latter representatives through the induced object of $X/f(x')$. Thus the colimit imposes exactly the zigzag relation defining components of X. Conversely each morphism in a comma category, and every transition between comma categories, preserves that zigzag component. These two observations construct mutually inverse maps in (C2).

Replacing $\pi_0(X/i)$ by $\pi_0(X_i)$ proves Proposition 12. The dual proof printed in the manuscript is equally valid, but after passing to presheaves its colimit is indexed by I^{op}; the printed I at ms. 117 suppresses this reversal. The precise proper/smooth criteria, their duality and their stability under composition and base change are given in Maltsiniotis (2005, Theorem 1.2 and Proposition 4.7). The result here concerns ordinary components and ordinary Kan extensions, so the connectivity hypothesis cannot be omitted just because the discussion takes place in a homotopical setting.

Commentary · Later developments [ms. 114]

Dwyer attachments and higher categorical pushouts

The adjoint condition belongs to the Dwyer maps of Thomason (1980, Definition 4.1 and Proposition 4.3). One subsequent correction matters when comparing them with model-category cofibrations. Classical Dwyer maps are not closed under retracts, and some Thomason cofibrations are not Dwyer maps. Cisinski (1999, Definition 1, Lemma 4 and Proposition 2) repairs the relevant argument with pseudo-Dwyer maps: these are retract-stable and include every Thomason cofibration. Thus the manuscript's search for a broader attachment condition addresses a distinction that cannot be removed by simply identifying the original Dwyer maps with all cofibrations.

The desired stability properties concern whether an ordinary attachment retains the information needed after passage to a homotopy theory. For classical Dwyer maps, a stronger result is now available. Hackney et al. (2024, Theorem 1.5) prove that, for a pushout $D = B \amalg_A C$ along a Dwyer inclusion $A \hookrightarrow B$, the comparison

$$NB \amalg_{NA} NC \longrightarrow ND$$

is a weak *categorical* equivalence in the Joyal model structure. Their general Theorem 1.6, in its expanded statement on p. 2179, treats discretely flat cofibrations. These are defined by requiring the corresponding functor of discrete simplicial categories to preserve Bergner weak equivalences under cobase change, together with injectivity on objects. Proposition 3.3 supplies this property for Dwyer maps; Example 3.5 includes co-Dwyer maps and pseudo-Dwyer maps. This gives one modern class that accommodates both orientations requested on p. 111.

This higher categorical assertion concerns the comparison between the ordinary categorical pushout and a pushout in the category of $(\infty, 1)$-categories. The weak homotopy type of a category discards all noninvertible-arrow information, whereas its image among $(\infty, 1)$-categories retains that information. Consequently the two ambient weak equivalence classes must be specified before comparing definitions of flatness. The theorem just cited does not identify discretely flat inclusions with the manuscript's W-Dwyer immersions, nor does it by itself establish the particular interval-product stability requested here. Those further identifications would require additional arguments. The concrete calculations in the preceding blocks keep the original question at the level at which it is posed.

Commentary · Development (commentators') [ms. 114]

Composition of aspherical functors and of dwyérienne immersions

Grothendieck doubts that strictly or totally W-aspherical functors, and the two classes of dwyérienne immersions, are stable under composition. For functors the doubt is unfounded; for immersions it is justified for some localizers and not for others. The statements below were not found in the sources consulted; no priority is claimed.

Theorem (functors compose). [ours] *Let W be a fundamental localizer.*

(a) *If $f : X \to Y$ is strictly W-aspherical and H is a totally W-aspherical presheaf on Y, then f^*H is a totally W-aspherical presheaf on X. Consequently strictly W-aspherical functors are stable under composition.*

(b) *Totally W-aspherical functors are stable under composition.*

(c) *If B is a totally W-aspherical category and $D : B \to \mathrm{Cat}$ a functor with totally W-aspherical values, the cofibred category $\int_B D$ is totally W-aspherical.*

Proof. (a) Let $p : X \to X'$ be arbitrary. For $y \in Y$ put $Q_y = p_! \operatorname{Hom}_Y(f(-), y)$, a presheaf on X', covariant in y. Each Q_y is totally W-aspherical, by the hypothesis on f and the lemma of ms. 112. Let Z be the category with full subcategories X' and Y, with $\operatorname{Hom}_Z(x', y) = Q_y(x')$ and no arrows from Y to X'; let $j : Y \hookrightarrow Z$ be the inclusion and $F = j_! H$. Then $F|_Y = H$ and

$$F|_{X'} = \int^{y \in Y} Q_y \times H(y) \cong p_! \Big(\int^{y} \operatorname{Hom}_Y(f(-), y) \times H(y) \Big) = p_! f^* H =: K.$$

Since H is total, Z/F is W-aspherical. The inclusion $l : X'/K \hookrightarrow Z/F$ is a sieve. Its comma category over an object (x', k) of X'/K has a terminal object. Its comma category over (y, h), $h \in H(y)$, has as objects the pairs (x', q) with $q \in Q_y(x')$ (the element of $K(x')$ is then the class of (q, h)) and as

arrows the arrows of X' that respect q; it is X'/Q_y, which is W-aspherical. By the relative form of Theorem A that defines a fundamental localizer, $l \in W$, and so X'/K is W-aspherical. As p was arbitrary, f^*H is total. If $g : Y \to Z_0$ is also strictly aspherical, apply this to $H = \mathrm{Hom}_{Z_0}(g(-), z)$, whose restriction along f is $\mathrm{Hom}_{Z_0}(gf(-), z)$.

(b) Let $f : X \to Y$ and $g : Y \to Z_0$ be totally aspherical and $z \in Z_0$. The functor $f_z : X/z \to Y/z$, $(x, \gamma) \mapsto (f(x), \gamma)$, has comma category over (y, β) canonically isomorphic to X/y, because the arrow to z is determined as $\beta g(h)$ by $h : f(x) \to y$. So f_z is totally aspherical, hence strictly aspherical by Proposition 8. The final presheaf of Y/z is total because g is totally aspherical; by (a) its restriction, the final presheaf of X/z, is total. That is, X/z is a totally W-aspherical category.

(c) Put $E = \int_B D$, with objects (b, x), $x \in D(b)$, and projection $\pi : E \to B$. For $b \in B$ the functor $D(b) \to E/b$, $x \mapsto (b, x, \mathrm{id}_b)$, has the left adjoint $(b', x, \beta) \mapsto D(\beta)(x)$. A right adjoint is final. So E/b is a final image of $D(b)$ and is total; π is a totally aspherical functor, as is $B \to e$, and (b) applies. □

Proposition (immersions: two counterexamples). [ours] *For $W = W_0$ and for $W = W_1$ neither the W-dwyérienne nor the totally W-dwyérienne sieves are stable under composition.*

Proof. Let V be the discrete category on two objects for W_0, and the category with two objects and two parallel arrows for W_1; BV is S^0, respectively S^1. Let $B = V^{\triangleleft}$ be V with an initial object o adjoined. Let X consist of B and of a second copy V_0 of V, with

$$X(v_0, b) = B(v, b), \qquad X(b, v_0) = \varnothing \qquad (v \in V,\ b \in B),$$

and composition induced by B. The sieve $V_0 \hookrightarrow X$ generates the cosieve $V_0 \cup V$, on which the inclusion of V_0 has the right adjoint $v \mapsto v_0$; it is a Dwyer immersion. The functor $X \to B$ forgetting the copy is left adjoint to the inclusion $B \subset X$, so $BX \simeq BB$ is contractible. A final functor is bijective on π_0 and surjective on π_1; hence X is totally W_0- and totally W_1-aspherical. Let $Y = X^{\triangleright}$ be X with a terminal object t adjoined. The sieve $X \hookrightarrow Y$ is totally W-dwyérienne, its only boundary category being $X/t = X$. For the composite sieve $V_0 \hookrightarrow Y$ the boundary category at t is $V_0/t \simeq V$ and the boundary presheaf is the final presheaf of V_0; neither is W-aspherical. □

The targets Y have six objects and 15, respectively 21, arrows.

Theorem (total immersions for W_∞). [ours] *For $W = W_\infty$ the totally W-dwyérienne sieves are stable under composition.*

Proof. We use the criterion of the commentary on Chapter II, ms. 36: a category A is totally W_∞-aspherical if and only if it is nonempty and connected and every connected component of the category of elements of every functor $A \to \mathrm{Set}$ is weakly contractible; and then those components are themselves totally W_∞-aspherical and any two objects of A have a common successor. A nonempty cosieve S of such an A is the category of elements of the functor with value a point on S and empty elsewhere; it is connected, because two of its objects have a common successor in A, which lies in S. So S is totally W_∞-aspherical.

Let $U \subset X \subset Y$ be totally W_∞-dwyérienne sieves and $y \in Y$ with $U/y \neq \varnothing$. Then X/y is total (it has a terminal object if $y \in X$). The objects (x, β) of X/y with $U/x \neq \varnothing$ form a nonempty cosieve S_y, total by the preceding paragraph, and the functor $(x, \beta) \mapsto U/x$ on S_y has total values. By part (c) of the theorem its cofibred category G is total. The functor $G \to U/y$ that composes $u \to x \to y$ has the left adjoint $(u, \gamma) \mapsto ((u, \gamma), (u, \mathrm{id}_u))$, so it is final, and U/y is total. □

The same proof works for the homology localizers W_R, with the homological form of the criterion (R-acyclic in place of weakly contractible). For the strict class, the W_R-dwyérienne sieves are also stable under composition: the restriction of a totally W_R-aspherical presheaf to a cosieve on which it is nonempty is totally W_R-aspherical, after which part (a) applies; the proof of the restriction statement is not reproduced here. For W_∞-dwyérienne sieves the question is undecided. It comes down to the question left open in the commentary at ms. 111: does a presheaf all of whose direct images have integrally acyclic categories of elements have only weakly contractible ones?

Commentary · Development (commentators') [ms. 114]

The endpoint product is not a cofibration

The class asked for in b) does not exist for W_∞: the inclusion α built from the simplest sieve is not a W_∞-cofibration at all. This is stronger than the observation that α is not a Dwyer immersion.

Theorem. [ours] *Let $n \geq 2$, $I = \Phi_n$, $\varepsilon = \{0, 2n\} \subset I$, and let $\alpha : A \hookrightarrow P$ be the inclusion of $A = (\{0\} \times I) \cup ([1] \times \varepsilon)$ in $P = [1] \times I$, deduced from $\{0\} \hookrightarrow [1]$. Let C be the four-object category*

of the commentary at ms. 100, of the homotopy type of S^2.

(a) *If W is a fundamental localizer for which a category of the homotopy type of S^3 is not W-aspherical (for instance W_∞, W_R with $R \neq 0$, or the m-equivalences with $m \geq 3$), then α is not a W-cofibration.*

(b) *If C is not W-aspherical (which includes the 2-equivalences), then α, which belongs to W, is not a trivial W-cofibration.*

Proof. Write $l_k = (0, k)$ and $u_k = (1, k)$. The objects of A are $l_0, \dots, l_{2n}, u_0, u_{2n}$; its nonidentity arrows are those of the lower copy of I and $l_0 \to u_0$, $l_{2n} \to u_{2n}$, and no two of them are composable. Both A and P have contractible classifying spaces, so $\alpha \in W_\infty \subseteq W$.

Recall that C has objects x, z, a, b and arrows $\alpha', \beta' : x \to z$, $r : z \to a$, $s : z \to b$ with $r\alpha' = r\beta'$, $s\alpha' = s\beta'$. Let D be either C or the category $C^{\triangleright}$ obtained by adjoining a terminal object ω. Define $p : A \to D$ by

$$p(l_0) = z, \qquad p(u_0) = b, \qquad p(l_k) = a \ (1 \leq k \leq 2n), \qquad p(u_{2n}) = a,$$

sending $l_0 \to l_1$ to r, $l_0 \to u_0$ to s and all other arrows to id_a. Let $Q = P \amalg_A D$. Since A is a sieve in P, the category Q consists of D, of the objects $u_1, \dots, u_{2n-1}$ with the arrows of the upper copy of I between them, and of the crossing sets $Q(v, u_k) = (p_! H_k)(v)$, where $H_k = \mathrm{Hom}_P(-, u_k)|_A$ (Theorem 1).

The presheaf H_1 is the final presheaf of the sieve $A_1 = \{l_0, l_1, l_2, u_0\}$ of A and is empty elsewhere. So $(p_! H_1)(v) = \pi_0(v \backslash A_1)$, the comma category being formed with the restriction $A_1 \to D$ of p. For $v = z$ it is A_1 itself, a tree; for $v = a$ it is $l_2 \to l_1$; for $v = b$ it is the point u_0; for $v = x$ it has the five objects $(l_0, \alpha'), (l_0, \beta'), (l_1, r\alpha'), (l_2, r\alpha'), (u_0, s\alpha')$ and is connected; for $v = \omega$ it is empty. Hence the object u_1 receives exactly one arrow from each object of C and none from ω. For $2 \leq k \leq 2n-1$ the category A/u_k is nonempty and connected and p is constant on it with value a, so $p_! H_k = D(-, a)$; the arrows between $u_2, \dots, u_{2n-1}$ induce identities of $D(-, a)$, and $u_2 \to u_1$ induces the unique map $D(-, a) \to p_! H_1$.

Let $R \subset Q$ be the full subcategory on D and u_1. The functor $\rho : Q \to R$ that is the identity on R, sends u_k to a for $k \geq 2$, is the identity on the crossing sets $D(v, a)$, sends the arrows between these u_k to id_a and $u_2 \to u_1$ to the arrow $a \to u_1$, satisfies $\rho|_R = \mathrm{id}_R$; and the arrows $a \to u_k$ corresponding to id_a are the components of a natural transformation from ρ, followed by the inclusion of R, to id_Q. So $BQ \simeq BR$.

(a) Take $D = C^{\triangleright}$. Then p is a functor between categories with contractible classifying spaces, so $p \in W_\infty \subseteq W$; it is a morphism of $A \backslash \mathrm{Cat}$ from id_A to p, and its image under cobase change along α is $P \to Q$. The category R is C with the two terminal objects ω and u_1 adjoined, with no arrow between them: its nerve is the union of two cones on NC, so $BR \simeq \Sigma BC \simeq S^3$. Thus P is W-aspherical and Q is not, and $P \to Q$ is not in W.

(b) Take $D = C$. Then R is C with one terminal object adjoined and $BQ \simeq BR$ is contractible. The cobase change $C \to Q$ of α along p goes from a category that is not W-aspherical to one that is, so it is not in W. □

For $n = 2$ the category Q of (a) has 8 objects and 30 arrows. Part (b) also excludes the cofibration property whenever a W-cofibration that belongs to W is a trivial W-cofibration. For W_∞ this is Batanin and Berger (2017, Lemma 1.10), applied to Thomason's model structure, which is left proper; there it adds nothing to (a).

Corollary (no class of the kind requested). [ours] *Let W be as in (a) and $n \geq 2$. If a class $\mathcal{K}$ of sieves consists of W-cofibrations and contains, with $i : U \hookrightarrow X$, the inclusion of $(U \times I) \cup (X \times \varepsilon)$ in $X \times I$, then every member of $\mathcal{K}$ is an isomorphism. The same holds for W as in (b) and classes of trivial W-cofibrations.*

Proof. W-cofibrations, and trivial W-cofibrations, are stable under retracts in the category of arrows, because a retract of a functor in W is in W. Let $i : U \hookrightarrow X$ be in $\mathcal{K}$. If there is an arrow $u \to x$ with $u \in U$, $x \notin U$, then $\{0\} \hookrightarrow [1]$ is a retract of i (by the functor $X \to [1]$ with fibre U over 0, and the functor $[1] \to X$ choosing that arrow), the endpoint product α of $\{0\} \hookrightarrow [1]$ is a retract of that of i, and the theorem is contradicted. If there is no such arrow, then $X = U \amalg V$; if $V \neq \varnothing$, the endpoint product of i is the inclusion of $(U \times I) \amalg (V \times \varepsilon)$ in $(U \amalg V) \times I$, which is in $\mathcal{K}$ and has the crossing arrow $(v, 0) \to (v, 1)$, so the first case applies to it. □

At the other extreme, for W_0 every functor is a W_0-cofibration, because $\pi_0 : \mathrm{Cat} \to \mathrm{Set}$ preserves pushouts, and all sieves form a class with the two properties. The same is true for W_1 and for every fundamental localizer containing W_1: the pushout along a functor injective on objects has the same

fundamental groupoid as the cofibred category of the span; this proof is not reproduced here. By Cisinski (2006a, Proposition 9.2.17) a fundamental localizer contains W_1 exactly when a category of the homotopy type of S^2 is aspherical for it. So for the localizers of homotopy theory proper the endpoint product has to be replaced by a homotopy-invariant construction, which is what the integration of the following pages provides.

2.5 Complément : critère d'asphéricité totale d'une catégorie W-propre sur une autre.

Commentary · Examples [ms. 115]

Why the interval test exceeds Dwyer maps

The preceding paragraph asks for enough cofibrations to build homotopies with prescribed endpoints. Its product with the zigzag interval is therefore a structural test, rather than an incidental counterexample. We can make the obstruction completely visible in a finite ordered set.

Write $P = [1] \times \Phi_n$ and

$$A = (\{0\} \times \Phi_n) \cup ([1] \times \{0, 2n\}).$$

Here $[1] = \{0 < 1\}$, and the even vertices of Φ_n map to their adjacent odd vertices. The inclusion $A \subset P$ is a sieve: a predecessor of an object in its bottom row is again in that row, and a predecessor of either of its two top endpoints is already in A. Every object $(1, k)$ receives a map from $(0, k)$, so the cosieve generated by A is all of P.

For a full inclusion of ordered sets, the existence of a right adjoint is particularly concrete. If r is right adjoint to $A \hookrightarrow P$, then $r(p)$ must be the greatest element of $\{a \in A : a \leq p\}$. At $p = (1, 1)$, this set has the two incomparable maximal elements $(1, 0)$ and $(0, 1)$; for $n \geq 2$ the other top endpoint cannot lie below p. There is consequently no greatest element, hence no right adjoint. This is exactly the obstruction in the definition of a Dwyer map, since the relevant cosieve is already P. The original inclusion $\{0\} \hookrightarrow [1]$ is Dwyer, with right adjoint the constant functor to 0. Thus the endpoint product operation genuinely leaves that class.

The definition and generated-cosieve criterion are those of Thomason (1980, Definition 4.1 and Lemma 5.2). There is a second, distinct limitation in the history of this class: retracts of Dwyer maps need not be Dwyer. Cisinski (1999, pp. 228–231, especially Proposition 2) gives the counterexample and repairs the properness argument for Thomason's model structure using pseudo-Dwyer maps. The interval calculation above concerns a different closure operation. Both facts explain why Grothendieck seeks a larger homotopically defined class rather than treating the adjoint criterion as the final definition of a cofibration.

Soit

$$f : X \longrightarrow I$$

une catégorie propre sur une catégorie d'indices I. Si I a un objet final i_0, alors X/i_0 s'identifie à X, et par suite l'inclusion

$$X_{i_0} \longrightarrow X$$

de la fibre de X en i_0 est W-asphérique `[plutôt W-coasphérique]`, et a fortiori est dans W. Donc X est asphérique si et seulement si X_{i_0} l'est. Nous voulons étendre ce résultat en un critère de *totale* W-asphéricité, de façon précise prouver la

Proposition 11 : *Soit $f : X \longrightarrow I$ W-propre, et soit i_0 un objet final de I. Si X_{i_0} est totalement W-asphérique* (déf. 1, page 88), *il en est de même de X.* (Sous réserve que W satisfasse l'axiome de connexité W(5).)

La démonstration sera donnée plus bas, après quelques préliminaires ayant un intérêt indépendant. Tout d'abord, rappelons que si X est W-propre sur I, alors il donne naissance à un foncteur

$$\begin{array}{ccc} I & \longrightarrow & \mathrm{Hot}_W \\ i & \longmapsto & \mathrm{hot}_W(X_i)(\simeq \mathrm{hot}_W(X/i)); \end{array}$$

en le composant avec le foncteur

$$\pi_0 : \mathrm{Hot}_W \longrightarrow \mathrm{Ens}$$

(sous réserve que l'axiome de connexité W(5) (p. 10) soit satisfait) on trouve un foncteur p. 79 [page 116]

$$i \longmapsto \underbrace{\pi_0(X_i)}_{\simeq \pi_0(X/i)} : I \longrightarrow \mathrm{Ens}.$$

Ceci posé, on a le résultat sorital

Commentary · Exposition [ms. 115]

Components of a proper family

Grothendieck wants to transfer a condition on every ordinary left Kan extension from the last fibre to the whole category. A weak equivalence of categories alone would not accomplish this: the functor $p_!$ here is the underived left Kan extension between categories of set-valued presheaves. The useful consequence of properness is that it controls the components of all the relevant comma categories.

We use $\widehat{Y} = \mathrm{Fun}(Y^{\mathrm{op}}, \mathrm{Set})$ and write 1_X for the terminal presheaf. For $p : X \to Y$ one has

$$(p_! 1_X)(y) = \pi_0(y\backslash X),$$

where an object of $y\backslash X$ is $(x, a : y \to p(x))$. In this chapter, "totally W-aspherical" means that $Y/(p_! 1_X)$ is W-aspherical for every Y and every $p : X \to Y$. This is the definition on manuscript pp. 88–89; the editors explicitly distinguish it from the earlier use of total asphericity in *Pursuing Stacks* (Grothendieck, 1990–1991d, Definition 1). It is this presheaf condition that Proposition 11 transfers.

The calculation of components has a direct proof that also fixes its variance. For any $f : X \to I$, without a properness hypothesis, the categories X/i form a covariant diagram by postcomposition. There is a canonical bijection

$$\operatorname*{colim}_{i \in I} \pi_0(X/i) \longrightarrow \pi_0(X). \tag{A1}$$

Indeed, every object x occurs as $(x, \mathrm{id}_{f(x)})$ in $X/f(x)$, so the map is surjective. The class of an arbitrary $(x, a : f(x) \to i)$ is identified in the colimit with the class of (x, id), by the transition functor associated to a. If $v : x \to x'$ is a morphism of X, the two resulting classes are equal: move the first object along $f(v)$ into $X/f(x')$, where v becomes a morphism to (x', id). These are precisely the relations defining $\pi_0(X)$. This proves injectivity as well.

If f is W_0-proper, the fibre inclusion $X_i \to X/i$ induces a bijection on components. Transporting the covariant structure through these bijections supplies the functor $i \mapsto \pi_0(X_i)$ and turns (A1) into Proposition 12. There is no choice of transport functors on the fibres in this argument. Under W(5), the inclusion $W \subseteq W_0$ makes W-properness sufficient. The two footnotes recommending W_0-properness identify the exact hypothesis needed for this calculation.

For the relative formula, apply the same argument to $y\backslash X \to I$. Its fibre over i is $y\backslash X_i$. The projection $y\backslash Y \to Y$ is a discrete opfibration, hence proper; properness is preserved by base change and composition. Consequently

$$(p_! 1_X)(y) \cong \operatorname*{colim}_{i \in I} (p_{i!} 1_{X_i})(y). \tag{A2}$$

Precomposition by a map $y' \to y$ commutes with every functor used to construct this bijection. Thus (A2) is an isomorphism of presheaves, not merely a collection of unrelated bijections. This supplies both the naturality and the universal property asserted in Corollary 1.

Proposition 12 : *Soit $f : X \longrightarrow I$ W-propre, et supposons que W satisfasse l'axiome de connexité* W(5) (sinon, la W-propreté ne nous sera d'aucune utilité …) ([81]). *On a alors une*

81. Il vaut mieux dire : Soit f W_0-propre, où W_0 est le localiseur de la 0-connexité …

bijection canonique

$$(*) \qquad \pi_0(X) \xleftarrow{\sim} \varinjlim_I \pi_0(X_i),$$

où la flèche est induite par les applications canoniques $\pi_0(X_i) \longrightarrow \pi_0(X)$.

Démonstration. Passant à $f^\circ : X^\circ \longrightarrow I^\circ$, on est ramené à prouver le même résultat pour X *W-lisse* sur I, avec la seule différence que le foncteur

$$i \longmapsto \pi_0(X_i)$$

sur I sera contravariant, i.e. un préfaisceau, ce qui offre l'avantage de l'intuition attachée au formalisme des préfaisceaux. Soit

$$g : I \longrightarrow e, \qquad \text{d'où } gf = p : X \longrightarrow e,$$

il est immédiat, par le calcul standard

$$p_!(F) = \pi_0(X/F) \qquad (F \in \mathrm{Ob}\, X^\wedge)$$

(où on a identifié $e^\wedge$ à (Ens)), qu'on a

$$\pi_0(X) = p_!(e_X) = g_!(f_!(e_X)).$$

Or le préfaisceau

$$i \longmapsto \pi_0(X_i) \qquad (\simeq \pi_0(i\backslash X), \text{ car } X \text{ } W\text{-lisse sur } I)$$

n'est autre que $f_!(e_X)$. D'autre part, pour un préfaisceau quelconque G sur I, on a

[page 117]

$$g_!(G) \simeq \pi_0(I/G) \simeq \varinjlim_I G(i),$$

et appliquant ceci à $f_!(e_X)$, on trouve la formule $(*)$ de la proposition 12.

Revenons à la situation avec f *W-propre,* et considérons un foncteur

$$p : X \longrightarrow Y,$$

nous sommes intéressés à 'calculer'

$$p_!(e_X) = (y \longmapsto \pi_0(y\backslash X)) \in \mathrm{Ob}\, Y^\wedge.$$

Considérons pour ceci le diagramme suivant

p. 80

$$\begin{array}{ccccc} y\backslash X_i & \longrightarrow & y\backslash X & \longrightarrow & y\backslash Y \\ \downarrow & & \downarrow & & \downarrow \\ X_i & \longrightarrow & X & \xrightarrow{p} & Y \\ \downarrow & & \downarrow f & & \\ \underset{\simeq e}{\{i\}} & \longrightarrow & I & & \end{array},$$

où les trois carrés sont cartésiens. Comme $y\backslash Y \longrightarrow Y$ est W-propre, il en est de même de $y\backslash X \longrightarrow X$ par changement de base, donc du composé $y\backslash X \longrightarrow X \longrightarrow I$ par transitivité. Le diagramme montre d'autre part que la fibre de $y\backslash X$ en $i \in \mathrm{Ob}\, I$ s'identifie à $y\backslash X_i$.

La proposition 12 nous donne donc la formule

[page 118]

$$\pi_0(y\backslash X) = \varinjlim_I \pi_0(y\backslash X_i),$$

laquelle formule ne peut s'empêcher d'être fonctorielle en y, tout comme celle de prop. 12 l'est dans $\underline{\mathrm{Prop}}_W I$. Or pour y variable dans Y, le préfaisceau sur Y

$$y \longmapsto \pi_0(y\backslash X_i)$$

n'est autre que $p_{i!}(e_{X_i})$, où

$$p_i : X_i \longrightarrow Y$$

est le composé $X_i \longrightarrow X \xrightarrow{p} Y$ (induit par p). On a ainsi prouvé

Corollaire 1 (de prop. 12). *Soit $f : X \longrightarrow I$ W-propre ([82]), et $p : X \longrightarrow Y$ un foncteur quelconque. Soit, pour tout $i \in \mathrm{Ob}\, I$, $p_i : X_i \longrightarrow Y$ le foncteur induit sur la fibre X_i de X en i. On a alors une loi* fonctorielle *naturelle*

$$i \longmapsto p_{i!}(e_{X_i}) : I \longrightarrow Y^\wedge,$$

et on a la formule

$$(*) \qquad p_!(e_X) \xleftarrow{\sim} \varinjlim_I p_{i!}(e_{X_i}),$$

où la flèche est induite par les morphismes canoniques

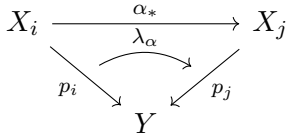
$$p_{i!}(e_{X_i}) \longrightarrow p_!(e_X)$$

induites par les inclusions $X_i \longrightarrow X$. p. 81

La loi fonctorielle de $p_{i!}(e_{X_i})$ en i a été explicitée en cours de démonstration. [page 119]

Notons que lorsque X sur I est cofibrée et scindée, i.e. provient d'un foncteur

$$i \longmapsto X_i, \quad I \longrightarrow \mathrm{Cat},$$



alors la loi fonctorielle de $p_{i!}(e_{X_i})$ en i s'explicite de façon particulièrement agréable : à une flèche

$$\alpha : i \longrightarrow j, \qquad \text{d'où } \alpha_* : X_i \longrightarrow X_j,$$

est associé

$$p_!(\alpha) : p_{i!}(e_{X_i}) \longrightarrow p_{j!}(e_{X_j}),$$

en notant qu'on a un diagramme

avec une flèche de commutativité

$$\lambda_\alpha : p_i \longrightarrow p_j \alpha_*$$

(pas `[un]` isomorphisme en général), d'où

$$p_{i!}(e_{X_i}) \xrightarrow{(\lambda_\alpha)_!} p_{j!}\underbrace{\alpha_{*!}(e_{X_i})}_{\longrightarrow e_{X_j}} \longrightarrow p_{j!}(e_{X_j}),$$

plus de doute c'est lui! ([83]).

82. dire W_0-propre …
83. Cette flèche `[la flèche` $(\lambda_\alpha)_!$`]` devrait être explicitée avec soin!

The comparison map requested in footnote 83

The point of the split-opfibration calculation is to see the transition map before passing to components. This also answers the request in footnote 83 without relying on a convention for mates of adjunctions.

Let $\alpha : i \to j$, let $\alpha_* : X_i \to X_j$ be the chosen transport, and let $\lambda_x : p_i(x) \to p_j(\alpha_* x)$ be the image under p of the chosen cocartesian arrow over α. For every $y \in Y$ there is a functor

$$y\backslash X_i \longrightarrow y\backslash X_j, \qquad (x, a) \longmapsto (\alpha_* x, \lambda_x a). \tag{A3}$$

A morphism $v : (x, a) \to (x', a')$ is sent to $\alpha_* v$. This is a morphism of the target comma category because

$$p_j(\alpha_* v)\lambda_x a = \lambda_{x'} p_i(v) a = \lambda_{x'} a'.$$

Passing to components gives the displayed map $p_!(\alpha)$ in the manuscript. It is natural in y because both routes for a map $b : y' \to y$ replace a by ab. For two composable base arrows, the split identities and the cocartesian composition law identify the two composites of (A3). Hence these maps form the asserted covariant diagram of presheaves.

To recover the factorization written by Grothendieck, first keep the intermediate object $\alpha_{*!} 1_{X_i}$ and apply the natural transformation of left Kan extensions induced by $\lambda : p_i \Rightarrow p_j \alpha_*$. Then use the counit-induced map $\alpha_{*!} 1_{X_i} \to 1_{X_j}$. The first arrow is the mate of $(p_j \alpha_*)^* \Rightarrow p_i^*$, whose component on a presheaf F is $F(\lambda_x)$. Formula (A3) proves that this mate has the stated direction. An invertible λ is unnecessary.

If I has terminal object i_0, the colimit in (A2) is its value at i_0. We therefore obtain, naturally for every $p : X \to Y$,

$$p_! 1_X \cong p_{i_0 !} 1_{X_{i_0}}.$$

If X_{i_0} is totally W-aspherical, the category of elements of the right-hand presheaf is W-aspherical, which proves Proposition 11. The printed $p_{i_0 !}(X_{i_0})$ on the next page is a source slip: the argument must be $1_{X_{i_0}}$. Taking $X = Z \times I$ proves Corollary 3, since the product projection is a split opfibration with final fibre Z. The argument in fact requires only W_0-properness of f together with the stated total W-asphericity of its final fibre.

Corollaire 2 : *Sous les conditions du corollaire 1, supposons que I ait un objet final i_0.* [page 120]
Alors

$$(p_{i_0})_!(e_{X_{i_0}}) \longrightarrow p_!(e_X)$$

est un isomorphisme dans $Y^\wedge$.

Commentary · Exposition [ms. 119]

The transition map on representatives

The footnote asks that the arrow induced by λ_α be written out. This matters because the triangle is only laxly commutative: replacing its natural transformation by an equality would erase the data that moves a fibre over i to a fibre over j.

Suppose $X \to I$ is the split opfibration associated to a strict functor $D : I \to \mathrm{Cat}$, and write $X_i = D(i)$. An arrow $\alpha : i \to j$ gives $\alpha_* : X_i \to X_j$ and chosen opcartesian arrows $x \to \alpha_* x$ in X. Applying $p : X \to Y$ gives a natural transformation

$$\lambda_\alpha : p_i \longrightarrow p_j \alpha_*.$$

For $y \in Y$, an object of $y\backslash X_i$ is a pair $(x, \beta : y \to p_i(x))$. Define

$$L_{\alpha,y}(x, \beta) = \big(\alpha_* x, \lambda_{\alpha,x}\beta\big) \quad \text{in } y\backslash X_j. \tag{C3}$$

If $h : x \to x'$ is a morphism in the first comma category, so that $p_i(h)\beta = \beta'$, its image is $\alpha_* h$. Naturality of λ_α gives

$$p_j(\alpha_* h)\lambda_{\alpha,x}\beta = \lambda_{\alpha,x'} p_i(h)\beta = \lambda_{\alpha,x'}\beta',$$

which verifies the comma-category condition. Hence (C3) is a functor. Taking connected components yields the value at y of the required presheaf map

$$(p_i)_! e_{X_i} \longrightarrow (p_j)_! e_{X_j}.$$

Precomposition with a map $y' \to y$ commutes strictly with (C3), proving naturality in y.

This also identifies the two arrows in the manuscript's displayed composite. First keep the object x in X_i and replace β by $\lambda_{\alpha,x}\beta$. That is the map induced by λ_α from $(p_i)_! e_{X_i}$ to $(p_j\alpha_*)_! e_{X_i}$. Next apply α_* to x; under transitivity of Kan extension this is the counit map

$$(p_j)_!(\alpha_*)_! e_{X_i} \longrightarrow (p_j)_! e_{X_j}.$$

Their composite is exactly (C3), so its direction is fixed without an appeal to an unspecified mate convention.

Functoriality in i follows from the split identities. For $\alpha : i \to j$ and $\gamma : j \to k$ one has

$$(\gamma\alpha)_* = \gamma_*\alpha_*, \qquad \lambda_{\gamma\alpha,x} = \lambda_{\gamma,\alpha_* x}\lambda_{\alpha,x}.$$

Substitution in (C3) gives $L_{\gamma,y}L_{\alpha,y} = L_{\gamma\alpha,y}$; identity arrows act identically. Thus the transition maps constitute an actual functor $I \to \widehat{Y}$, not merely objectwise maps in a localization. With a non-split opfibration the comparison isomorphisms of a cleavage make the same formulas agree after taking components.

For a general W-proper functor, still assuming W(5), the manuscript obtains these transitions through the comma-category construction. The projection $y\backslash Y \to Y$ is a discrete opfibration, hence proper; base change and composition make $y\backslash X \to I$ proper. Its fibre over i is $y\backslash X_i$. Proposition 12 applied there gives

$$\pi_0(y\backslash X) \cong \varinjlim_{i\in I} \pi_0(y\backslash X_i).$$

The construction is natural in y and so proves the presheaf isomorphism of Corollary 1. If I has a terminal object, the colimit is its value at that object, recovering (C1). In the product case $X = Z \times I$, the terminal fibre is Z, which proves Corollary 3 as well.

D'où aussitôt la proposition 11 : si X_{i_0} est totalement W-asphérique, alors X l'est, car pour tout $p : X \longrightarrow Y$, $p_!(e_X) \simeq p_{i_0\,!}(X_{i_0})$, et ce dernier élément de $Y^\wedge$ est W-asphérique par hypothèse sur X_{i_0}.

Notons le cas particulier :

Corollaire 3. *Soit Z un objet totalement W-asphérique dans* Cat. *Alors son produit $Z \times I$ par toute I dans* Cat *ayant un objet final est aussi totalement W-asphérique.* p. 82

Commentary · Development (commentators') [ms. 120]

Total asphericity depends on more than homotopy type

The transfer result just proved has a stronger content than invariance of the classifying space. The finite construction developed below, in "A strict cocone can repair the wrong pushout", makes this distinction explicit.

Corollary (failure of homotopy invariance). [ours] Total W_∞-asphericity in the sense of this chapter is not invariant under weak homotopy equivalences of categories.

Proof. The cited construction supplies finite face posets E, S and a functor $f : E \to S$ such that BE is contractible, $BS \simeq S^2$, and every E/s is nonempty and connected. Their construction and all these properties are proved there. Set $p = f^{\mathrm{op}} : E^{\mathrm{op}} \to S^{\mathrm{op}}$. For each $s \in S$,

$$(p_! 1_{E^{\mathrm{op}}})(s) = \pi_0(s\backslash E^{\mathrm{op}}) = \pi_0((E/s)^{\mathrm{op}}) = \{*\}.$$

Thus $p_! 1_{E^{\mathrm{op}}}$ is the terminal presheaf on S^{op}, whose category of elements is S^{op}. Its classifying space is a two-sphere, so E^{op} is not totally W_∞-aspherical. Nevertheless $E^{\mathrm{op}} \to e$ is a weak homotopy equivalence. The category e is totally W_∞-aspherical: along any functor selecting $y \in Y$, its terminal presheaf is sent by left Kan extension to the representable $Y(-, y)$, and the category of elements Y/y has a terminal object. □

This corollary is a consequence of the explicit finite calculation below, not an assertion that the underlying topological phenomenon is new. It explains why Proposition 11 uses properness to identify ordinary Kan extensions rather than inferring total asphericity merely from $X_{i_0} \to X \in W$.

Commentary · Exposition [ms. 120]

A span is remembered by its transition arrows

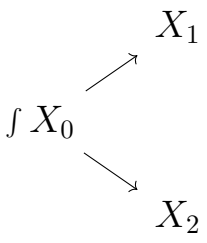
The next construction turns an arbitrary span into a category in which the gluing instructions remain visible as morphisms. The ordinary pushout identifies their images. Integration keeps those images separate and inserts comparison arrows between them. This small change is what retains the homotopy information of the gluing.

Write $\Phi = (1 \to 0 \leftarrow 2)$ and let the span $X_1 \xleftarrow{\alpha_1} X_0 \xrightarrow{\alpha_2} X_2$ be the functor $\Phi^{\mathrm{op}} \to \mathrm{Cat}$. Its fibred Grothendieck construction $\mathcal{X}$ has the disjoint union of the three sets of objects. Within a fibre the morphisms are unchanged. The only morphisms between distinct fibres go from a side fibre to the middle fibre, and are

$$\mathrm{Hom}_{\mathcal{X}}(a, x) = \mathrm{Hom}_{X_k}(a, \alpha_k x), \qquad a \in X_k,\ x \in X_0,\ k = 1, 2. \tag{A4}$$

Composition on the source side is ordinary composition in X_k; composition with $v : x \to x'$ on the target side uses $\alpha_k(v)$. These rules satisfy associativity because α_k is a functor. They also show directly that $\mathcal{X} \to \Phi$ is a split fibration.

The identity of $\alpha_k x$ determines a morphism

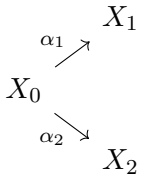


$$i_k \alpha_k(x) \longrightarrow i_0(x).$$

Naturality follows from the composition rule in (A4). These two transformations are the missing sides of the apparently noncommutative square on manuscript p. 123. Their sources and targets are usually different objects, so the square is not strictly commutative. Natural transformations give homotopies on nerves; for every fundamental localizer the resulting functors become equal after localization. The assertion that the square commutes in Hot_W is therefore correct, but does not replace the two transformations that constructed it.

This is the variance of the *smooth* integral used in this section. An opfibred construction of the covariant span places the transition arrows in the opposite direction. Grothendieck compares those two constructions later in §3.3. Reversing only the base while leaving the fibres untouched is not an innocuous notational change.

For $W = W_\infty$, realization of the nerve of $\mathcal{X}$ is a homotopy pushout of $BX_1 \leftarrow BX_0 \to BX_2$, where $BC = |NC|$. The closed-piece calculation below gives a direct proof in this particular shape. The general Grothendieck-construction theorem is due to Thomason (1979, Theorem 1.2); a primary modern proof and an explicit comparison map are given in Cegarra (2020, §3, equation (9) and Theorem 3). The manuscript expresses the corresponding fact intrinsically as a left Kan extension in the category of coherent diagrams. Its footnote 84 correctly retains the stronger localization hypothesis needed by the preceding construction of that adjoint.



3 Sommes amalgamées et intégration

3.1 Réduction canonique au cas d'un diagramme d'immersions fermées

Considérons un diagramme

(∗)

dans Cat. Nous pouvons le regarder comme un contrafoncteur

$$\Phi^\circ \longrightarrow \mathrm{Cat},$$

où

$$\Phi = \begin{pmatrix} & & 1 \\ & \swarrow & \\ 0 & & \\ & \nwarrow & \\ & & 2 \end{pmatrix},$$

donc comme définissant une catégorie fibrée (scindée) $\mathscr{X}$ sur Φ. Il est parfois commode de représenter cette catégorie $\mathscr{X}$ par le 'signe d'integration'

$$\begin{array}{ccc} & & X_1 \\ & \nearrow & \\ \int X_0 & & \\ & \searrow & \\ & & X_2, \end{array}$$

et la regarder comme une sorte de 'somme amalgamée homotopique' de X_1 et X_2 sous X_0, ou comme une 'limite inductive homotopique' du diagramme de départ $(*)$.

Il faut entendre par là que (pour $W \subseteq \mathrm{Fl}(\mathrm{Cat})$ donné) l'image $\mathrm{hot}_W(\mathscr{X})$ de $\mathscr{X}$ dans Hot_W [page 122]
a un 'sens homotopique' remarquable en termes de $(*)$, de façon précise, le diagramme $(*)$ définit un objet ξ de $\mathrm{HOT}_W(\Phi)$ (qui est une catégorie de fractions de la catégorie de tous les diagrammes du type $(*)$ …), et si

$$\pi : \Phi \longrightarrow e$$

désigne la projection absolue de Φ, on a

$$\pi_!(\xi) = \mathrm{hot}_W(\mathscr{X}),$$

Commentary · Context [ms. 121]

Integration as a calculus of gluing

Grothendieck's integral is designed to make a family and its transition maps into one geometric object. Grothendieck's discussion of integration in Chapter VI, manuscript pages 81 and 146, gives the general background. Here the additional issue is quite specific: the total category must retain enough information to decide whether a given cocone is a homotopy pushout.

In *Pursuing Stacks*, §69, Grothendieck (1983) connects diagram categories to the trace problems of SGA 5, then describes integration by a total cofibred category. He also singles out presheaf categories as a setting where actual amalgamated sums are available. These two concerns meet in the present pages. The integral supplies the homotopical comparison; the last theorem shows that a pushout of presheaves along a monomorphism gives an actual categorical pushout with the required homotopy type. The intervening analysis of open immersions is the bridge between the two constructions.

The letter to Thomason of 2 April 1991 gives a closely related explanation of why one diagram category cannot suffice: a derived category "ne vient jamais seule" (Grothendieck, 1991a, §2). In §1 of the same letter, Grothendieck places weak equivalences and localization before the auxiliary classes used in model structures. This explains the order of the present argument. He constructs a comparison map first and asks whether it belongs to W; cofibration criteria are then ways of proving that assertion.

The source is also a record of the distinctions being worked out. A natural transformation provides a homotopy without becoming an equality of functors; a weak equivalence of total categories need not preserve every ordinary Kan extension; a gluing theorem need not reflect equivalences backwards. The proofs below keep the transition arrows, the presheaf adjunctions, and the excision hypotheses visible at precisely the steps where each is used.

Commentary · Exposition [ms. 122]

Integration retains the homotopy of the span

The shift to integration changes what is being glued. An ordinary pushout identifies the common category immediately. The integrated category instead retains a copy of that category and arrows connecting it to both sides. These arrows provide the homotopies needed for a derived colimit.

For the span $X_1 \xleftarrow{\alpha_1} X_0 \xrightarrow{\alpha_2} X_2$, the manuscript uses the indexing category $\Phi = (1 \to 0 \leftarrow 2)$ and a contravariant functor on it. The associated fibred category $\mathscr{X}$ has objects (k, x) with $x \in X_k$. It contains each X_k fully, and its additional morphisms are

$$\operatorname{Hom}_{\mathscr{X}}((k,x),(0,z)) = \operatorname{Hom}_{X_k}(x, \alpha_k z), \qquad k = 1, 2.$$

There are no arrows between the 1- and 2-fibres, nor from the 0-fibre to either of them. Composition with an arrow in X_k is precomposition; composition with an arrow $z \to z'$ in X_0 is postcomposition by its image under α_k. These rules give the split Grothendieck construction with precisely the variance used by Grothendieck. This continues the discussion of variance in Chapter VI, manuscript p. 81, rather than replacing it by a covariant convention without explanation.

For this span one can prove the homotopy-pushout assertion directly. Let M_k be the full subcategory of $\mathscr{X}$ on its 0- and k-fibres. It is a categorical mapping cylinder for α_k. The functor

$$r_k : M_k \longrightarrow X_k$$

is the identity on X_k and sends $z \in X_0$ to $\alpha_k z$. If $s_k : X_k \hookrightarrow M_k$ is the inclusion, then $r_k s_k = \mathrm{id}$, and the canonical arrow $\alpha_k z \to z$ in M_k gives a natural transformation $s_k r_k \to \mathrm{id}_{M_k}$, equal to the identity on X_k. Thus Br_k is a homotopy equivalence, and its restriction to BX_0 is $B\alpha_k$.

Every composable string in $\mathscr{X}$ lies in M_1 or M_2, and their intersection is exactly X_0. Therefore

$$N\mathscr{X} = NM_1 \amalg_{NX_0} NM_2.$$

Both maps out of NX_0 are monomorphisms, so this is a homotopy pushout of simplicial sets. The two homotopy equivalences Br_k, together with the identity on BX_0, now identify its homotopy type with

$$B\mathscr{X} \simeq \operatorname{hocolim}\big(BX_1 \leftarrow BX_0 \to BX_2\big).$$

This is the span instance of Thomason (1979, Theorem 1.2), whose statement is also recorded by Chachólski and Scherer (2001, Corollary 26.9); the direct proof records the orientation and the connecting morphisms needed in these pages.

For example, take X_0 to be two discrete objects and $X_1 = X_2 = e$. The ordinary pushout is e. The integrated category has four objects and four nonidentity arrows: each of the two side objects maps to each of the two middle objects. Its nerve is a square with no two-dimensional nondegenerate simplices, hence has realization S^1. The integration remembers the circle formed by the two independent identifications; the ordinary pushout has forgotten it.

The final formula $\pi_!(\xi) = \mathrm{hot}_W(\mathscr{X})$ expresses this construction in the derivator already under discussion. It is a canonical isomorphism in the localized category, rather than a literal equality of chosen representatives. For W_∞ the preceding argument gives its concrete meaning. For another W the formula presupposes the standing hypotheses under which the diagram localization and its homotopy Kan extension are available; an arbitrary class of arrows would not by itself justify that notation. The advertised reduction to a diagram of closed immersions begins here; it is not completed on manuscript page 122.

Overview · XIIb-a

Attachments, ordinary direct images, and homotopy.

These pages, Chapter XII, section V, manuscript pp. 59–122, begin with a concrete problem: how to attach one category to another along a full subcategory, and how to recognize when the attachment respects weak equivalences. The first part answers the categorical question completely. The second discovers how much more is needed for the homotopical question. Along the way Grothendieck introduces total asphericity, isolates the Dwyer condition, and reaches the Grothendieck construction as a replacement for an ordinary pushout. The text is exploratory in a mathematically consequential sense. Some tentative arguments are explicitly retracted; one proposed theorem survives in the text even though its asserted reverse implication is false. The commentary keeps these different situations separate.

An "open" subcategory $U \subseteq X$ is a sieve: an arrow whose target lies in U has its source there as well. Its complementary full subcategory T is a cosieve. There are no arrows from T to U, so the information not already contained in these two categories is exactly the bifunctor

$$H : U^{\mathrm{op}} \times T \longrightarrow \mathrm{Set}, \qquad H(u,t) = \mathrm{Hom}_X(u,t).$$

Its two functorial actions encode composition on either side of a crossing arrow. Conversely any such bifunctor constructs a category on the disjoint union of the object sets. This is the collage of a profunctor. Maps and natural transformations out of the collage have equally explicit descriptions. The formulas on manuscript p. 61 must be read relatively: changing U and T by pullback of H gives a cartesian lifting over the category of pairs of categories, not the unqualified representability asserted in the printed displays. The corrected universal property is proved in the commentary.

This description also explains the relation with open–closed gluing of topoi. A presheaf on the collage is a pair of presheaves on U and T, together with the restriction data across H. The gluing functor is

$$\varphi(F)(t) = \mathrm{Hom}_{\widehat{U}}(H(-,t), F).$$

It preserves limits and is right adjoint to the cocontinuous extension of $t \mapsto H(-,t)$. The converse recovers the collage from an accessible gluing functor preserving small limits. This is already the construction of SGA 4, Exposé IV, Exercise 9.5.10; the comparison is exact, including the characterization of the resulting topos as a presheaf topos (Artin et al., 1972). Natural transformations between right adjoints reverse the direction of transformations between their left adjoints, a convention that must be retained when stating the category-level equivalence. The historical connection helps explain why the categorical attachment problem first appears here in the language of an open and its closed complement.

The advantage of the collage is that a pushout can be computed by an ordinary Kan extension. Given $p : U \to U'$ and $r : T \to T'$, the new crossing bifunctor is

$$H' = \mathrm{Lan}_{p^{\mathrm{op}} \times r}\, H.$$

Its pointwise coend description records a crossing arrow together with paths in the new categories to its two ends, modulo the relations imposed by composition. When only U changes, this becomes

$$\mathrm{Hom}_{X'}(u',t) \cong \pi_0(u' \backslash U / t), \qquad X' = X \amalg_U U'.$$

The category on the right remembers factorizations through U; the ordinary pushout retains only their connected components. This formula proves that U' is again a sieve, that the complement remains T, and that the support of the gluing weight is unchanged. It is also the source of the later difficulty: taking components does not preserve the higher homotopy of a factorization category.

The gluing theorem that survives, and the reverse implication that fails.

If a category is the union of two sieves, every simplex of its nerve lies in one of them. Its nerve is therefore the simplicial union along the intersection, and the square is a homotopy pushout. Consequently weak equivalences on the intersection and on both pieces induce a weak equivalence on the union. This is the valid gluing direction. It does not imply the symmetric rule W(7), which asks that any two among equivalence on the intersection, equivalence on both pieces, and equivalence on the union imply the third.

Theorem 2 on manuscript p. 78 asserts that this stronger rule holds for W_∞. A complete counterexample uses a connected acyclic noncontractible finite complex. Take a finite poset A with that homotopy type and adjoin two incomparable terminal cone points. The two one-cone subcategories are sieves, each contractible, and their union has the homotopy type of the suspension of BA. The suspension is simply connected and acyclic, hence contractible, whereas BA remains noncontractible. Thus the map from a cone to the union is a weak equivalence, but the opposite map from the intersection to the other cone is not. The counterexample refutes both the reverse part of W(7 bis) and the full W(7); it does not merely exhibit a missing proof.

The commentary gives the classical two-cell input explicitly, verifies its homology and a nontrivial fundamental-group quotient, and passes to a finite simplicial model and its face poset (Hatcher, 2002, Example 2.38 and Theorem 2C.5). A further development supplies finite tests against every bounded homotopy-group version of the axiom. It also explains why the proposed Mayer–Vietoris argument succeeds for fixed-coefficient homology equivalences: the three mapping-cone complexes form a short exact sequence. The failure occurs in passing from that homological statement to the asserted unstable homotopical converse.

This finding changes how the subsequent pages must be read. Assertions deduced under W(7) or W(7 bis) remain conditional assertions. Their application to W_∞ cannot use Theorem 2. In particular, the proposed one-point converse to asphericity on pp. 84–85 is not an unconditional theorem about weak homotopy equivalences. The audit records the actual hypotheses and, where possible, supplies a direct proof of a useful consequence that avoids the false reverse principle.

Total asphericity measures ordinary images.

For a presheaf F on U, total W-asphericity means that the category of elements of $p_!F$ is W-aspherical for every functor $p : U \to U'$. These are ordinary set-valued Kan extensions. For a category V, the definition applies to its terminal presheaf. It is substantially stronger than $V \to e \in W$, and it is not interchangeable with other uses of "totally aspherical" in the literature on test categories.

The relevant ordinary factorization sends $f : V \to V'$ to

$$V \longrightarrow V'/f_!e_V \longrightarrow V'.$$

The second map is a discrete fibration; the first is final in the ordinary categorical sense. Its undercategories are nonempty and connected, rather than necessarily contractible. This is the comprehensive factorization. The commentary proves its universal property and relates it to the treatment of Street–Walters in Kelly's account (Kelly, 1982, §4.7). It yields a useful formulation developed here: a category is totally W-aspherical exactly when every target of an ordinary final functor out of it is W-aspherical. In particular the class of totally aspherical categories is closed under ordinary final images. This reformulation identifies the quantified condition without confusing ordinary finality with homotopy finality.

Grothendieck's attempted stability under unions fails because a left Kan extension need not preserve the monomorphisms describing a cover. His attempted use of retractions does not repair that defect: a categorical retraction does not supply a splitting of the associated inclusion of presheaves. A finite example makes both issues explicit. A final functor from the contractible outgoing three-object fork lands in a four-object category whose classifying

space is S^2. Its relevant comma category is a square, connected but not contractible. Two distinct representatives of a Kan-extension value become equal after adjoining one branch. The construction was located in Grothendieck's Appendix XII and is credited there. It also produces the pushout failures on pp. 104–107; adjoining a further cone gives a classifying space S^3, so their validity can be checked independently of the disputed one-point converse.

The converse from totality of a presheaf to totality of its category of elements is established here for subterminal presheaves, as the source proposes. A general answer was not located in the primary literature checked. The same limitation applies to certain composition and classification questions posed later in these pages. An unsuccessful search is not turned into a claim of present-day openness.

Good attachments and the passage to integration.

A W-Dwyer sieve asks that every nonempty crossing weight be totally W-aspherical. Ordinary Kan-extension transitivity proves that this condition is preserved by pushout. The stronger version, expressed through totality of the categories of elements themselves, uses the final first map of the comprehensive factorization. Classical Dwyer immersions are the representable case: the inclusion of U into the cosieve it generates admits a right adjoint. Filtered examples show why total asphericity is broader than the existence of a terminal object. The interval-product calculation on p. 114, however, shows directly why the classical adjoint condition is too rigid for every intended homotopy attachment.

The manuscript's W-cofibrations have since been studied as h-cofibrations, defined by preservation of weak equivalences under cobase change on undercategories. In left proper model categories they characterize attachments whose pushouts compute homotopy pushouts; the theory also recovers the equivalence between trivial h-cofibrations and couniversal weak equivalences (Batanin and Berger, 2017, Proposition 1.6, Corollary 1.9 and Lemma 1.10). This is a precise later form of the useful gluing principle. For classical Dwyer maps, the nerve comparison is now known to be a weak categorical equivalence, with a generalization to discretely flat cofibrations (Hackney et al., 2024, Theorems 1.5–1.6). These later notions are compared with the definitions here without identifying their different ambient weak equivalences.

The final properness criterion is independent of the failed cube axiom. Under the necessary connectivity hypothesis, the inclusion of a terminal fibre is ordinary final. Its terminal presheaf therefore has direct image equal to the terminal presheaf of the total category. Composing Kan extensions proves that total asphericity of that fibre implies total asphericity of the total category. The commentary gives the general component-colimit formula and writes out the natural transformation requested in the footnote on p. 119, including its action on representatives and its compatibility with composition.

The text then begins a new construction. Integrating a span retains its middle category and the arrows connecting it to both sides. For two points mapping to a point on each side, the ordinary pushout is a point, whereas the integrated category has classifying space a circle. Two categorical mapping cylinders give a direct proof that the integrated span models the homotopy pushout. The final displayed identity $\pi_! \xi \cong \mathrm{hot}_W(\mathscr{X})$ states the intended derivator interpretation. The announced reduction to closed immersions continues after that identity, beyond manuscript page 122.

d'après le calcul connu du foncteur $\pi_!$, adjoint à gauche du foncteur π^* p. 83

$$\mathrm{HOT}_W(e) \overset{\text{déf}}{=} \mathrm{Hot}_W \longrightarrow \mathrm{HOT}_W(\Phi)$$

Commentary · Examples [ms. 123]

A circle hidden by an ordinary pushout

The distinction between a homotopy colimit and a colimit in the homotopy category is already visible in a span of finite discrete categories. Take $X_0 = \{a, b\}$ and $X_1 = X_2 = e$, with both structure maps the unique functor. Call the two side objects l, r. Formula (A4) gives precisely four nonidentity arrows:

$$l \to a, \quad l \to b, \quad r \to a, \quad r \to b.$$

No two nonidentity arrows are composable. The nondegenerate nerve is consequently a graph with four vertices and four edges, namely a four-cycle. Its realization is a circle. One can compute this without any homotopy-colimit theorem: choose three of the edges as a spanning tree and collapse

84. Cela suppose qu'on a W(2), non seulement W(2 bis).

that tree; the remaining edge is one loop. Thus $\pi_1(B\mathcal{X}) \cong \mathbb{Z}$, $H_1(B\mathcal{X};\mathbb{Z}) \cong \mathbb{Z}$, and all reduced homology in other degrees vanishes.

The ordinary pushout $e \amalg_{\{a,b\}} e$ in Cat is e. Indeed, a strictly compatible pair of functors from its two copies of e to Y chooses a single object of Y; both points of X_0 impose the same equality. The canonical comparison $\mathcal{X} \to e$ therefore collapses the circle and is not in W_∞. This example will fail Definition 3 exactly where it should.

The ordinary pushout of the same diagram also exists in the homotopy category of spaces and is a point. For a space T, a homotopy class $e \to T$ is a component of T. Compatibility of two such classes along the discrete two-point space forces them to be the same component, so the set of compatible pairs is $\pi_0(T)$, represented by e. A homotopy pushout instead remembers two paths implementing the two compatibilities; their difference produces the circle. Thus even existence of the ordinary colimit does not give the desired answer.

The parenthetical uncertainty on manuscript p. 123 about infinite discrete indexing categories should not be carried into the modern statement: the homotopy category of spaces has all small coproducts, represented by disjoint unions of CW models. What fails is a general ordinary-colimit calculus that recovers coherent homotopy colimits. The four-object calculation isolates that failure without making an unnecessary nonexistence assertion.

p. 84

Soient

$$\begin{aligned} 1\backslash\mathcal{X} = \mathcal{X} \times_\Phi 1\backslash\Phi &= \mathcal{X} \times_\Phi F_1 \\ 2\backslash\mathcal{X} = \mathcal{X} \times_\Phi 2\backslash\Phi &= \mathcal{X} \times_\Phi F_2 \end{aligned}$$

les images inverses de F_1, F_2 dans $\mathcal{X}$, on a donc

$$1\backslash\mathcal{X} \cap 2\backslash\mathcal{X} = X_0, \qquad 1\backslash\mathcal{X} \cup 2\backslash\mathcal{X} = \mathcal{X},$$

donc le diagramme

(∗∗)

$$\begin{array}{ccccc} & & X_0 & & \\ & {\scriptstyle\alpha'_1}\swarrow & & \searrow{\scriptstyle\alpha'_2} & \\ 1\backslash\mathcal{X} & & & & 2\backslash\mathcal{X} \\ & {\scriptstyle i'_1}\searrow & & \swarrow{\scriptstyle i'_2} & \\ & & \mathcal{X}, & & \end{array}$$

déduit du diagramme similaire

$$\begin{array}{ccccc} & & \{0\} & & \\ & \swarrow & & \searrow & \\ F_1 & & & & F_2 \\ & \searrow & & \swarrow & \\ & & \Phi, & & \end{array}$$

est (comme ce dernier) un carré d'immersions fermées à la fois cartésien et cocartésien. D'autre part, on a un homomorphisme canonique du diagramme (∗) dans (∗∗), qui est l'identité sur les sommets X_0 et $\mathcal{X}$, et qui sur X_1, X_2 est donné par les inclusions canoniques [page 125]

$$\underbrace{X_1}_{\mathcal{X}_1 \text{ fibre de } \mathcal{X} \text{ en } 1} \longrightarrow 1\backslash\mathcal{X}, \qquad \underbrace{X_2}_{\mathcal{X}_2 \text{ fibre de } \mathcal{X} \text{ en } 2} \longrightarrow 2\backslash\mathcal{X}.$$

Ces inclusions, on le sait, sont W-asphériques (elles ont même un adjoint à droite), a fortiori elles sont dans W. Donc le diagramme non commutatif (∗) est isomorphe, en tant que diagramme dans Hot_W, au diagramme commutatif cartésien et cocartésien (∗∗) formé d'immersions fermées. Comme $\mathcal{X}$ est bel et bien somme amalgamée de ses deux fermées $1\backslash\mathcal{X}$, $2\backslash\mathcal{X}$ sous leur intersection X_0, cela étaye l'intuition qui voit $\mathcal{X}$ comme une 'somme amalgamée homotopique'. Donnons tout de suite l'application suivante :

Commentary · Exposition [ms. 125]

Closed pieces give a genuine gluing diagram

Grothendieck now replaces the informal square by a strict cover, so that an excision axiom can actually be applied. The construction is a categorical version of replacing the two legs of a span by mapping cylinders.

Let C_k be the full subcategory of $\mathcal{X}$ on $X_k \amalg X_0$. This is $k\backslash\mathcal{X}$ in the manuscript. It is a cosieve: an arrow starting in its side fibre can only remain there or enter X_0, and arrows starting in X_0 remain in X_0. We have

$$C_1 \cap C_2 = X_0, \qquad C_1 \cup C_2 = \mathcal{X}, \qquad \mathcal{X} = C_1 \amalg_{X_0} C_2. \tag{A5}$$

The last equality holds in Cat, not just on objects. A string of composable arrows cannot pass from one side fibre to the other; it can enter the common fibre but cannot leave it. Giving a functor out of $\mathcal{X}$ is therefore exactly giving functors out of the two pieces that agree on X_0. The intersection statement also makes the square cartesian.

The inclusion $j_k : X_k \to C_k$ has right adjoint r_k, defined by $r_k(a) = a$ on X_k and $r_k(x) = \alpha_k x$ on X_0. On the mixed morphisms it uses (A4). Indeed, for every $a \in X_k$ and $z \in C_k$,

$$\mathrm{Hom}_{C_k}(j_k a, z) = \mathrm{Hom}_{X_k}(a, r_k z).$$

The unit is the identity and the counit is the canonical transition arrow on the middle fibre. Thus Bj_k and Br_k are mutually inverse homotopy equivalences, and both functors belong to every fundamental localizer.

For spaces, (A5) proves the promised homotopy-pushout calculation. Every simplex of $N\mathcal{X}$ lies in NC_1 or NC_2, and their intersection is NX_0. Hence it is the pushout of these nerves. The two inclusions of NX_0 are simplicial monomorphisms, whose realizations are CW-subcomplex inclusions, so this ordinary union computes the homotopy pushout of $BC_1 \leftarrow BX_0 \to BC_2$. The retractions r_k give a strictly commuting map of this span to $BX_1 \leftarrow BX_0 \to BX_2$, because $r_k|_{X_0} = \alpha_k$; all three components are homotopy equivalences. Homotopy invariance of the double mapping cylinder proves the result.

The phrase "homomorphism of diagrams" on p. 125 must retain this distinction: the inclusions from the original side fibres form a comparison with specified natural transformations, and become a comparison of commutative squares in Hot_W. The retractions just written give a strict map of spans in the other direction. No strict commutativity of the original square is being asserted or needed. For a general W, the same replacement reduces Proposition 13 to precisely the closed-cover form of the stated axiom W(7 bis).

Proposition 13. *Soit un diagramme* $X_1 \xleftarrow{\alpha_1} X_0 \xrightarrow{\alpha_2} X_2$ *dans* Cat, *d'où le diagramme* (∗), *p. 123,*

p. 85

$$\begin{array}{ccccc} & & X_0 & & \\ & \swarrow^{\alpha_1} & & \searrow^{\alpha_2} & \\ X_1 & & & & X_2 \\ & \searrow_{i_1} & & \swarrow_{i_2} & \\ & & \mathcal{X}, & & \end{array}$$

commutatif dans Hot_W *(mais non dans* Cat, *sauf si* $X_0 = \emptyset$*). Supposons que* W *satisfait* W(7 bis) (axiome du carré cocartésien, cf. p. 75). *Alors on a* [page 126]

$$\begin{cases} \alpha_1 \in W \iff i_2 \in W \\ \alpha_2 \in W \iff i_1 \in W. \end{cases} (^{85})$$

Démonstration. Utilisant l'homomorphisme précédent de (∗) dans (∗∗), on voit que chacune

85. **NB** Pour l'implication $\Longrightarrow$ on n'a besoin que de la forme directe de W(7 bis), i.e. (avec les notations de

des flèches α_1, α_2, i_1, i_2 est dans W, si et seulement si la flèche correspondante α'_1, α'_2, i'_1 ou i'_2 l'est. Donc les équivalences ci-dessus équivalent à

$$\alpha'_1 \in W \iff i'_2 \in W$$
$$\alpha'_2 \in W \iff i'_1 \in W,$$

lesquelles sont vraies en vertu de W(7 bis) (formulation duale) appliqué à $\mathcal{X}$ et aux deux fermés $1\backslash\mathcal{X}$, $2\backslash\mathcal{X}$ de $\mathcal{X}$.

Commentary · Development (commentators') [ms. 126]

Why converse excision is an additional axiom

Proposition 13 is correctly proved under its stated hypothesis. The strength of that hypothesis nevertheless matters: the displayed equivalences contain converse excision, whereas the usual invariance of a homotopy pushout under weak equivalences gives only the forward implication. A suspension makes the difference precise.

Proposition (the acyclic test for converse excision). [ours]Let W contain the weak homotopy equivalences of small categories and satisfy two-out-of-three. Suppose that, whenever $C = C_1 \cup C_2$ is a union of two full cosieves with intersection A, the implication

(A6) $$C_2 \longrightarrow C \text{ belongs to } W \quad\Longrightarrow\quad A \longrightarrow C_1 \text{ belongs to } W$$

holds. Then every category A whose classifying space is connected and integrally acyclic is W-aspherical.

Proof. Adjoin to A two distinct initial vertices l, r, with one arrow from each vertex to every object of A, and no arrows between l and r. Call the resulting category C and its two one-vertex enlargements C_1, C_2. The full subcategories C_1, C_2 are cosieves, and their intersection is A. Their classifying spaces are cones on BA; the classifying space of C is their union along BA, namely the unreduced suspension ΣBA.

Since BA is connected, van Kampen applied to the two slightly enlarged cones makes ΣBA simply connected. The reduced Mayer–Vietoris sequence gives $\widetilde{H}_n(\Sigma BA;\mathbb{Z}) \cong \widetilde{H}_{n-1}(BA;\mathbb{Z}) = 0$ for every n. A simply connected acyclic CW complex is contractible: if it had a first nonzero homotopy group, the Hurewicz theorem would identify it with a nonzero homology group; with all homotopy groups zero, Whitehead's theorem applies. Equivalently, use Hatcher (2002, Corollary 4.33). Thus $C_2 \to C$ is a weak homotopy equivalence, and lies in W. By (A6), $A \to C_1$ lies in W. Since $C_1 \to e$ also lies in W, two-out-of-three gives $A \to e \in W$. □

For completeness, an explicit finite CW complex shows why this conclusion is too strong for W_∞. Let K have one vertex, three oriented edges x, y, z, and three two-cells with relators

$$x^2(xyz)^{-1}, \qquad y^3(xyz)^{-1}, \qquad z^5(xyz)^{-1}.$$

Its cellular boundary $C_2(K;\mathbb{Z}) \to C_1(K;\mathbb{Z})$ has, in these bases, the matrix

$$M = \begin{pmatrix} 1 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 4 \end{pmatrix}, \qquad \det M = -1.$$

It is an isomorphism. The other reduced cellular groups are zero, so K is acyclic. Its fundamental group is nontrivial: with permutation multiplication read from right to left, send

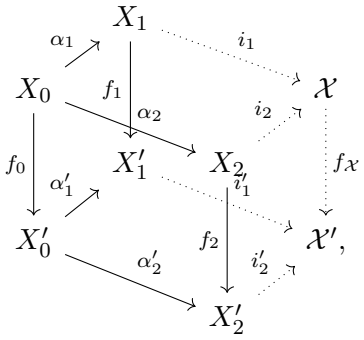
$$x \longmapsto (1\,2)(3\,4), \quad y \longmapsto (1\,3\,5), \quad z \longmapsto (1\,2\,5\,3\,4).$$

These permutations have orders $2, 3, 5$ respectively and product $xyz = 1$, so they satisfy the three relators and define a homomorphism with nontrivial image in A_5. A finite simplicial complex homotopy equivalent to K exists by Hatcher (2002, Theorem 2C.5); let A be its poset of nonempty faces. The nerve of A is its barycentric subdivision. Thus BA is connected and acyclic but has nontrivial fundamental group.

Apply the construction in the proof to this finite poset. Then C_1, C_2, and C are weakly contractible, while A is not. Hence $C_2 \to C$ belongs to W_∞ but $A \to C_1$ does not. This disproves

XVI) de Loc(6′a).

full W(7 bis) for W_∞. Mapping this closed-cover square to the trivial square of one-point categories also disproves the implication $b\,\&\,c \Rightarrow a$ in full W(7). The same example disproves the corresponding converses in Proposition 13 and the corollaries if their extra hypotheses are deleted. It does not contradict the propositions as actually stated.



The topology behind the example is classical; compare the acyclic presentation complex in Hatcher (2002, Example 2.38). We checked that example, the manuscript's definitions of W(7 bis) and W(7), and the standard nerve and suspension arguments. We did not find this exact formulation as a test of these manuscript axioms in the references inspected. The proposition records the deduction needed here, without a claim of priority. In particular the assertion earlier in the chapter that W_∞ satisfies full W(7) cannot be justified by a Mayer–Vietoris argument alone: local systems on the contractible union restrict to constant systems on A, and do not test its nontrivial fundamental group.

There is a precise positive form of the five-lemma intuition. For a closed cover, every nondegenerate nerve simplex belongs to one of the two pieces, so normalized integral chains form a natural short exact sequence

$$0 \longrightarrow C_*(NA) \longrightarrow C_*(NC_1) \oplus C_*(NC_2) \longrightarrow C_*(NC) \longrightarrow 0. \tag{A7}$$

The first map has signs $(+,-)$ and the second adds the two inclusions. Exactness follows separately on each simplex, including degree zero. Given a map of two covers, if any two of the maps on the three terms of (A7) are quasi-isomorphisms, the third is a quasi-isomorphism by the associated long exact homology sequences. For the middle term this is equivalent to being a homology isomorphism on each piece. Thus all three implications of the cube axiom hold for integral homology equivalences of closed covers. The passage from this homological statement to weak homotopy equivalences is exactly the passage that the counterexample prevents.

Corollaire : *Considérons* deux *diagrammes de type* Φ°*, et un homomorphisme* $f = (f_0, f_1, f_2)$ *de l'un dans l'autre (cf. diagramme en traits pleins ci-contre* `[ci-dessous]`*):*

d'où un homomorphisme [page 127]

$$f_{\mathcal{X}} = \int f : \quad \mathcal{X} = \int \begin{array}{ccc} & & X_1 \\ X_0 & \nearrow & \\ & \searrow & \\ & & X_2 \end{array} \qquad \longrightarrow \qquad \mathcal{X}' = \int \begin{array}{ccc} & & X_1' \\ X_0' & \nearrow & \\ & \searrow & \\ & & X_2', \end{array}$$

s'insérant dans un diagramme cubique (cf. diagramme précédent complété par des pointillés). p. 86
Considérons les conditions suivantes.

a) $f_0 \in W$.

b) f_1 *et* f_2 *sont* `[dans]` W.

c) $f_{\mathcal{X}} = \int (f_0, f_1, f_2) \in W$.

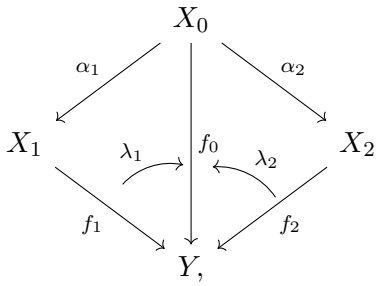
Supposons l'axiome W(7) ('lemme des 5', cf. page 76) *satisfait. Alors deux parmi les conditions a), b), c) impliquent la troisième*

$$\begin{cases} a \,\&\, b & \Longrightarrow & c \\ b \,\&\, c & \Longrightarrow & a \\ c \,\&\, a & \Longrightarrow & b. \end{cases}$$

En effet, on a un homomorphisme du diagramme cubique ci-dessus dans le diagramme similaire, où X_1, X_2, X'_1, X'_2 sont remplacés respectivement pas les fermés $1\backslash\mathcal{X}$, $2\backslash\mathcal{X}$ de $\mathcal{X}$, et $1\backslash\mathcal{X}'$, $2\backslash\mathcal{X}'$ de $\mathcal{X}'$, les deux carrés supérieur et inférieur étant des inclusions d'ouverts `[plutôt de fermés]` de $\mathcal{X}$ resp. de $\mathcal{X}'$. Ainsi, les conditions a), b), c) sont équivalentes respectivement aux conditions similaires pour le nouveau diagramme cubique (a) et c) n'ayant d'ailleurs pas [page 128] changé, et b) donnant

b′) $f'_1 : \mathcal{X}/1 \longrightarrow \mathcal{X}'/1$ et $f'_2 : \mathcal{X}/2 \longrightarrow \mathcal{X}'/2$ sont dans W.

`[plutôt` $f'_1 : 1\backslash\mathcal{X} \longrightarrow 1\backslash\mathcal{X}'$ `et` $f'_2 : 2\backslash\mathcal{X} \longrightarrow 2\backslash\mathcal{X}'$`]`). Alors la conclusion du corollaire est équivalente à W(7) (formulation duale) dans le cas du nouveau diagramme cubique, q.e.d.



3.2 Comparaison de $\int X_0 \begin{matrix} \nearrow X_1 \\ \searrow X_2 \end{matrix}$ avec une somme amalgamée ordinaire.

Carrés W-homotopiquement cocartésiens.

La catégorie intégrée $\mathcal{X} = \int X_0 \begin{matrix} \nearrow X_1 \\ \searrow X_2 \end{matrix}$ est solution du problème universel suivant,

variante 2-catégorique de celui qui définit la limite inductive des diagrammes. Il s'agit, pour Y objet variable dans Cat, de considérer les systèmes de trois foncteurs f_0, f_1, f_2 et des deux homomorphismes fonctoriels λ_1, λ_2 : p. 87

(∗)

$$\begin{aligned} \lambda_1 : \quad f_1\alpha_1 &\longrightarrow f_0 \\ \lambda_2 : \quad f_2\alpha_2 &\longrightarrow f_0. \end{aligned}$$

Se donner une flèche de Cat [page 129]

$$\mathcal{X} \longrightarrow Y$$

'revient au même' que de se donner un système $(f_0, f_1, f_2, \lambda_1, \lambda_2)$ comme dessus, et ceci 'fonctoriellement en Y'. C'est là le cas particulier de la détermination générale des foncteurs de la catégorie fibrée 'intégrée' d'un contrafoncteur

$$I^\circ \longrightarrow \mathrm{Cat}, \qquad \begin{aligned} i &\longmapsto X_i \\ u &\longmapsto u^* \end{aligned}$$

vers une catégorie Y, en termes d'un système de foncteurs

$$X_i \xrightarrow{f_i} Y,$$

et d'homomorphismes fonctoriels

$$f_i \circ u^* \xrightarrow{\lambda_u} f_j$$

pour $u : i \longrightarrow j$, d'où $u^* : X_j \longrightarrow X_i$, avec des conditions de transitivité pour des flèches composées, dont on n'a pas à tenir compte dans le cas actuel, vu qu'il n'y a pas de flèches composées à regarder dans $I = \Phi$ (sauf des composées avec une flèche identique, qu'on peut se dispenser de regarder ici …).

Commentary · Exposition [ms. 129]

The universal property keeps its two-cells

The universal property on these pages explains why integration is a useful replacement for an ordinary colimit. It represents functors equipped with comparison transformations. Those transformations are part of the input and are allowed to be noninvertible.

We can prove the assertion directly from (A4). Suppose given $f_i : X_i \to Y$ and $\lambda_k : f_k\alpha_k \Rightarrow f_0$ for $k = 1, 2$. Define $F : \mathcal{X} \to Y$ to be f_i on each fibre. A mixed morphism from $a \in X_k$ to $x \in X_0$, represented by $h : a \to \alpha_k x$, must be sent to

$$f_k(a) \xrightarrow{f_k(h)} f_k(\alpha_k x) \xrightarrow{\lambda_{k,x}} f_0(x). \tag{A8}$$

This rule respects precomposition in X_k. It respects postcomposition by $v : x \to x'$ because naturality says

$$f_0(v)\lambda_{k,x} = \lambda_{k,x'} f_k(\alpha_k v).$$

There are no composites of two mixed arrows, so these checks prove functoriality. Conversely, restrict F to the fibres and apply it to the mixed arrows represented by identities. This recovers the f_i and the λ_k, and every mixed arrow factors as an internal arrow followed by one of these identities. The constructions are inverse.

The assertion also holds at the level of categories of functors. A natural transformation $F \Rightarrow G$ corresponds to transformations $\theta_i : f_i \Rightarrow g_i$ such that, for $k = 1, 2$,

$$\theta_0\lambda_k = \mu_k(\theta_k\alpha_k),$$

where μ_k are the comparison transformations for G. Necessity is naturality on the canonical mixed arrows; sufficiency follows from their factorization just used. Thus the universal property is a natural isomorphism of categories with the category of these lax cocones. The word "lax" here is fixed by the displayed direction $f_k\alpha_k \to f_0$, so it carries no hidden variance convention.

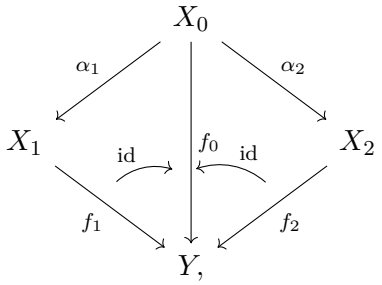
For a general strict functor $I^{\mathrm{op}} \to \mathrm{Cat}$, the additional condition is explicit. If $u : i \to j$ and $v : j \to k$, with maps $u^* : X_j \to X_i$ and $v^* : X_k \to X_j$, then

$$\lambda_{vu} = \lambda_v \circ (\lambda_u v^*), \qquad \lambda_{\mathrm{id}_i} = \mathrm{id}_{f_i}.$$

For the two-legged shape these conditions have no nonidentity instances. This is why the construction can be given here without a separate coherence argument.

When the original square is strictly commutative, set $f_0 = f_k\alpha_k$ and take both λ_k to be identities. Formula (A8) then defines φ_Q on every morphism and shows immediately that $\varphi_Q i_i = f_i$. Every chosen cartesian transition arrow is sent to an identity. This supplies the requested construction in footnote 87; the comma-category calculations announced there are carried out in the later lemmas on pp. 152–154. Definition 3 asks whether this particular comparison belongs to W. A bare commutative square in Hot_W would not determine the comparison, because it has forgotten the transformations from which it was made.

Si en particulier on a un diagramme *commutatif* dans Cat [page 130]



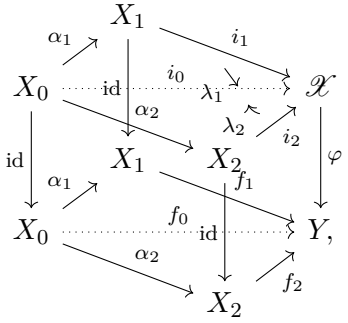
p. 88

$$Q \quad = \quad \begin{array}{ccccc} & & X_0 & & \\ & \overset{\alpha_1}{\swarrow} & & \overset{\alpha_2}{\searrow} & \\ X_1 & & & & X_2 \\ & \underset{f_1}{\searrow} & & \underset{f_2}{\swarrow} & \\ & & Y, & & \end{array}$$

on peut le compléter par

$$f_0 \overset{\text{déf}}{=} f_1\alpha_1 = f_2\alpha_2$$

en un diagramme



ce qui montre qu'on a une donnée du type $(*)$ ci-dessus, définissant donc une flèche

$$\varphi_Q : \quad \mathscr{X} = \int \begin{array}{c} X_1 \\ \nearrow \\ X_0 \\ \searrow \\ X_2 \end{array} \qquad \longrightarrow \qquad Y$$

qui donne lieu à un diagramme cubique

[page 131]

commutatif sauf le carré supérieur, i.e. on a p. 89

$$\varphi i_1 = f_1, \qquad \varphi i_2 = f_2, \qquad \text{et de plus} \quad \varphi i_0 = f_0,$$

φ transformant de plus les homomorphismes fonctoriels

$$\lambda_1 : i_1\alpha_1 \longrightarrow i_0, \qquad \lambda_2 : i_2\alpha_2 \longrightarrow i_0$$

en les homomorphismes fonctoriels identiques pertinents.

Définition 3. On dit que le diagramme commutatif

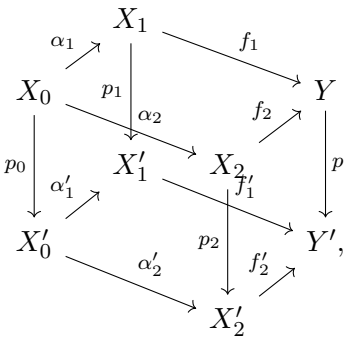
$(*)$

$$\begin{array}{ccccc} & & X_0 & & \\ & \overset{\alpha_1}{\swarrow} & & \overset{\alpha_2}{\searrow} & \\ X_1 & & & & X_2 \\ & \underset{f_1}{\searrow} & & \underset{f_2}{\swarrow} & \\ & & Y & & \end{array}$$

est W-*homotopiquement cocartésien* ([86]) si l'homomorphisme canonique

$$\mathscr{X} = \int \begin{array}{ccc} & \nearrow & X_1 \\ X_0 & & \\ & \searrow & X_2 \end{array} \xrightarrow{\varphi} Y$$

qu'il définit est dans W. ([87])



On a alors le : [page 132]

Corollaire 1. *Supposons* W(7 bis). *Si le carré* $(*)$ *est* W*-homotopiquement cocartésien, alors*

$$\begin{cases} \alpha_1 \in W & \Longleftrightarrow \quad f_2 \in W \\ \alpha_2 \in W & \Longleftrightarrow \quad f_1 \in W. \end{cases}$$

Cela résulte aussitôt du diagramme cubique de la page précédente, où toutes les flèches verticales sont dans W, et de l'énoncé similaire concernant la face supérieure du cube, donné dans la proposition 13, p. 125.

Corollaire 2. *Supposons* W(7). *Considérons un diagramme cubique* p. 90

où les deux faces inférieure et supérieure du cube sont des carrés W*-homotopiquement cocartésiens. Considérons les conditions* [page 133]

a) $p_0 \in W$.

b) p_1 *et* $p_2 \in W$.

c) $p \in W$.

Alors deux de ces conditions impliquent la troisième.

Résulte aussitôt de la définition 3, et du résultat similaire (cor. page 126) pour le diagramme cubique similaire, avec Y, Y' remplacées par $\mathscr{X} = \int \begin{array}{ccc} & \nearrow & X_1 \\ X_0 & & \\ & \searrow & X_2 \end{array}$ et $\mathscr{X}' = \int \begin{array}{ccc} & \nearrow & X'_1 \\ X'_0 & & \\ & \searrow & X'_2 \end{array}$.

86. ou simplement W-cocartésien, ou qu'il définit Y comme somme amalgamée W-homotopique de etc.

87. Introduire φ dans une proposition en forme, et donner ses propriétés essentielles : flèches strictement cartésiennes sont transformées en flèches *identiques* + lemmes 1 et 2 des p. 152, 154.

3.3 Intégration propre versus intégration lisse. Énoncé d'équivalence entre les deux points de vue. Commentaires sur le cas des limites W-homotopiques quelconques.

La définition 3, et les corollaires précédents, n'ont d'intérêt que dans la mesure où on dispose de critères maniables, permettant d'affirmer qu'un carré commutatif est bel et bien homotopiquement cocartésien. C'est ce qu'on va essayer de faire tantôt. Il y a aussi une perplexité, concernant le rôle privilégié joué, dans la théorie développée ici, par les immersions fermées, à l'exclusion des immersions ouvertes. Nous avons en somme ramené, du point de vue homotopique, les diagrammes quelconques $\begin{array}{ccc} & & X_1 \\ & \nearrow & \\ X_0 & & \\ & \searrow & \\ & & X_2 \end{array}$ dans Cat, au cas d'un diagramme d'immersions fermées, où la somme amalgamée prend des allures familières. Mais pourquoi pas aussi bien le ramener au cas d'immersions ouvertes? On considérerait alors le diagramme de départ comme définissant une catégorie *cofibrée* sur

p. 91 [page 134]

$$\Phi^\circ = \Psi = \begin{array}{ccc} & & 1 \\ & \nearrow & \\ 0 & & \\ & \searrow & \\ & & 2, \end{array}$$

soit $\tilde{\mathscr{X}}$. On a dans Ψ les deux ouverts

$$\underbrace{\Psi/1}_{=\{0,1\}} = U_1, \qquad \underbrace{\Psi/2}_{=\{0,2\}} = U_2, \qquad U_1 \cap U_2 = \{0\},$$

d'où dans $\tilde{\mathscr{X}}$ deux ouverts images inverses

$$\tilde{\mathscr{X}}/1, \qquad \tilde{\mathscr{X}}/2, \qquad \text{avec } \tilde{\mathscr{X}}/1 \cap \tilde{\mathscr{X}}/2 = X_0,$$

d'où un diagramme commutatif d'inclusions ouvertes

(∗)
$$\begin{array}{ccccc} & & X_0 & & \\ & \swarrow^{\alpha'_1} & & \searrow^{\alpha'_2} & \\ \tilde{\mathscr{X}}/1 & & & & \tilde{\mathscr{X}}/2 \\ & \searrow_{i'_1} & & \swarrow_{i'_2} & \\ & & \tilde{\mathscr{X}}, & & \end{array}$$

Commentary · Exposition [ms. 133]

The other orientation of integration

Grothendieck wants the definition of a homotopy pushout to belong to the span itself, without retaining the auxiliary choice of open or closed inclusions used to construct it. The question is quite concrete. The smooth integral introduced above has transition arrows pointing from the two outer fibres towards the central fibre. The proper integral has transition arrows in the other direction. Neither construction is obtained by merely changing the names of the objects.

Write $A = X_0$, $B = X_1$, $C = X_2$, and let $a : A \to B$ and $b : A \to C$ be the given functors. The proper integral P has the objects of A, B, and C, retained as three disjoint sets. In addition to the arrows within those categories, its mixed hom-sets are

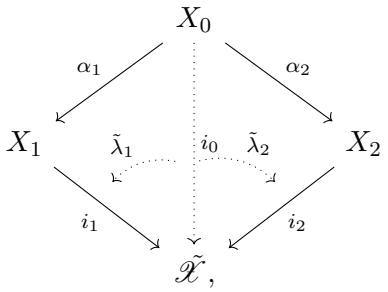
$$P(x, y) = B(a(x), y), \qquad P(x, z) = C(b(x), z) \quad (x \in A,\ y \in B,\ z \in C).$$

There are no mixed arrows in the opposite directions, or between B and C. Composition is composition in B and C, with a and b applied when necessary. Thus a functor $P \to Y$ consists of functors f_A, f_B, f_C and transformations

$$f_A \longrightarrow f_B a, \qquad f_A \longrightarrow f_C b.$$

This is the reverse of the transformation data described in "A span is remembered by its transition arrows". For a strictly commuting cocone these transformations are identities, so both constructions have a canonical comparison with Y.

The full subcategory P_1 on A and B is a sieve in P, as is the corresponding P_2 on A and C. Their intersection is A, and their union is P. The inclusion $j : B \to P_1$ has a left adjoint r: it is the identity on B and sends $x \in A$ to $a(x)$. The identity



$$P_1(x, jy) = B(r(x), y)$$

proves the adjunction, including its mixed case. Consequently j is a weak equivalence for every fundamental localizer. The same argument applies to $C \to P_2$. This explains the parallel with the closed-cover replacement of the smooth integral: the two replacements have the same three vertex homotopy types, but their transition arrows have opposite orientations.

The equivalences asserted on manuscript page 135 inherit the hypotheses of their earlier counterparts. In particular, the reverse implication from an outer inclusion being in W to the corresponding original leg being in W uses the strong form of W(7 bis). The cube statement uses W(7). These are the additional excision assumptions analysed in "Why converse excision is an additional axiom". The comparison between the two integrals, which is the object of Proposition 14, does not require either converse-excision principle.

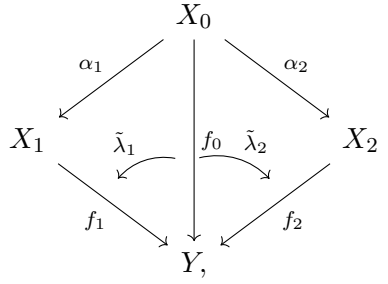
[page 135]

lequel reçoit le diagramme non commutatif

p. 92

les flèches

$$X_1 \longrightarrow \tilde{\mathscr{X}}/1, \qquad X_2 \longrightarrow \tilde{\mathscr{X}}/2$$

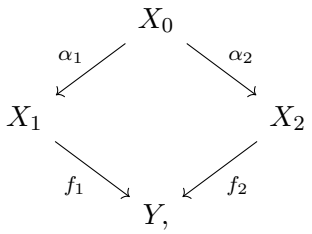


étant dans W (et même W-coasphériques - elles ont même un adjoint à gauche).

Donc on trouve, comme précédemment

$$\begin{cases} \alpha_1 \in W & \Longleftrightarrow \quad i_2 \in W \\ \alpha_2 \in W & \Longleftrightarrow \quad i_1 \in W, \end{cases}$$

et de même on peut formuler un 'lemme des cinq' comme le corollaire page 125 `[plutôt 126]`, mais avec $\tilde{\mathscr{X}}$, $\tilde{\mathscr{X}}'$ au lieu de $\mathscr{X}$, $\mathscr{X}'$.



De plus, $\tilde{\mathscr{X}}$ est la solution d'un problème universel dans Cat, en termes de données

[page 136]

la seule différence avec celui formulé à la page 128 étant la direction opposée des flèches λ_1, λ_2. Pour tout carré commutatif

$(*)$

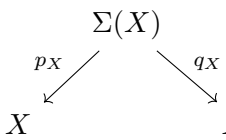
on trouve encore une flèche canonique

$$\tilde{\varphi} : \tilde{\mathscr{X}} \longrightarrow Y.$$

Il serait tout aussi raisonnable de dire que le carré $(*)$ est W-homotopiquement cocartésien, lorsque $\tilde{\varphi}$ est `[dans]` W, que d'adopter la définition 3, page 131 - on trouverait exactement les mêmes corollaires. Les deux définitions seraient elles équivalentes??

Je note que $\tilde{\mathscr{X}}$ étant cofibrée sur $\Psi = \Phi^\circ$, $\tilde{\mathscr{X}}^\circ$ est fibrée sur $\Psi^\circ = \Phi$. De façon précise, on aura p. 93

$$\tilde{\mathscr{X}}^\circ = \int \begin{array}{ccc} & \overset{\alpha_1^\circ}{\nearrow} & (X_1)^\circ \\ (X_0)^\circ & & \\ & \underset{\alpha_2^\circ}{\searrow} & (X_2)^\circ, \end{array}$$



et il s'agit donc de comparer les deux intégrales [page 137]

$$\mathscr{X} = \int \begin{array}{ccc} & \overset{\alpha_1}{\nearrow} & X_1 \\ X_0 & & \\ & \underset{\alpha_2}{\searrow} & X_2 \end{array}, \qquad \tilde{\mathscr{X}}^\circ = \int \begin{array}{ccc} & \overset{\alpha_1^\circ}{\nearrow} & (X_1)^\circ \\ (X_0)^\circ & & \\ & \underset{\alpha_2^\circ}{\searrow} & (X_2)^\circ \end{array},$$

notamment comme objets de $\mathrm{HOT}_W(\Phi)$. Pour cela, je reprends la construction du foncteur

$$X \longmapsto \Phi(X) : \mathrm{Cat} \longrightarrow \mathrm{Cat}$$

de I, p. 72-75, mais je préfère ici noter ce foncteur $\Sigma(X)$ (car Φ désigne déjà une petite catégorie $\begin{array}{ccc} & & 1 \\ & \swarrow & \\ 0 & & \\ & \nwarrow & \\ & & 2 \end{array}$). On utilisera les homomorphismes fonctoriels en X :

qui sont W-asphériques, donc $\in W$. De plus, $\Sigma(X^\circ) = \Sigma(X)$, $p_{X^\circ} = q_X$, $q_{X^\circ} = p_X$. Ainsi, si

$$X_* \quad = \quad \begin{array}{ccc} & & X_1 \\ & \overset{\alpha_1}{\nearrow} & \\ X_0 & & \\ & \underset{\alpha_2}{\searrow} & \\ & & X_2 \end{array} \qquad \in \quad \mathrm{Hom}(\Phi^\circ, \mathrm{Cat})$$

$$X_*^\circ \quad = \quad \begin{array}{ccc} & & (X_1)^\circ \\ & \overset{\alpha_1^\circ}{\nearrow} & \\ (X_0)^\circ & & \\ & \underset{\alpha_2^\circ}{\searrow} & \\ & & (X_2)^\circ \end{array} \qquad \in \quad \mathrm{Hom}(\Phi^\circ, \mathrm{Cat}),$$

on trouve [page 138]

$$\Sigma(X_*) = \begin{pmatrix} & & \Sigma(X_1) \\ & \overset{\Sigma(\alpha_1)}{\nearrow} & \\ \Sigma(X_0) & & \\ & \underset{\Sigma(\alpha_2)}{\searrow} & \\ & & \Sigma(X_2) \end{pmatrix}$$

et les flèches p. 94

$$\begin{array}{ccc} & \Sigma(X_*) & \\ \overset{p_{X_*}}{\swarrow} & & \overset{q_{X_*}}{\searrow} \\ X_* & & X_*^\circ, \end{array}$$

dans $\underline{\mathrm{Hom}}(\Phi^\circ, \mathrm{Cat})$. Ces flèches sont dans W terme à terme, donc les homomorphismes dans Cat

$$\begin{array}{ccc} & \int \Sigma(X_*) & \\ \overset{\int p_{X_*}}{\swarrow} & & \overset{\int q_{X_*}}{\searrow} \\ \mathscr{X} = \int X_* & & \int X_*^\circ = \tilde{\mathscr{X}}^\circ \end{array}$$

sont dans W.

Commentary · Exposition [ms. 137]

A common resolution of a category and its opposite

Grothendieck's comparison uses a resolution that reverses the category without reversing the direction of the functors between categories. This distinction is responsible for the utility of Σ. Taking opposites is a covariant operation on Cat: a functor $u : A \to B$ gives $u^\circ : A^\circ \to B^\circ$ in the same direction. Applied objectwise, it therefore preserves the shape of the span.

Here is a concrete convention for $\Sigma(C)$. Its objects are arrows $h : x \to y$ of C. An arrow from $h : x \to y$ to $h' : x' \to y'$ is a pair

$$r : x \to x', \qquad s : y' \to y, \qquad h = sh'r.$$

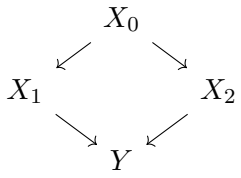
The projections $p_C(h) = x$ and $q_C(h) = y$ take values in C and C°, respectively. This is the opposite of one common convention for the twisted-arrow category. Reversing every displayed arrow identifies $\Sigma(C^\circ)$ with $\Sigma(C)$ and interchanges p and q. The equality written in the manuscript may be read as this specified canonical identification.

For completeness, the asphericity of the projections can be seen from their fibres. The projection p_C is a split fibration: over $r : x \to x'$ the inverse-image functor sends $h' : x' \to y'$ to $h'r : x \to y'$. Its fibre over x is $(x\backslash C)^\circ$, which has the final object id_x. To test asphericity, pull back along $C/c \to C$. The resulting category $\Sigma(C)/c$ is again split fibred, now over C/c, with those same aspherical fibres.

Since C/c has a final object, the fibre theorem gives that $\Sigma(C)/c$ is W-aspherical. Thus p_C is W-aspherical. Applying the identical argument to C° proves the assertion for q_C.

The importance of the resolution is its strict functoriality. For a diagram $F : I \to \mathrm{Cat}$, it supplies a diagram of natural transformations

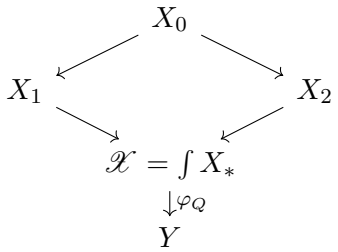
$$F \xleftarrow{p_F} \Sigma F \xrightarrow{q_F} F^\circ$$



whose components lie in W. Integrating the two transformations again gives weak equivalences. At the level of total categories this compares the smooth integral of F with the smooth integral of F°, the latter being canonically the opposite of the proper integral of F. Applying the same resolution once more to that total category removes the final opposite.

For a strict cocone Q into Y, all these maps commute with the comparison maps into Y, $\Sigma(Y)$, or Y°. The calculation on manuscript page 140 is therefore a calculation in an arrow category, not merely a list of equivalences between their sources. In each commuting square, both horizontal maps belong to W; two-out-of-three gives that one vertical comparison belongs to W precisely when the other does. This proves the equivalence of the four conditions in Proposition 14(b), and the same zigzags prove the stronger assertions about coherent diagrams in parts (c) and (d).

This proof is also useful for its scope. It compares the images after inverting the chosen weak equivalences; it does not assert that C and C° are equivalent categories. The fork $0 \to 1$, $0 \to 2$ already separates those statements, since it has an initial object and no final object, while its opposite has a final object and no initial object.



Finalement, l'innocent carré commutatif

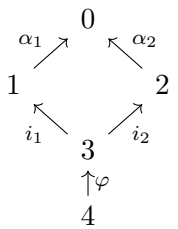
(∗∗) $\widehat{Q}$ =

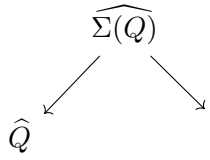


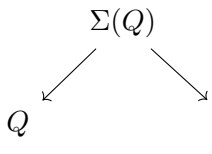
)

donne naissance, en le transformant par $X \longmapsto X^\circ$ et par $X \longmapsto \Sigma(X)$, et en tenant compte des homomorphismes fonctoriels en X [page 139]

, à trois diagrammes du type (∗∗), i.e. modelés sur la catégorie opposée de

Γ =





(i.e. $\mathbf{\Delta}^1 \times \mathbf{\Delta}^1$ ([88]), auquelle on a rajouté un objet initial)

([89]), savoir

88. faux, car le carré n'est pas commutatif

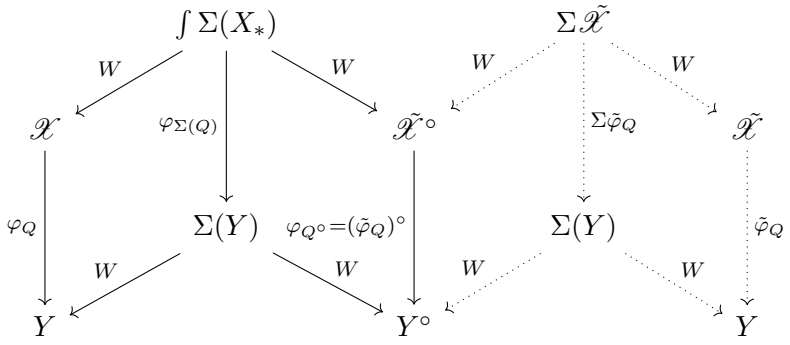
$$\widehat{Q}, \qquad \widehat{\Sigma(Q)}, \qquad \widehat{Q^\circ},$$

et deux homomorphismes de diagrammes ([dans] $\underline{\mathrm{Hom}}(\Gamma^\circ, \mathrm{Cat})$)

$(***)$  (déduit de ),

lesquels sont dans W terme à terme (i.e. sont dans $W_\Gamma \subseteq \mathrm{Fl}(\underline{\mathrm{Hom}}(\Gamma^\circ, \mathrm{Cat}))$). Explicitement, en les sommets $i = 0, 1, 2$, resp. 4 de Γ, $(***)$ n'est autre que

$$D_i = \left(\begin{array}{ccc} & \Sigma(X_i) & \\ {\scriptstyle p_{X_i}} \swarrow & & \searrow {\scriptstyle q_{X_i}} \\ X_i & & X_i^\circ \end{array} \right) \qquad \text{resp.} \qquad \begin{array}{ccc} & \Sigma(Y) & \\ {\scriptstyle p_Y} \swarrow & & \searrow {\scriptstyle q_Y} \\ Y & & Y^\circ, \end{array}$$



en le sommet 3 c'est

$$\begin{array}{ccc} & \int \Sigma(X_*) & \\ {\scriptstyle \int p_{X_*}} \swarrow & & \searrow {\scriptstyle \int q_{X_*}} \\ \mathscr{X} = \int X_* & & \int X_*^\circ = \tilde{\mathscr{X}}^\circ, \end{array}$$

obtenu par intégration des flèches

$$\begin{array}{ccc} & \Sigma(X_*) & \\ {\scriptstyle p_{X_*}} \swarrow & & \searrow {\scriptstyle q_{X_*}} \\ X_* & & X_*^\circ. \end{array}$$

Regardant la restriction des deux morphismes de diagrammes $(***)$ aux parties des trois diagrammes de type Γ° au dessus de la queue $\{3, 4\}$ de Γ on trouve le diagramme en traits pleins que voici [page 140]

qu j'ai complété par un deuxième volet en pointillés. Dans ce diagramme de quatre carrés accolés, les côtés horizontaux des carrés représentent des flèches de Cat qui sont dans W. On trouve ainsi : p. 96

$$\varphi_Q \in W \iff \varphi_{\Sigma Q} \in W \iff (\varphi_{Q^\circ} = \tilde{\varphi}_Q^\circ) \in W \iff \Sigma\tilde{\varphi}_Q \in W \iff \tilde{\varphi}_Q \in W.$$

On trouve aussi que les cinq flèches verticales sont isomorphes, en tant que flèches de Hot_W. Pour résumer :

89. On a $\alpha_1 i_1 \neq \alpha_2 i_2$, mais la relation $\alpha_1 i_1 \varphi = \alpha_2 i_2 \varphi$.

Commentary · Exposition [ms. 139]

The indexing category must retain both paths

Grothendieck keeps the entire comparison diagram because the two routes from X_0 to the integral become equal only after applying the map to Y. The correction in footnotes 88 and 89 is essential to that purpose. Before reaching Y, the routes even land in different fibres of the integral. They cannot be made equal by calling the drawing a commutative square.

Let $J = \Gamma^\circ$. A precise presentation has vertices $0, 1, 2, 3, 4$, arrows

$$0 \xrightarrow{a_1} 1 \xrightarrow{j_1} 3 \xrightarrow{v} 4, \qquad 0 \xrightarrow{a_2} 2 \xrightarrow{j_2} 3,$$

and the single relation $vj_1a_1 = vj_2a_2$. The two arrows $j_1a_1, j_2a_2 : 0 \to 3$ remain distinct. Thus 4 is terminal, but the full subcategory on $0, 1, 2, 3$ is the free diamond, not the ordered square $[1] \times [1]$. This is exactly the relation stated by footnote 89, with the orientation reversed.

To include the dotted central inclusion mentioned in footnote 91, add a generator $r : 0 \to 3$ and the relation $vr = vj_1a_1$. The natural transformations connecting j_1a_1 and j_2a_2 with r are additional two-dimensional data; they are not relations in this ordinary indexing category. Every resolution used in Proposition 14 also preserves r, so adding it causes no difficulty for the objectwise weak-equivalence argument. It simply records more of the construction.

Proposition 14. *Considérons un diagramme (carré commutatif)*

$$Q \quad = \quad \begin{array}{ccc} & X_0 & \\ \swarrow & & \searrow \\ X_1 & & X_2 \\ \searrow & & \swarrow \\ & Y & \end{array}$$

dans Cat*, et le diagramme 'opposé' déduit par* $X \longmapsto X^\circ$

$$Q^\circ \quad = \quad \begin{array}{ccc} & X_0^\circ & \\ \swarrow & & \searrow \\ X_1^\circ & & X_2^\circ \\ \searrow & & \swarrow \\ & Y^\circ, & \end{array}$$

et les flèches correspondantes [page 141]

$$\begin{cases} \varphi_Q : \quad \mathscr{X}_Q \quad = \quad \left(\int \begin{array}{ccc} & & X_1 \\ X_0 & \nearrow & \\ & \searrow & \\ & & X_2 \end{array} \right) \quad \longrightarrow \quad Y \\ \varphi_{Q^\circ} : \quad \mathscr{X}_{Q^\circ} \quad = \quad \left(\int \begin{array}{ccc} & & X_1^\circ \\ X_0^\circ & \nearrow & \\ & \searrow & \\ & & X_2^\circ \end{array} \right) \quad \longrightarrow \quad Y^\circ. \end{cases}$$

Enfin, considérons aussi les flèches $\tilde{\varphi}_Q$, $\tilde{\varphi}_{Q^\circ}$ *canoniques, relative à l'intégrale propre* $\int_{\mathrm{pr}}$ *(au* p. 97

lieu de l'intégrale lisse $\int = \int_{\mathrm{lis}}$)

$$\begin{cases} \tilde{\varphi}_Q : \ \tilde{\mathscr{X}}_Q \ = \ \left(\int_{\mathrm{pr}} X_0 \begin{array}{c} \nearrow X_1 \\ \searrow X_2 \end{array} \right) \longrightarrow Y \\ \tilde{\varphi}_{Q^\circ} : \ \tilde{\mathscr{X}}_{Q^\circ} \ = \ \left(\int_{\mathrm{pr}} X_0^\circ \begin{array}{c} \nearrow X_1^\circ \\ \searrow X_2^\circ \end{array} \right) \longrightarrow Y^\circ. \end{cases}$$

On a alors ce qui suit :

ⓐ $\varphi_{Q^\circ} \simeq (\tilde{\varphi}_Q)^\circ$, $\varphi_Q \simeq (\tilde{\varphi}_{Q^\circ})^\circ$ *(d'où résulte déjà que* $\begin{cases} \varphi_Q \in W & \Longleftrightarrow & \tilde{\varphi}_{Q^\circ} \in W \\ \varphi_{Q^\circ} \in W & \Longleftrightarrow & \tilde{\varphi}_Q \in W \end{cases}$ *([90]))*.

ⓑ *Les relations*

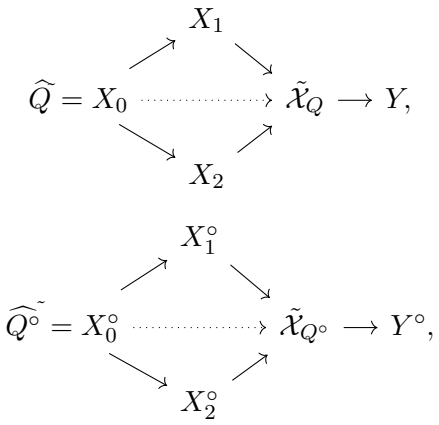
$$\varphi_Q \in W, \qquad \varphi_{Q^\circ} \in W, \qquad \tilde{\varphi}_Q \in W, \qquad \tilde{\varphi}_{Q^\circ} \in W$$

sont équivalentes, en d'autres termes : pour que le carré soit W-homotopiquement cocartésien (version intégrale lisse), il faut et il suffit que le carré opposé Q° le soit, et ces conditions équivalent aussi aux conditions correspondantes en termes des intégrales propres (au lieu des intégrales lisses).

ⓒ *Les quatre flèches φ_Q, φ_{Q°, $\tilde{\varphi}_Q$, $\tilde{\varphi}_{Q^\circ}$ de* Cat *en tant que flèches dans* Hot_W*, sont isomorphes dans* $\underline{\mathrm{Fl}}(\mathrm{Hot}_W)$*. Plus précisément, en tant que flèches de* Cat*, elles définissent des objets isomorphes de* $\mathrm{HOT}_W(\mathbf{\Delta}^1)$*.* [page 142]

ⓓ *Plus précisément encore, les quatre diagrammes dans* Cat *de type* Γ°*, où*

$$\Gamma = \begin{array}{ccccc} & & 1 & & \\ & \overset{\alpha_1}{\swarrow} & & \overset{i_1}{\nwarrow} & \\ 0 & & & & 3 \overset{\varphi}{\longleftarrow} 4, \\ & \underset{\alpha_2}{\nwarrow} & & \underset{i_2}{\swarrow} & \\ & & 2 & & \end{array}$$



$\alpha_1 i_1 \varphi = \alpha_2 i_2 \varphi$, dans lesquels s'insèrent les quatre flèches qu'on vient d'envisager, savoir

$$\widehat{Q} = \begin{array}{ccccc} & \overset{\alpha_1}{\nearrow} & X_1 & \overset{i_1}{\searrow} & \\ X_0 & \cdots\cdots & & \cdots\cdots\rightarrow & \mathscr{X}_Q \overset{\varphi_Q}{\longrightarrow} Y, \\ & \underset{\alpha_2}{\searrow} & X_2 & \underset{i_2}{\nearrow} & \end{array}$$

p. 98

$$\widehat{Q^\circ} = \begin{array}{ccccc} & \overset{\alpha_1^\circ}{\nearrow} & X_1^\circ & \overset{i_1'}{\searrow} & \\ X_0^\circ & \cdots\cdots & & \cdots\cdots\rightarrow & \mathscr{X}_{Q^\circ} \longrightarrow Y^\circ, \\ & \underset{\alpha_2^\circ}{\searrow} & X_2^\circ & \underset{i_2'}{\nearrow} & \end{array}$$

90. et que les flèches φ_Q et $\tilde{\varphi}_{Q^\circ}$ d'une part, φ_{Q° et $\tilde{\varphi}_Q$ d'autre part, sont isomorphes comme flèches dans Hot_W.

([91]) *sont isomorphes dans* $\mathrm{Hot}_W(\Gamma)$. *De façon plus précise encore, on a les isomorphismes dans* $\underline{\mathrm{Hom}}(\Gamma^\circ, \mathrm{Cat})$

$$(\widetilde{Q})^\circ \simeq \widetilde{Q^\circ},$$

d'où en l'appliquant à Q° *au lieu de* Q,

$$(\widetilde{\widehat{Q^\circ}})^\circ \simeq \widehat{Q},$$

ce qui implique (via les isomorphismes canoniques valables dans $\mathrm{HOT}_W(S)$ *pour tout objet* S *dans* Cat *et tout* $X_* \in \mathrm{Ob}\,\underline{\mathrm{Hom}}(S, \mathrm{Cat})$, $X_* \simeq X_*^\circ$ ([92])*, qu'on a les isomorphismes canoniques*

$$\left.\begin{array}{c} \widehat{Q} \simeq \widetilde{\widehat{Q^\circ}} \\ \widehat{Q^\circ} \simeq \widehat{\widetilde{Q}} \end{array}\right\} \qquad \textit{dans } \mathrm{HOT}_W(\Gamma),$$

mais aussi directement

$$\widehat{\widetilde{Q}} \simeq \widehat{\widetilde{Q^\circ}}, \qquad \widetilde{\widehat{Q}} \simeq \widetilde{\widehat{Q^\circ}} \qquad \textit{dans } \mathrm{HOT}_W(\Gamma)$$

(et il reste à vérifier qu'on a ainsi un système transitif *d'isomorphismes canoniques dans* $\mathrm{HOT}_W(\Gamma)$*, entre les quatre objets envisagés, ce qui doit être essentiellement sorital …).* [page 143]

Commentary · Development (commentators') [ms. 143]

The four comparisons form a coherent system

Grothendieck leaves a small but real task after Proposition 14: the canonical comparisons should compose transitively. Without this check, choosing a route through the four constructions could leave an unspecified automorphism. The following argument supplies the check directly in the localized category of diagrams. We did not find this particular four-comparison verification stated separately in the literature consulted; it is a formal completion of the construction on these pages, with no claim of priority.

Coherence of the four integration comparisons. [ours] Let Q be a strictly commuting cocone on a small category-valued diagram, and use the same expanded indexing category J for the integral, the cocone, and their structural inclusions. In the localization

$$\mathcal{L}_J = \mathrm{Fun}(J, \mathrm{Cat})[W_J^{-1}],$$

the comparisons furnished by Σ between the smooth and proper integrals of Q and of Q° form a transitive system of isomorphisms. The assertion includes the arrows from the integral to the cocone vertex and the optional central inclusions.

Proof. Write O for objectwise passage to opposite categories. It preserves W_J, so it acts on $\mathcal{L}_J$. The resolution of the preceding block gives a natural isomorphism

$$\eta_D : D \xrightarrow{\sim} OD, \qquad \eta_D = q_D p_D^{-1}.$$

91. **NB** On devrait encore compléter ces diagrammes (non commutatifs) par les flèches en pointillés …
92. via le foncteur Σ utilisé plus haut …

Because $\Sigma(OD)$ is identified with $\Sigma(D)$ with its projections exchanged,

$$\eta_{OD} = \eta_D^{-1}.$$

Naturality holds first for actual maps of diagrams and then for their inverses in the localization; hence it holds for every arrow in $\mathcal{L}_J$. Applying it to η_D gives

$$O(\eta_D)\eta_D = \eta_{OD}\eta_D, \qquad O(\eta_D) = \eta_D^{-1}.$$

Thus the opposite operation and its canonical comparison already satisfy the required involution identity.

Now put $A = \widehat{Q}_{\mathrm{lis}}$ and $B = \widehat{Q^\circ}_{\mathrm{lis}}$. Integrating the objectwise resolution of the original diagram, while using $\Sigma(Y)$ at the cocone vertex, gives

$$\alpha_Q : A \xrightarrow{\sim} B.$$

The same resolution for Q° interchanges its two projections, including at the integrated vertex. Consequently $\alpha_{Q^\circ} = \alpha_Q^{-1}$. By the strict descriptions of the two Grothendieck constructions, the other two objects are canonically

$$C = \widehat{Q}_{\mathrm{pr}} = OB, \qquad D = \widehat{Q^\circ}_{\mathrm{pr}} = OA.$$

Proper integration is the composite of objectwise opposite, smooth integration, and objectwise opposite again. Since $O(\eta_Q) = \eta_Q^{-1}$ also holds in the localized category of input cocones, applying this composite to the resolution shows that its direct proper comparison from C to D is $O(\alpha_Q^{-1})$. Naturality of η for α_Q says exactly

$$\eta_B\alpha_Q = O(\alpha_Q)\eta_A,$$

or, equivalently,

$$O(\alpha_Q^{-1})\eta_B\alpha_Q = \eta_A.$$

This is the commutativity of the square formed by the four constructions. Together with the involution identities, it shows that the composite around the square, in either direction, is the identity. Every route between two vertices can be reduced by cancelling inverse adjacent edges and using this square identity. The resulting comparison is independent of the route, and its composites are transitive. All equalities take place in $\mathcal{L}_J$, so they also hold after restricting to the comparison arrow or to any other subdiagram. □

The argument is unchanged for an arbitrary index category. For $F : I \to \mathrm{Cat}$, one may define J by freely adjoining a vertex v and arrows $r_i : i \to v$, then a terminal vertex y, so that the composites $i \to v \to y$ satisfy the relations of the given strict cocone. The arrows $r_j u$ and r_i are not identified for $u : i \to j$; their images in the integral are linked by transition transformations. With this presentation, the arbitrary-shape claim on manuscript pages 143–144 follows from the same proof. The phrase "without commutation relations" describes the first, free adjunction of v; only the subsequent vertex y is terminal. Keeping these two operations distinct prevents the indexing error already corrected on page 139.

Remarques.

1) Ce qu'on vient de dire dans le cas des diagrammes dans Cat de type $\Phi^\circ = \Psi$, a l'air de garder un sens pour les diagrammes de type quelconque

$$X_* : S^\circ \longrightarrow \mathrm{Cat}, \qquad s \longmapsto X_s$$

(S un objet de Cat). On peut l'intégrer de façon lisse, $\int X_* = \int_{\mathrm{lis}} X_*$, obtenant une catégorie fibrée (scindée) sur S, ou de façon propre, $\int_{\mathrm{pr}} X_*$, obtenant une catégorie cofibrée scindée sur S°. On peut également considérer X_*°, composé de X_* avec l'automorphisme $Y \longmapsto Y^\circ$ dans Cat, et l'intégrer de façon soit propre, soit lisse. Dans tous ces cas, on trouve un diagramme de type $\widehat{S}^\circ$, où $\widehat{S}$ est déduit de S en ajoutant un élément qui p. 99

s'envoie par une flèche 'canonique' (donnée) dans chacun des autres (*sans* relations de commutation!) Un *système inductif* de morphismes dans Cat [page 144]

$$f \qquad X_s \xrightarrow{f_s} Y$$

donne alors un morphisme

$$\int_{\text{lis}} X_* \xrightarrow{\varphi_Q} Y,$$

où Q désigne le diagramme, de type $\widehat{S}^\circ$, formé des X_s, de Y, des $u^* : X_t \longrightarrow X_s$ (pour $u : s \longrightarrow t$ dans S) et des f_s. De même on aura

$$\int_{\text{prop}} X_* \xrightarrow{\tilde{\varphi}_Q} Y,$$

et si

$$\Gamma = (\widehat{S} + \text{objet initial}),$$

on trouve des diagrammes $\widehat{Q}$, $\widetilde{Q}$ de type Γ° dans Cat. Sauf erreur, les relations entre $\widehat{Q}$, $\widetilde{Q}$, $\widehat{Q^\circ}$, $\widetilde{\widehat{Q}^\circ}$ sont les mêmes que celles explicitées dans la proposition 14 ci-dessus. Je ne vais pas m'arrêter là-dessus avec le soin requis, sauf en cas de besoin. On dira qu'un diagramme Q définit Y comme $\varinjlim_I W$-homotopique [où $I = S^\circ$] si $\varphi_Q \in W$. Il revient au même de dire que $\varphi_{Q^\circ} \in W$, ou que $\tilde{\varphi}_Q \in W$ ou que $\tilde{\varphi}_{Q^\circ} \in W$ … [page 145]

Commentary · Later developments [ms. 144]

The comparison map in later formalisms

The definition by a specified map from an integral has a direct later interpretation. For ordinary homotopy types, put

$$\mathbb{D}(J) = \mathrm{Fun}(J, \mathrm{Cat})[W_{\infty,J}^{-1}] = \mathrm{HOT}_{W_\infty}(J^{\mathrm{op}}).$$

The opposite in the last expression corrects for the manuscript's presheaf convention. A square is an object of $\mathbb{D}(\square)$, where $\square = [1] \times [1]$. Let $i : \ulcorner \hookrightarrow \square$ omit the terminal vertex. In the derivator formulation a square Q is cocartesian when the counit

$$i_! i^* Q \longrightarrow Q$$

is an isomorphism (Groth, 2013, Definition 3.9). At the three vertices of $\ulcorner$ its components are already isomorphisms. At the last vertex, the component is the homotopy-colimit comparison represented here by φ_Q. This identifies Definition 3 with the later coherent-square definition. It also explains why a square merely drawn in $\mathbb{D}(e)$ is insufficient: it need not specify the coherent object to which $i_!$ applies.

The composition and cancellation theorem for adjacent cocartesian squares is Groth (2013, Proposition 3.13). Its hypotheses concern squares inside one coherent rectangle. They do not assert that an arbitrary map between homotopy pushouts reflects an equivalence on the intersection from equivalences on the pieces and the union. The latter is the stronger cube assertion tested by the acyclic example above.

There is a second distinction when the fibres are retained as categories. A Cartesian fibration classified by a diagram of ∞-categories models its colimit only after its Cartesian transition edges have been inverted; see Lurie (2009, Corollary 3.3.4.3 and Warning 3.3.4.4). Passing further to the groupoid completion inverts every edge. The corresponding space-valued statement is Proposition 3.3.4.5 of the same reference. This is compatible with the classifying-space interpretation of the manuscript's integral, while preserving the stronger categorical information before localization.

The constant terminal-category diagram over [1] makes the distinction concrete. Its ordinary total category is [1]. The colimit of the diagram in categories is e, and its colimit in Cat_∞ is also e. The unique nonidentity arrow of [1] is a transition arrow; inverting it gives a

> category equivalent to e. Before that inversion, [1] and e are not equivalent categories: the two objects of [1] are not isomorphic. Their classifying spaces are nevertheless both contractible. Thus the three assertions—a total category, a categorical colimit, and a colimit of homotopy types—agree only after the indicated operations. The present text is computing the last of them and retaining a strict representative for its map to the proposed target.

2) Le cas 'universel', pour $\begin{array}{ccc} & & X_1 \\ X_0 & \nearrow & \\ & \searrow & \\ & & X_2 \end{array}$ donné, d'un carré commutatif $Q = \begin{array}{ccccc} & & X_1 & & \\ X_0 & \nearrow & & \searrow & \\ & & & & Y \\ & \searrow & & \nearrow & \\ & & X_2 & & \end{array}$

dans Cat, donnant naissance à

$$\varphi_Q : \left(\begin{array}{ccc} & & X_1 \\ & \nearrow & \\ \int X_0 & & \\ & \searrow & \\ & & X_2 \end{array} \right) \longrightarrow Y,$$

est celui de $Y = X_1 \amalg_{X_0} X_2$, donnant naissace à

p. 100

$$Q_0 = Q(X_*) = \begin{array}{ccccc} & & X_1 & & \\ X_0 & \nearrow & & \searrow & \\ & & & & X_1 \amalg_{X_0} X_2. \\ & \searrow & & \nearrow & \\ & & X_2 & & \end{array}$$

Le cas général s'y ramène, car on aura un diagramme commutatif

$$\begin{array}{ccccc} \left(\begin{array}{ccc} & & X_1 \\ & \nearrow & \\ \int X_0 & & \\ & \searrow & \\ & & X_2 \end{array} \right) & & \xrightarrow{\varphi_{Q_0} = \varphi_{Q(X_*)}} & & X_1 \amalg_{X_0} X_2 \\ & \searrow^{\varphi_Q} & & & \downarrow{\scriptstyle \alpha_Q} \\ & & & & Y. \end{array}$$

Mais il doit y avoir des cas intéressants où φ_{Q_0} n'est *pas* dans W, i.e. le carré Cat-cocartésien $\begin{array}{ccc} & & X_1 \\ X_0 & \nearrow & \\ & \searrow & \\ & & X_2 \end{array}$ $\begin{array}{ccc} & & \\ & \searrow & \\ X_1 \amalg_{X_0} X_2 & & \\ & \nearrow & \\ & & \end{array}$ n'est pas W-homotopiquement cocartésien, et où pourtant on peut trouver un carré commutatif Q complétant X_*, de telle façon que ce carré soit W-homotopiquement commutatif `[plutôt cocartésien]`, i.e. que $\varphi_Q = \alpha_Q \varphi_{Q_0}$ soit dans W. C'est d'autant plus plausible que dans Cat, les sommes amalgamées ont tendance à

[page 146]

ne pas avoir des bonnes propriétés homotopiques, même si l'une des flèches α_1, α_2 est [un] monomorphisme (voire une immersion ouverte), contrairement à ce qui se passe dans $\mathbf{\Delta}^\wedge$, et plus généralement dans les catégories de la forme $Z^\wedge$ (Z dans Cat).

Commentary · Development (commentators') [ms. 146]

A strict cocone can repair the wrong pushout

Grothendieck asks for more than a strict pushout that fails to be a homotopy pushout. He asks whether its failure can disappear after mapping that pushout to a different target, while retaining the original span. The following finite example answers his question affirmatively for W_∞, even when one leg is an open immersion. The sources checked on preservation of pushouts, including the Dwyer-map criterion and its refinement in Hackney et al. (2024, Theorems 1.5–1.6, arXiv v3), do not supply this particular construction. We give a complete argument rather than a priority claim.

A finite repair example. [ours] There exist finite posets $E \subset B$, with E a sieve in B, such that BE and BB are contractible, while the categorical pushout $P = B \amalg_E e$ has classifying space S^3. Consequently the canonical comparison

$$c : \int_{\mathrm{lis}} (B \leftarrow E \to e) \longrightarrow P$$

is not in W_∞, but its composite with $P \to e$ is in W_∞. Here $BD = |ND|$ denotes the classifying space of a category D.

Proof. We first construct a map from a contractible face poset to a spherical one whose comma categories are connected. Let K be the finite simplicial complex with six vertices a, b, c, A, B, C and maximal faces

$$abc, \quad abB, \quad aBA, \quad bcC, \quad bCB, \quad caA, \quad cAC.$$

It is the disk obtained by placing the triangle abc inside the triangle ABC and triangulating the surrounding annulus with the remaining six triangles. In particular it is contractible. This description can also be checked without a drawing: successive free-face collapses remove

$$(AB, aAB),\ (AC, cAC),\ (aA, acA),\ (A, cA),\ (BC, bBC),$$
$$(aB, abB),\ (B, bB),\ (bC, bcC),\ (C, cC),$$
$$(ab, abc),\ (a, ac),\ (b, bc),$$

leaving the vertex c. In each pair the first simplex is a free codimension-one face of the second at the moment it is removed.

Let L be the boundary of the tetrahedron on vertices a, b, c, n. The vertex map fixing a, b, c and sending A, B, C to n is simplicial from K to L: the seven triangles have images abc, abn, an, bcn, bn, can, cn. Let E and S be the posets of nonempty faces of K and L, and let $f : E \to S$ send a face to its image. Thus BE is a subdivided disk and BS a subdivided two-sphere.

For every face s of L, the comma category E/s is the face poset of the subcomplex consisting of faces whose image is contained in s. If $n \notin s$, this subcomplex is the simplex on s, so it is connected and nonempty. If $n \in s$, it contains the entire outer boundary $AB \cup BC \cup CA$. Every inner vertex allowed by s attaches to that boundary by a radial edge: a by aA, b by bB, and c by cC. Every remaining simplex contains vertices of this same connected subcomplex. It follows that

$$\pi_0(E/s) = \{*\} \quad \text{for every } s \in S.$$

Only connectedness is claimed: for $s = \{n\}$ the comma category is the face poset of the outer boundary circle.

Adjoin an initial object o to S and call the resulting poset T. Define a poset B on the disjoint union of E and T. Keep their internal orders and add

$$e \le s \quad \Longleftrightarrow \quad f(e) \le s \qquad (e \in E,\ s \in S).$$

There are no relations from T to E, and none from E to o. Transitivity follows from monotonicity of f. The subposet E is a sieve. The functor $r : B \to T$ which is the identity on T and sends e to $f(e)$ is left adjoint to the inclusion $j : T \to B$, because

$$B(b, jt) = T(r(b), t)$$

for every $b \in B$, $t \in T$, including the empty hom-sets when $t = o$ and $b \in E$. Hence Bj is a homotopy equivalence. The initial object o makes BT, and therefore BB, contractible.

It remains to compute the categorical pushout, since a topological quotient would give the wrong answer. Collapsing the sieve E to one object $*$ introduces no arrows from T to $*$ and does not change arrows within T. Any arrow from $*$ to $s \in S$ is represented by a relation $e \leq s$ in B. The relations after collapsing E identify two representatives exactly along zigzags of comparable elements in E/s. Thus

$$\mathrm{Hom}_P(*, s) = \pi_0(E/s) = \{*\}, \qquad \mathrm{Hom}_P(*, o) = \emptyset.$$

For clarity, this description also verifies the universal property: a functor out of B that is constant on E assigns the same arrow to any two representatives in one such connected component, and therefore factors uniquely through the displayed category. Conversely every functor from that category supplies exactly such compatible data on B and e. Composition is induced by the maps $E/s \to E/s'$ for $s \leq s'$.

Consequently P is the poset with two incomparable minimal objects $o, *$, both lying below every object of S. Its order complex is exactly the simplicial join

$$NP = N\{o, *\} * NS, \qquad BP \cong S^0 * |\operatorname{sd} L| \cong S^3.$$

The three categories in the original span $B \leftarrow E \to e$ are contractible. Their smooth integral is a split fibration over the contractible indexing fork, with contractible fibres, and hence is contractible. Its canonical map c cannot be a weak equivalence to P, whose third homology is $\mathbb{Z}$. On the other hand the unique functor from the integral to e is a weak equivalence, and it is precisely the composite $P \to e$ after c. This proves the assertion. □

The construction has 25 objects in E, 14 in S, 40 in B, and 16 in P. The accompanying finite computation checks the face lists, the elementary collapses, all fourteen connected comma categories, and the homology of NP; the join calculation above identifies its entire homotopy type. The mechanism is visible in the proof: the ordinary categorical pushout keeps only $\pi_0(E/s)$ in each mixed hom-set. It replaces a family containing a circular comma category by a family of singletons, and the resulting total category acquires the additional sphere. Sending that sphere to a point supplies the strict cocone envisaged on manuscript pages 145–146.

3.4 Critères pour les carrés homotopiquement cocartésiens.

Les critères que j'ai dégagé sont tous contenus dans l'énoncé suivant :

Théorème 4 ([93], [94]). *Considérons un diagramme carré commutatif dans* Cat

(∗)
$$Q \quad = \quad \begin{array}{ccc} X_0 & \xrightarrow{\alpha_1} & X_1 \\ {\scriptstyle \alpha_2}\downarrow & \overset{f_0}{\searrow} & \downarrow{\scriptstyle f_1} \\ X_2 & \xrightarrow[f_2]{} & Y, \end{array}$$

et considérons le morphisme canonique

p. 101

$$\varphi_Q : \quad \mathcal{X} = \Big(\int \quad \begin{array}{ccc} & & X_1 \\ & \overset{\alpha_1}{\nearrow} & \\ X_0 & & \\ & \underset{\alpha_2}{\searrow} & \\ & & X_2 \end{array} \Big) \quad \longrightarrow \quad Y,$$

l'intégrale étant l'intégrale lisse. *(Il y a un énoncé dual concernant l'intégrale propre de*

[page 147]

93. **NB** Dans ce théorème, et les corollaires 1, 2, 3, on n'a besoin que de la *forme faible* de W(7 bis), savoir $i_0 \in W \Longrightarrow i \in W$ (cf. p. 79) (Loc(6′a) avec les notations de XVI).

94. **NB** Au total, le théorème (partie directe) est valable sans hypothèse W(7 bis) ou W(7 bis faible) sur W, et il en est de même de ses corollaires 1 à 3 (à l'exclusion des corollaires 4, 5, qui eux utilisent W(7 bis) dans toute sa force).

$$\begin{array}{ccc} & & X_1 \\ & \nearrow & \\ X_0 & & .) \\ & \searrow & \\ & & X_2 \end{array}$$

a) Pour que φ_Q soit W-lisse, il faut et il suffit que f_1, f_2 et $f_0 = f_1\alpha_1 = f_2\alpha_2$ le soient. (Moyennant W(7 bis) ([95])).

b) La fibre de φ_Q en un élément y de Y est isomorphe à

$$(**) \qquad \int \begin{array}{ccc} & & X_{1\,y} \\ & \nearrow & \\ X_{0\,y} & & \\ & \searrow & \\ & & X_{2\,y} \end{array} \qquad (\simeq \mathcal{X}_y).$$

Corollaire 1. ([97]) *Supposons f_1, f_2 et $f_1\alpha_1 = f_2\alpha_2$ W-lisses, et les catégories intégrées $(**)$ W-asphériques pour tout $y \in \mathrm{Ob}\, Y$. (NB Il s'agit encore de l'intégrale lisse, mais peu importe au fond, car on a vu (cf. partie supérieure du diagramme p. 140, qui implique que $\mathcal{X}$* `[est]` *W-asphérique si et seulement si $\tilde{X}$ l'est) que l'une est W-asphérique si et seulement si l'autre l'est.) Alors $\varphi_Q \in W$, i.e. le carré $(*)$ est W-homotopiquement cartésien* `[plutôt cocartésien]`*. Par dualité, même conclusion si on suppose f_1, f_2, $f_1\alpha_1 = f_2\alpha_2$* propres *au lieu de lisses. (Car Q W-homotopiquement trivial* `[plutôt cocartésien]`*, si et seulement si Q° l'est, par* `[la]` *prop. 14.)*

En effet, un morphisme dans Cat qui est W-lisse et à fibres W-asphériques est dans W (et c'est même une W-équivalence universelle …). [page 148]

Commentary · Exposition [ms. 147]

Smoothness and the two different uses of a fibre

Grothendieck now turns the comparison into a criterion that can be checked on a given square. There are two separate operations in Theorem 4. The fibre formula is an identity of categories: imposing that the comparison map has the value y imposes the same condition in each of its three pieces. Smoothness is a local lifting condition, tested on slices at objects of the integral. The latter condition is what permits a strict fibre to determine the homotopy-theoretic conclusion.

It is useful to read the annotations as a refinement of the hypotheses, rather than as several competing versions of the theorem. If f_0, f_1, f_2 are W-smooth, then φ_Q is W-smooth for every fundamental localizer. The reverse implication for f_0 is asserted under the strong form of W(7 bis). No extra excision axiom is required for the fibre identity

$$(\mathcal{X}_Q)_y \cong \int_{\mathrm{lis}} (X_{1y} \leftarrow X_{0y} \rightarrow X_{2y}).$$

The calculations on manuscript pages 152–157 establish these assertions; their local content is explained below at the two lemmas. In particular, the annotations do not justify removing the strong hypothesis from the converse.

The last step of Corollary 1 deserves to be made explicit. If $u : E \to Y$ is W-smooth, the fibre inclusion $E_y \to y\backslash E$ is W-aspherical. If every E_y is W-aspherical, two-out-of-three gives that every $y\backslash E$ is W-aspherical. The dual of the fundamental Theorem A then yields $u \in W$. This proof is stable under arbitrary base change: smoothness is stable under base change and the new strict fibres

95. Pour la partie directe (f_0, f_1, f_2 lisses $\Longrightarrow$ φ_Q lisse), on n'a besoin que de W(7 bis) ([96]), forme faible. Ce n'est que pour la réciproque (qui ne m'a encore jamais servie) qu'on a besoin de W(7 bis), dans toute sa force.

96. On n'a pas même besoin de W(7 bis) faible, cf. annotation page 156. On utilise une hypothèse restrictive sur W dans la réciproque seulement (φ_Q lisse $\Longrightarrow$ f_0, f_1, f_2 lisses).

97. Valable sans hypothèse sur W (autre que Loc(1,2,3 bis)).

are the old ones. Hence u is in fact a universal W-equivalence. The same argument with properness uses E/y instead. These are the fibre criteria formalized in Maltsiniotis (2005, Theorem 1.2).

Consequently the forward criterion in Corollary 1 has precisely the strength needed later: smoothness of all three structure maps, together with asphericity of the integrated fibres, proves the square homotopy cocartesian, and even proves the comparison a universal weak equivalence. The qualifications in the first two footnotes to Theorem 4 correctly anticipate this result.

Corollaire 2. *On suppose que W satisfait* W(7 bis) (axiome du carré cocartésien) ([98]). *Supposons le carré Q cocartésien dans* Cat ([99]), *et que α_1 soit une immersion ouverte (resp.* p. 102 *fermée) et f_1 lisse (resp. propre). Alors Q est W-homotopiquement cocartésien.* ([100])

Il suffit d'établir le résultat non respé, l'autre en résultera par dualité (puisque Q est W-cocartésien si et seulement si Q° l'est). Par hypothèse f_1 est W-lisse, d'autre part α_1 et f_2 sont des immersions ouvertes, donc W-lisses, donc $f_1\alpha_1$ est W-lisse aussi. (D'ailleurs α_2 aussi, car le carré est aussi cartésien, donc α_2 déduit de f_1 (qui est W-lisse par hypothèse) par changement de base $X_2 \longrightarrow Y$.) Donc φ_Q est [W-]lisse, et il suffit de voir que ses fibres sont W-asphériques. Le calcul $(**)$ donne, pour y dans $Y\backslash X_2$,

$$\mathcal{X}_y \simeq \int \begin{array}{ccc} & & e \\ \emptyset & \nearrow & \\ & \searrow & \\ & & \emptyset \end{array} \simeq e, \qquad \text{O.K.}$$

Et pour y dans X_2

$$\mathcal{X}_y \simeq \int \begin{array}{ccc} & & X_{1\,y} \\ X_{0\,y} & \overset{\sim}{\nearrow} & \\ & \searrow & \\ & & e \end{array} .$$

Comme $X_{0\,y} \longrightarrow X_{1\,y}$ est un isomorphisme, donc est dans W, il s'ensuit que $e \longrightarrow \mathcal{X}_y$ l'est [page 149] aussi (prop. 13, p. 125), moyennant W(7 bis), donc $\mathcal{X}_y$ est W-asphérique, O.K. ([101]).

Corollaire 3. (Moyennant W(7 bis) ([102]).) *Soit X dans* Cat, *U_1, U_2 deux ouverts de X tels que $X = U_1 \cup U_2$, $U_0 = U_1 \cap U_2$ l'ouvert intersection. Alors le carré d'immersions ouvertes*

$$\begin{array}{ccc} U_0 & \hookrightarrow & U_1 \\ \downarrow & & \downarrow \\ U_2 & \hookrightarrow & X \end{array}$$

est W-cocartésien. (Énoncé dual pour deux fermés T_1, T_2 tels que $T_1 \cup T_2 = X$, avec $T_0 = T_1 \cap T_2$.)

On applique le corollaire 2. On sait que le carré est cocartésien dans Cat ([103]), de plus $U_1 \hookrightarrow X$ est bien W-lisse, étant une immersion ouverte.

p. 103

98. inutile.

99. NB On n'utilise pas vraiment que Q soit cocartésien, plutôt que Q est *cartésien,* et f_2 (donc aussi α_1) une immersion ouverte (resp. fermée), et que pour $y \in Y\backslash X_2$, $X_{1\,y}$ soit W-asphérique. (Dans le cas où Q est cocartésien, $X_{1\,y}$ est $\simeq e$.)

100. On a besoin ici de W(7 bis), forme directe, i.e. de Loc(6′a) (notation de XVI).

101. On n'a besoin que de la forme directe de W(7 bis), i.e. (notation de XVI) de Loc(6′a).

102. inutile.

103. On n'a pas même besoin de le savoir, cf. annotation marginale du corollaire 2.

Corollaire 4. (Moyennant W(7 bis) ([104]).) *Soit $U \overset{i}{\hookrightarrow} X$ une immersion ouverte telle que $T = X\backslash U$ soit isomorphe à la catégorie ponctuelle e. Pour que $i \in W$, il faut et il suffit que i soit W-asphérique, i.e. que U/t (où t est l'unique objet de T) soit W-asphérique.*

Il suffit bien sûr de prouver que

$$i \in W \Longrightarrow U/t \text{ } W\text{-asphérique.}$$

Considérons le carré cartésien [page 150]

$$\begin{array}{ccc} U/t & \xhookrightarrow{i/t} & X/t \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ U & \xhookrightarrow{i} & X, \end{array}$$

nous allons prouver qu'il est W-cocartésien. Moyennant W(7 bis), il s'ensuivra que $i \in W$ implique $i/t \in W$, et comme X/t est W-asphérique (ayant un objet final), cela signifie que U/t est W-asphérique, ce qu'on veut prouver.

Commentary · Examples [ms. 149]

Why the cover criterion needs no converse excision

Grothendieck's cover criterion is meant to provide a large supply of actual homotopy pushouts. The annotations correctly remove W(7 bis) from Corollaries 2 and 3, although the displayed proof still invokes it. The missing simplification is elementary: one of the maps in the only nontrivial fibre is an isomorphism, and that special case admits a direct contraction.

For a category A, consider

$$E = \int_{\mathrm{lis}} (A \xleftarrow{\mathrm{id}} A \longrightarrow e).$$

Keep the central copy A_0 and the outer point $*$, and call their full subcategory K. There is a unique arrow $* \to a$ for every $a \in A_0$, so $*$ is initial in K. Define $R : E \to K$ to be the identity on K and to send the outer copy $a \in A_1$ to its central copy in A_0. On mixed arrows it uses the corresponding arrow of A. The canonical transition arrows $a_1 \to a_0$ give a natural transformation $\mathrm{id}_E \to jR$, where $j : K \to E$ is the inclusion, and $Rj = \mathrm{id}_K$. Thus j and R are homotopy inverse after taking nerves. Since K has an initial object, E is W-aspherical for every fundamental localizer. This proof also covers $A = \emptyset$.

In Corollary 2, a point outside X_2 has integrated fibre e. At a point of X_2, cartesianness identifies $X_{0y} \to X_{1y}$ with an isomorphism, and the fibre is of the form just contracted. The three maps to Y are smooth: f_1 by hypothesis, f_2 because it is a sieve inclusion, and $f_0 = f_1\alpha_1$ by composition. The forward part of Theorem 4 therefore proves the conclusion without W(7 bis). This also establishes the stronger version recorded in footnote 99: strict cocartesianness may be replaced by cartesianness, the sieve condition on f_2, smoothness of f_1, and W-asphericity of X_{1y} outside X_2. In that version the exterior fibres need not be singletons.

For a cover $X = U_1 \cup U_2$ by sieves, there is a second, particularly transparent argument in ordinary homotopy theory. Every simplex $x_0 \to \cdots \to x_n$ in NX lies in a member of the cover containing x_n, because a sieve contains every predecessor of its objects. Therefore

$$NX = NU_1 \cup_{N(U_1 \cap U_2)} NU_2$$

is an equality of simplicial sets. The two inclusions are monomorphisms, so its realization is a pushout along subcomplex inclusions and computes the homotopy pushout. For cosieves one uses the first vertex x_0 instead. This calculation explains why categorical open and closed covers are especially well adapted to excision.

As a worked example, let X be the poset of nonempty proper faces of a tetrahedron. Let U_1 consist of the faces of one facet, and let U_2 consist of the faces of the other three facets. Both are downward closed, and their union is X. Their intersection is the face poset of the boundary of the

104. Ici on a besoin de W(7 bis) forme forte, i.e. $i_0 \in W \iff i \in W$ (cf. annotation th. 4).

first facet. The order complexes are barycentric subdivisions: BU_1 is one triangle, BU_2 is the disk made of the other three triangles, and $B(U_1 \cap U_2)$ is their common boundary circle. The integral therefore has homotopy type

$$D^2 \overset{h}{\underset{S^1}{\cup}} D^2 \simeq S^2,$$

and the canonical comparison identifies this sphere with BX, the subdivided tetrahedral boundary. The comparison is determined by the actual inclusions of face posets; it is not merely an abstract equivalence between two spaces known to be spheres.

Il suffit, en vertu du corollaire 2, de prouver que le carré est cocartésien dans Cat, puisque i/t est une immersion ouverte (i l'étant), et $X/t \longrightarrow X$ est un isomorphisme local, donc W-lisse. On voit que $(X/t)\backslash(U/t) \simeq e$ (catégorie ponctuelle), d'ailleurs l'unique élément de $(X/t)\backslash(U/t)$ est l'élément final $t_0 : t \xrightarrow{\mathrm{id}_t} t$ de X/t. Ainsi $H_{t_0} \simeq e_{U/t}$ (préfaisceau final), et $p_!(H_{t_0}) \simeq H'_t \overset{\text{déf}}{=} (u \longmapsto \mathrm{Hom}_X(u,t))$, ce qui caractérise la somme amalgamée dans Cat …

Le corollaire 4 n'est autre que le corollaire non démontré de la proposition 7 (p. 85).

Voici une variante du corollaire 4.

Corollaire 5. (Moyennant W(7 bis) ([105]).) *Soit $i : U \hookrightarrow X$ une immersion ouverte, soit $t_0 \in \mathrm{Ob}\, T$ un point* fermé *de $T = X\backslash U$, tel que $\{t_0\}$ soit isomorphe à la catégorie ponctuelle,* [page 151] *i.e.* $\mathrm{Hom}_X(t_0,t_0) = \{\mathrm{id}\}$. *Supposons que pour tout $t \in T\backslash\{t_0\}$, U/t soit W-asphérique. Pour que l'on ait $i \in W$, il faut et il suffit que i soit asphérique, i.e. que U/t_0 soit également W-asphérique.*

Il faut prouver que $i \in W$ implique que U/t_0 est W-asphérique. Considérons l'inclusion

$$i_0 : U \longrightarrow U' \overset{\text{déf}}{=} X\backslash\{t_0\},$$

l'hypothèse sur les U/t, pour $t \in T\backslash\{t_0\}$, signifie que i_0 est W-asphérique. Donc i_0 est dans W, et comme le composé $i : U \xrightarrow{i_0} U' \xrightarrow{i'} X$ est dans W, cela implique que $i' : U' \longrightarrow X$ p. 104 est dans W. Nous sommes maintenant dans la situation du corollaire 4, qui implique que i' est W-asphérique. Donc $i = i'i_0$ est W-asphérique, comme composé de deux morphismes W-asphériques, q.e.d.

Commentary · Exposition [ms. 151]

A single missing point and the role of the strong axiom

Grothendieck uses the preceding criterion to finish a result deferred earlier in the chapter. When only one object is missing, the slice over that object records every possible attachment to the open subcategory. The square on manuscript page 150 is consequently both a strict pushout and a homotopy pushout. The remaining implication is a reflection statement, and this is where the strong form of W(7 bis) enters.

Here is the strict pushout assertion in detail. Suppose $U \subset X$ is a sieve, its complement consists of one object t, and $\mathrm{End}_X(t) = \{\mathrm{id}_t\}$. Let $F : U \to Z$ and $G : X/t \to Z$ agree on U/t after projection to U. Define $H : X \to Z$ on U to be F, and set $H(t) = G(\mathrm{id}_t)$. For an arrow $a : u \to t$, define $H(a)$ to be the image under G of the canonical arrow from (u,a) to (t,id_t) in X/t. The source of this image is $F(u)$ by the agreement assumption. If $b : u' \to u$ lies in U, the factorization of $(u',ab) \to (t,\mathrm{id}_t)$ through (u,a) gives

$$H(ab) = H(a)F(b).$$

There are no arrows from t into U, since U is a sieve, and the only endomorphism at t is its identity. Thus these rules define a functor, and they determine it uniquely. This proves the pushout universal property of the slice square, without any appeal to the presheaf notation H_{t_0} used in the manuscript.

The projection $X/t \to X$ is a discrete fibration, hence smooth. Corollary 2 proves that this square is homotopy cocartesian without an extra excision hypothesis. If the lower inclusion $U \to X$

105. forme forte.

is in W, however, deducing that the upper inclusion $U/t \to X/t$ is in W is exactly a converse-excision step. Under strong W(7 bis), Proposition 13 supplies it. The target X/t has a final object, so U/t is then W-aspherical. Conversely, if U/t is W-aspherical, the inclusion $U \to X$ is W-aspherical: its slices at objects of U have final objects, and its only remaining slice is U/t. Theorem A gives the weak equivalence.

The reduction in Corollary 5 is now precise. Because t_0 is closed in $X \setminus U$ and U is a sieve, t_0 has no arrow to any other object of X. Hence $U' = X \setminus \{t_0\}$ is again a sieve. The hypotheses make $U \to U'$ aspherical. If $U \to X$ is in W, two-out-of-three makes $U' \to X$ a weak equivalence; Corollary 4 makes it aspherical. Composition then makes $U \to X$ aspherical, which supplies the remaining slice condition at t_0. The argument is complete under its stated strong hypothesis. It should not be read as a general converse to Theorem A for ordinary weak homotopy equivalences.

Démonstration de th. 4.

ⓐ Critère de lissité de $\varphi_Q : \mathcal{X} = \int \begin{array}{ccc} & & X_1 \\ & \nearrow & \\ X_0 & & \longrightarrow Y. \\ & \searrow & \\ & & X_2 \end{array}$

Comme $\{1\}$, $\{2\}$ sont des ouverts de $\Phi = \begin{array}{ccc} & & 1 \\ & \swarrow & \\ 0 & & \\ & \nwarrow & \\ & & 2 \end{array}$, $i_1 : X_1 \longrightarrow \mathcal{X}$ et $i_2 : X_2 \longrightarrow \mathcal{X}$ sont des immersions ouvertes. Comme $\varphi_Q \circ i_1 = f_1$, $\varphi_Q \circ i_2 = f_2$, on voit déjà que [page 152]

f_1 et f_2 lisses $\iff$ φ_Q lisse sur l'ouvert réunion de $i_1(X_1)$ et $i_2(X_2)$, i.e. sur $\mathcal{X} \setminus i_0(X_0)$.

Il reste à exprimer la lissité de φ_Q en les points x_0 de $i_0(X_0)$. Soient x_1, x_2, y les images de x_0 dans X_1, X_2, Y respectivement. Il faut exprimer que les fibres de

$$(*) \qquad (\varphi_Q)/x_0 : \mathcal{X}/x_0 \longrightarrow Y/y$$

sont asphériques. Nous allons pour cela expliciter $\mathcal{X}/x_0$ et la flèche $(*)$ en termes du carré commutatif

$$(**) \qquad \begin{array}{ccc} X_0/x_0 & \xrightarrow{\alpha_1/x_0} & X_1/x_1 \\ {\scriptstyle \alpha_2/x_0}\downarrow & & \downarrow{\scriptstyle f_1/x_1} \\ X_2/x_2 & \xrightarrow{f_2/x_2} & Y/y, \end{array}$$

induit par Q. Je dis

Lemme 1. *Soit un carré commutatif*

$$Q \quad = \quad \begin{array}{ccc} X_0 & \xrightarrow{\alpha_1} & X_1 \\ {\scriptstyle \alpha_2}\downarrow & & \downarrow{\scriptstyle f_1} \\ X_2 & \xrightarrow{f_2} & Y \end{array}$$

dans Cat, $x_0 \in \mathrm{Ob}\, X_0$, *$x_1$, x_2, y ses images dans X_1, X_2, Y respectivement, Q/x_0 le carré* $(**)$ *ci-dessus, induit par Q sur les localisées X_0/x_0 etc., $\mathcal{X} = \int \begin{array}{ccc} & & X_1 \\ & \nearrow & \\ X_0 & & \\ & \searrow & \\ & & X_2 \end{array}$. On a alors un* p. 105 [page 153]

isomorphisme canonique

$$\mathcal{X}/x_0 \quad \simeq \quad \int \begin{array}{ccc} & & X_1/x_1 \\ X_0/x_0 & \nearrow & \\ & \searrow & \\ & & X_2/x_2 \end{array} \quad ,$$

et la flèche $(\varphi_Q)/x_0$, localisée de $\varphi_Q : \mathcal{X} \longrightarrow Y$ en x_0, s'identifie à la flèche $\varphi_{(Q/x_0)}$:

$$\varphi_{(Q/x_0)} : \quad \int \begin{array}{ccc} & & X_1/x_1 \\ X_0/x_0 & \nearrow & \\ & \searrow & \\ & & X_2/x_2 \end{array} \quad \longrightarrow \quad Y/y.$$

Démonstration du Lemme. On sait que

$$\mathcal{X}/x_0 \longrightarrow \mathcal{X}$$

est Cat-fibrée (scindée) (à fibres discrètes), et comme

$$\mathcal{X} \longrightarrow \Phi$$

est aussi Cat-fibrée (scindée), il s'ensuit qu'il en est de même de la flèche composée

$$\mathcal{X}/x_0 \longrightarrow \Phi.$$

Donc pour 'calculer' $\mathcal{X}/x_0$, en tant que catégorie sur Φ, il faut expliciter ses trois fibres, et les deux foncteurs de changement de base qui les relient. On trouve aussitôt que ces fibres sont canoniquement isomorphes à

$$X_0/x_0, \qquad X_1/x_1, \qquad X_2/x_2,$$

et on admettra (!) que les foncteurs changement de base

$$X_0/x_0 \longrightarrow X_1/x_1, \qquad X_0/x_0 \longrightarrow X_2/x_2$$

(définis à isomorphisme unique près) ne sont autres que les localisés α_1/x_0 et α_2/x_0 de $\alpha_1 : X_0 \longrightarrow X_1$ et $\alpha_2 : X_0 \longrightarrow X_2$. Cela montre donc qu'on a un isomorphisme [page 154]

$$\mathcal{X}/x_0 \quad \simeq \quad \int \begin{array}{ccc} & & X_1/x_1 \\ X_0/x_0 & \nearrow & \\ & \searrow & \\ & & X_2/x_2 \end{array} \quad ,$$

et l'on admettra aussi que la flèche $(\varphi_Q)/x_0 : \mathcal{X}/x_0 \longrightarrow Y/y$ s'identifie à $\varphi_{(Q/x_0)}$.

Pour exprimer la W-lissité de φ_Q en $x_0 \in \mathrm{Ob}\, X_0 \subseteq \mathrm{Ob}\, \mathcal{X}$, on est donc ramené à exprimer la W-asphéricité des fibres de

$$\varphi_{(Q/x_0)} : \quad \int \begin{array}{ccc} & & X_1/x_1 \\ X_0/x_0 & \nearrow & \\ & \searrow & \\ & & X_2/x_2 \end{array} \quad \longrightarrow \quad Y/y. \qquad \text{p. 106}$$

Pour expliciter ces fibres, on a besoin d'un autre lemme auxiliaire

Commentary · Exposition [ms. 154]

The slice of the integral, with its arrows

Grothendieck is reducing smoothness to a calculation at one object. The reduction succeeds because the smooth integral remembers the arrows into the central stratum, rather than merely the three categories as disjoint pieces. We make this calculation explicit; it supplies both identifications which the proof asks us to admit.

Write E for the smooth integral of $X_0 \xrightarrow{\alpha_i} X_i$, $i = 1, 2$. Its objects are the tagged objects of the three categories. Arrows within a stratum are the original arrows, and the additional hom-sets are

$$\mathrm{Hom}_E((i,b),(0,a)) = \mathrm{Hom}_{X_i}(b, \alpha_i a), \qquad i = 1, 2.$$

There are no arrows in the reverse direction or between the two outer strata. Composition is composition in X_i, using α_i when a central arrow is involved. Thus the cartesian arrow over $i \to 0$ has the direction

$$(i, \alpha_i a) \longrightarrow (0, a).$$

The arrows printed in the opposite direction on manuscript page 155 are an edition slip, not a different convention for this integral. The functor $\varphi_Q : E \to Y$ sends an additional arrow represented by $h : b \to \alpha_i a$ to $f_i(h)$, whose target is $f_i\alpha_i(a) = f_0(a)$. In particular it sends the cartesian arrow just displayed to an identity. This is the property which the source notices it had left implicit.

Fix $x_0 \in X_0$ and put $x_i = \alpha_i x_0$. An object of E/x_0 in the central stratum is precisely an arrow $g : a \to x_0$ in X_0. An object in stratum i is an arrow $h : b \to x_i$ in X_i. A cross-stratum morphism from h to g is an arrow $k : b \to \alpha_i a$ satisfying

$$(\alpha_i g)k = h.$$

This is exactly a morphism from h to the image of g in X_i/x_i. Within each stratum we have the ordinary slice morphisms. These descriptions identify objects, hom-sets, identities, and compositions, giving the asserted canonical isomorphism

$$E/x_0 \cong \int_{\mathrm{li}} (X_0/x_0 \longrightarrow X_1/x_1,\ X_0/x_0 \longrightarrow X_2/x_2).$$

Under it the functor to Y/y, $y = f_0 x_0$, sends g to $f_0 g$ and h to $f_i h$; on a cross-stratum arrow it is $f_i k$. This proves the compatibility with φ_{Q/x_0} as well as the isomorphism of the source categories.

The same description proves Lemma 2 without a further coherence argument. The strict fibre over y consists of objects mapping to y and arrows mapping to 1_y. A cross-stratum arrow belongs to this fibre exactly when its representing arrow in X_i does. Consequently

$$E_y \cong \int_{\mathrm{li}} (X_{0y} \longrightarrow X_{1y},\ X_{0y} \longrightarrow X_{2y}).$$

Strict fibres need not be full subcategories. For instance, the strict fibre of the identity functor of a one-object group category over its object is the terminal category, whereas the full subcategory on that object is the whole group category. Keeping the identity condition on arrows is essential in the present calculation.

For an arrow $u : y' \to y$, set

$$A_i(u) = (X_i/x_i)_u.$$

Its objects are arrows $a \to x_i$ whose image is exactly u; its morphisms are commuting triangles whose remaining edge maps to $1_{y'}$. The preceding two identifications now give, with no choices,

$$(E/x_0)_u \cong \int_{\mathrm{li}} (A_0(u) \longrightarrow A_1(u),\ A_0(u) \longrightarrow A_2(u)).$$

This is the precise local input to the smoothness criterion. For the later systematic treatment, the locality of smoothness under passage to slices is Proposition 4.10 of Maltsiniotis (2005); the argument here retains the additional explicit description needed for this particular integral.

Lemme 2 ([106]). *Soit un carré commutatif dans* Cat

$$Q \quad = \quad \begin{pmatrix} X_0 & \xrightarrow{\alpha_1} & X_1 \\ {\scriptstyle\alpha_2}\downarrow & & \downarrow{\scriptstyle f_1} \\ X_2 & \xrightarrow{f_2} & Y \end{pmatrix},$$

d'où

$$\varphi_Q : \quad \left(\int \begin{array}{ccc} & & X_1 \\ X_0 & \nearrow & \\ & \searrow & \\ & & X_2 \end{array} \right) \quad \longrightarrow \quad Y,$$

et soit $y \in \operatorname{Ob} Y$. Alors la fibre de φ_Q en y [page 155]

$$\mathcal{X}_y = \varphi_Q^{-1}(\underbrace{\{y\}}_{\text{catégorie ponctuelle}})$$

est donnée par (comme catégorie au dessus de Φ)

$$\mathcal{X}_y \quad \simeq \quad \int \begin{array}{ccc} & & X_{1\,y} \\ X_{0\,y} & \nearrow & \\ & \searrow & \\ & & X_{2\,y} \end{array} .$$

Démonstration. Il est immédiat qu'on a

$$\mathcal{X}_y \cap \underbrace{\mathcal{X}_s}_{X_s} \simeq (X_s)_y \qquad \text{pour } s \in \operatorname{Ob}\Phi = \{0,1,2\},$$

et (le hasard fait bien les choses) les foncteurs changement de base

$$X_0 \longrightarrow X_1, \qquad X_0 \longrightarrow X_2$$ p. 107

envoient la sous-catégorie (non pleine) $X_{0\,y}$ de X_0 dans les sous-catégories (non pleines) $X_{1\,y}$ et $X_{2\,y}$ de X_1 et X_2 respectivement.

$$\begin{array}{ccccc} X_{s\,y} & \longrightarrow & \mathcal{X}_y & \longrightarrow & \{y\} \\ \downarrow & \text{cart.} & \downarrow & \text{cart.} & \downarrow \\ X_s & \longrightarrow & \mathcal{X} & \longrightarrow & Y \\ \downarrow & \text{cart.} & \downarrow & & \\ \{s\} & \longrightarrow & \Phi & & \end{array}$$

On a donc une sous-catégorie fibrée de $\mathcal{X}$, sous réserve de vérifier que les flèches strictement cartésiennes

$$x_0 \longrightarrow \alpha_1(x_0), \qquad x_0 \longrightarrow \alpha_2(x_0)$$

dans $\mathcal{X}$, pour x_0 dans $X_{0\,y}$, sont dans $\mathcal{X}_y$, i.e. sont au-dessus de la flèche identique de y. Or c'est là la propriété essentielle du foncteur $\varphi_Q : \mathcal{X} \longrightarrow Y$, qu'on a oublié d'expliciter dans 3.2.

106. NB C'est le b) du th. 4. [page 156]

Ça a vraiment l'air de marcher (comme sur des roulettes!)

Appliquons le Lemme 2 au diagramme carré Q/x_0 et à $\varphi_{(Q/x_0)}$ (page 154), on voit donc que les fibres à examiner en les $u \in \mathrm{Ob}\, Y/y$ $(u : y' \longrightarrow y)$ peuvent s'écrire comme les intégrales

$$\mathcal{X}(x_0,u) \overset{\text{déf}}{=} \int \begin{array}{ccc} & & (X_1/x_1)_u \\ & \nearrow & \\ (X_0/x_0)_u & & \\ & \searrow & \\ & & (X_2/x_2)_u \end{array} .$$

Utilisons maintenant le fait que f_1, f_2 sont W-lisses (exprimant que φ_Q est W-lisse dans $\mathcal{X}\backslash X_0$), donc que $(X_1/x_1)_u$ et $(X_2/x_2)_u$ sont W-asphériques. Dans le carré W-cocartésien

$$\begin{array}{ccc} & (X_1/x_1)_u & \\ {\scriptstyle \alpha_1(x_0,u)} \nearrow & & \searrow {\scriptstyle i_1(x_0,u)} \\ (X_0/x_0)_u & & (\mathcal{X}/x_0)_u \simeq \mathcal{X}(x_0,u) \\ {\scriptstyle \alpha_2(x_0,u)} \searrow & & \nearrow {\scriptstyle i_2(x_0,u)} \\ & (X_2/x_2)_u & \end{array}$$

([107]), il faut exprimer que $(\mathcal{X}/x_0)_u$ est W-asphérique, sachant que $(X_1/x_1)_u$ et $(X_2/x_2)_u$ le sont. Donc cela équivaut à p. 108

$$i_1(x_0,u) \in W \qquad (\text{ou } i_2(x_0,u) \in W),$$

donc aussi (moyennant W(7 bis)) à [page 157]

$$\alpha_1(x_0,u) \in W, \qquad \text{i.e. } (X_0/x_0)_u \text{ } W\text{-asphérique.}$$

Dire que c'est vrai pour tout u dans Y/y, signifie que $f_0 : X_0 \longrightarrow Y$ est lisse en u `[plutôt en` x_0`]`.

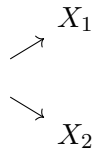
Donc on a prouvé a), sous la forme plus précise :

Commentary · Exposition [ms. 157]

Repairing the noncommuting fibre square

The aim of the calculation on page 156 is to reconstruct smoothness at the central object from smoothness on the three pieces. The displayed diamond cannot itself be used as a commutative square: its two composites land in different outer strata of the integral. They are related to the inclusion of the central stratum by cartesian natural transformations. Footnote 107 correctly withdraws that use of the square.

Here is the direct argument, with its hypotheses visible. Suppose f_i is W-smooth at x_i for $i = 0, 1, 2$. For every $u : y' \to y$, all three categories $A_i(u)$ from the preceding block are W-aspherical. Their smooth integral L_u is a split fibration over $\Phi = (1 \to 0 \leftarrow 2)$, hence is W-smooth. For each $s \in \Phi$, smoothness identifies its strict fibre, up to a W-equivalence, with the comma category $s\backslash L_u$. These comma categories are therefore W-aspherical. The dual form of the relative Theorem A gives $L_u \to \Phi$ in W. Since 0 is final in Φ, L_u is W-aspherical. The slice calculation identifies L_u with $(E/x_0)_u$, proving smoothness of φ_Q at x_0. No pushout reflection axiom has entered.



107. attention, ce n'est pas un carré commutatif. Dire plutôt que $(\mathcal{X}/x_0)_u \simeq \int \begin{array}{cc} \nearrow & \\ & \searrow \end{array}$ est lisse sur Φ à fibres W-asphériques (si f_0, f_1, f_2 sont lisses), donc W-asphérique puisque Φ l'est.

For the converse, suppose the two outer maps are smooth at x_1, x_2, and retain the *strong* form of W(7 bis) stipulated in the source. Then $A_1(u)$ and $A_2(u)$ are W-aspherical. Proposition 13, applied to their integral and its closed mapping-cylinder replacement, gives

$$A_1(u) \longrightarrow L_u \text{ in } W \quad \Longleftrightarrow \quad A_0(u) \longrightarrow A_2(u) \text{ in } W.$$

The left side is equivalent to asphericity of L_u, and the right side to asphericity of $A_0(u)$, by two-out-of-three. This proves the asserted equivalence. It applies Proposition 13 to the correctly constructed integral; it does not promote the original noncommuting diamond to a strict square. The reverse implication is a reflection statement, stronger than the preservation statement used in the direct proof. The counterexample to strong reflection discussed earlier in the commentary on this chapter explains why it cannot be transferred without its hypothesis to ordinary weak homotopy equivalences.

At an outer object x_i, every arrow with target x_i already belongs to X_i, since that stratum is open. Hence $E/x_i = X_i/x_i$, and local smoothness is exactly that of f_i. At a central object the hypotheses on both outer objects remain necessary for the converse equivalence just established. The final sentence after Corollary 6 drops them, as the editorial annotation observes; the following finite example measures precisely what is lost.

Corollaire 6. *Soit* $x \in \mathrm{Ob}\,\mathcal{X}$ *(où* $\mathcal{X} = \int$  *.) On veut exprimer la* W*-lissité de*

$$\varphi_Q : \mathcal{X} \longrightarrow Y$$

en x*.*

a) Si $x \in \mathrm{Ob}\,X_i$ *(*$i \in \{1,2\}$*),* φ_Q *est* W*-lisse en* x *si et seulement si* $f_i : X_i \longrightarrow Y$ *l'est.*

b) Supposons W(7 bis) ([108])*. Soit* $x_0 \in \mathrm{Ob}\,X_0$*, et supposons* f_1*,* f_2 *lisses en* x_1*,* x_2*. Alors* φ_Q *est* W*-lisse en* x_0 *si et seulement si* $f_0 : X_0 \longrightarrow Y$ *l'est.*

Donc (moyennant W(7 bis)) *dans les trois cas* $x \in \mathrm{Ob}\,X_i$ *(*$i \in \{0,1,2\}$*) on trouve que* φ_Q *est* W*-lisse en* x *si et seulement si* $f_i : X_i \longrightarrow Y$ *l'est* `[pas vraiment pour` $i = 0$`]`.

ⓑ Quant à b) du théorème 4, c'est le lemme 2 ci-dessus. Donc tout est prouvé!

[page 158]

Commentary · Development (commentators') [ms. 157]

A finite witness for the missing outer hypothesis

Grothendieck has isolated a useful local criterion, but the final formulation would make the middle map alone control the whole neighbourhood. We give a small witness showing why the two outer hypotheses must stay in the statement. We did not find this particular finite witness in the smoothness discussion of Maltsiniotis (2005) or the integration discussion of Cisinski (2006a, §3.3); it is an elementary application of their criteria, not a claim of priority.

Proposition (failure of the unconditional central criterion). [ours] Let W be a fundamental localizer satisfying W(5), so that every W-equivalence induces a bijection on connected components. There is a commutative square of finite posets for which f_0 is smooth and f_2 is smooth, but the smooth integral map φ_Q is not W-smooth at an object of the central stratum.

Proof. Let $Y = X_0 = X_2 = [1] = (0 \to 1)$, with $f_0 = f_2 = \alpha_2 = 1$. Let X_1 be the poset with objects a, b, c and only nonidentity relations $a < c$ and $b < c$. Define

$$f_1(a) = f_1(b) = 0, \qquad f_1(c) = 1, \qquad \alpha_1(0) = a, \quad \alpha_1(1) = c.$$

Both nonidentity arrows of X_1 map to $u : 0 \to 1$. These formulas define functors and give $f_1\alpha_1 = 1_Y$, so the required square commutes. Identity functors are smooth; this proves the assertions about f_0 and f_2.

108. Inutile pour la partie directe, en supposant `[phrase incomplète]`.

Take $x_0 = 1$, $x_1 = c$, $x_2 = 1$ and the arrow $u : 0 \to 1$ in Y. The three strict lift categories are

$$A_0(u) = e, \qquad A_1(u) = \{a \to c,\ b \to c\}_{\mathrm{disc}}, \qquad A_2(u) = e.$$

The first map chooses $a \to c$, and the second is the unique map between terminal categories. Their smooth integral has four objects: a central object z, outer objects a_*, b_* in stratum 1, and d_* in stratum 2. Its only nonidentity arrows are

$$a_* \longrightarrow z \longleftarrow d_*.$$

The object b_* is isolated. Thus its connected-component set has two elements. By W(5) it is not W-aspherical. The slice identification gives this category as $(E/x_0)_u$, which violates the defining local smoothness test. □

The failure occurs in a missing lift relation at the first outer stratum. It involves no question about strictification and no exotic homotopy type. In Corollary 6(b), the assumption that f_1 is smooth at x_1 excludes exactly this additional component.

3.5 Applications aux sommes amalgamées dans une catégorie $X^\wedge$ (avec $X \in \mathrm{Ob}\,\mathrm{Cat}$).

D'abord une caractérisation des sommes amalgamées impliquant une immersion ouverte :

Proposition 15. *Soit* p. 109

$$Q : \qquad \begin{array}{ccc} U & \xrightarrow{\ i\ } & X \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ U' & \xrightarrow{\ i'\ } & X' \end{array}$$

un carré commutatif dans Cat. *Pour que ce carré soit cocartésien dans* Cat, *avec i (donc i') une immersion ouverte, il faut et il suffit que les conditions suivantes soient satisfaites :*

a) Q est cartésien.

b) i' est une immersion ouverte (donc i aussi).

c) Si $T' = X'\backslash U'$, et $T = X \times_{X'} T' = X\backslash U$, $T \longrightarrow T'$ est un isomorphisme.

d) Pour tout $t \in T$, si t' est son image dans T', le foncteur induit par p

$$p/t : \underbrace{U/t}_{=V_t} \longrightarrow \underbrace{U'/t'}_{=V'_{t'}}$$

satisfait à $(p/t)_!(e_{U/t}) \simeq e_{U'/t'}$, ou ce qui revient au même, les 'fibres colocales' de p/t, $v'\backslash V_t$, avec v' dans $V'_{t'}$, sont 0-connexes.

Démonstration immédiate - ça devrait plutôt remonter au §1. [page 159]

Commentary · Exposition [ms. 158]

Gluing the morphisms across an open immersion

Grothendieck now changes scale: the homotopical assertion will rest on an ordinary categorical pushout. An open immersion $U \hookrightarrow X$ is a full sieve. Its complementary full subcategory T is a cosieve; there are no arrows from T to U. Thus X is specified by U, T, and the bifunctor of crossing arrows

$$H : U^{\mathrm{op}} \times T \longrightarrow \mathrm{Set}, \qquad H(u,t) = \mathrm{Hom}_X(u,t).$$

Precomposition and postcomposition encode every composition involving a crossing arrow. This description explains the four conditions in Proposition 15: the first three identify the two pieces, while the fourth identifies the arrows joining them.

Assume first that Q is cartesian, that $U' \hookrightarrow X'$ is open, and that the induced map $T \to T'$ is an isomorphism. Identify T with T' by this specified map. For $t \in T$, let H_t and H'_t be the presheaves $\mathrm{Hom}_X(-,t)$ and $\mathrm{Hom}_{X'}(-,t)$ on U and U'. The square supplies a natural comparison

$$p_! H_t \longrightarrow H'_t.$$

The universal category obtained by pushing $U \hookrightarrow X$ along p has pieces U' and T and crossing-arrow presheaf $p_! H_t$. Indeed, a functor from this category to Z is a pair of functors on U' and T, together with compatible images of crossing arrows; by the defining adjunction of $p_!$, these data are exactly a functor $X \to Z$ and a functor $U' \to Z$ agreeing on U. Composition with arrows of T is preserved because H_t varies functorially with t. This proves the universal property, not merely an objectwise description. Consequently Q is a pushout precisely when all the displayed comparisons are isomorphisms.

We can test these comparisons by explicit factorization categories. An element of $(p_! H_t)(u')$ is represented by a pair

$$b : u' \longrightarrow p(u), \qquad a : u \longrightarrow t,$$

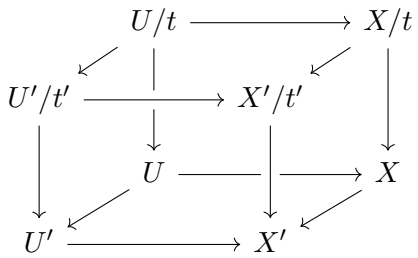
modulo the relation generated by morphisms $h : u \to v$ with $a = a_v h$ and $p(h)b = b_v$. Its image is the composite $q(a)b : u' \to t$ in X'. Fix such a composite $a' : u' \to t$. The category of its representatives and these morphisms is exactly

$$(u', a')\backslash(U/t),$$

where $U/t \to U'/t$ is induced by p. Thus the fibre of the comparison over a' is the set of connected components of this category. The comparison is bijective for every u' if and only if every such category is nonempty and connected. This proves condition (d), including the equivalence with $(p/t)_! e = e$.

Conversely, the explicit universal category just constructed has U' as a full sieve, has complement exactly T, and its inverse image of U' is exactly U. Hence a pushout along $U \hookrightarrow X$ necessarily satisfies (a)–(c); its crossing-arrow comparison is an isomorphism, so it also satisfies (d). This completes both directions of Proposition 15. The argument is entirely about ordinary categories and ordinary left Kan extension.

There is a small example showing why the last condition cannot be omitted. Take $U = U' = e$, X the discrete category on u, t, and $X' = (u \to t)$, with q the identity on objects and $p = 1$. The square is cartesian; both open subcategories are $\{u\}$, and the complements are the same terminal category. But U/t is empty whereas $U'/t = e$. The missing crossing arrow makes the factorization category empty, so (d) fails. The pushout along the identity p is X, not X'. The condition about connected factorization categories is exactly the information which the object sets and the two strata do not contain.



Corollaire 1. *Soit Q un carré* cartésien (cf. page 158), *avec i' une* immersion ouverte *(donc i aussi), et q W-*lisse *(donc p aussi). On suppose que W satisfait l'axiome* W(5) *de connexité* ([109]). *Soit $T' = X'\backslash U'$, $T = X\backslash U$, supposons que $T' \longrightarrow T$ soit un isomorphisme. Alors Q est cocartésien.*

Il suffit de prouver la condition d) de prop. 15. Considérons le carré

$$(*) \qquad \begin{array}{ccc} U/t & \xrightarrow{i/t} & X/t \\ {\scriptstyle p/t}\downarrow & & \downarrow{\scriptstyle q/t} \\ U'/t' & \xrightarrow{i'/t'} & X'/t', \end{array}$$

je dis qu'il est *cartésien.* Cela résulte de la seule hypothèse que Q soit cartésien, sans hypothèse de lissité sur q ni que i' soit une immersion ouverte, et se voit p. ex. en regardant le diagramme cubique : p. 110

109. Donc il suffit q W_0-lisse, où $W_0 = \{f \in \mathrm{FlCat} \mid \pi_0(f) \text{ bijectif}\}$.

([110]). Dans ce diagramme, la face antérieure et postérieure du cube est cartésienne, par définition de U/t et de U'/t' respectivement, et la base l'est par hypothèse. Il en résulte que [page 160] la face supérieure du cube est également un carré cartésien.

Ceci vu, commme q est lisse, il en est de même de q/t dans le carré cartésien $(*)$, donc aussi de p/t par changement de base. D'autre part, la lissité de q implique que q/t est à fibres W-asphériques, donc par changement de base il en est de même de p/t (qui est donc une W-équivalence universelle, i.e. une W-fibration triviale). De plus, à cause de la lissité de p/t, pour v' dans U'/t', l'inclusion

$$(U/t)_{v'} \longrightarrow v'\backslash(U/t)$$

est dans W, donc (par W(5)) définit une bijection sur les π_0. Comme $(U/t)_{v'}$ est W-asphérique par ce qui précède, il s'ensuit (par W(5)) que son π_0 est de cardinal 1, donc il en est de même de $v'\backslash(U/t)$, i.e. celui-ci est 0-connexe. Or c'est là la condition d) de la proposition 15, qu'il fallait établir.

[page 161]

Corollaire 2. *Soit Q un carré cartésien* (p. 158), *avec i' (donc aussi i) une immersion ouverte, et q (donc aussi p) un* isomorphisme local. *Soit $T = X\backslash U$, $T' = X'\backslash U'$ (donc $T \simeq X \times_{X'} T'$), et supposons $T' \longrightarrow T$ isomorphisme. Alors Q est cocartésien.*

C'est un cas particulier du corollaire 1, mais sans référence explicite à un localiseur W. On peut pendre $W = W_\infty$, ou $W = W_0$, pour se ramener au corollaire 1. Mais il est plus raisonnable de dire que dans le carré cartésien $(*)$, l'hypothèse que q soit un isomorphisme local implique que q/t est un isomorphisme, donc p/t l'est aussi. Il en résulte bien que les $v'\backslash(U/t)$ sont 0-connexes, cette catégorie étant isomorphe à $v'\backslash(U'/t')$, donc a un objet initial.

Commentary · Exposition [ms. 161]

From smoothness to the connected factorization test

The two corollaries of Proposition 15 replace its explicit factorization condition by familiar geometric hypotheses. Their force is that a condition on the ambient map q controls every crossing arrow simultaneously.

For a cartesian square Q and an object $t \in X$, the square of slices displayed on page 159 is cartesian. An object of its pullback is an arrow $x \to t$ in X together with a chosen lift of its image-source to U'; the cartesian property of Q identifies that choice with an object of U lying above x. The same description of morphisms gives the isomorphism with U/t. No smoothness is needed for this step.

If q is W-smooth, then $q/t : X/t \to X'/t'$ is W-smooth and has W-aspherical strict fibres. The first assertion is locality of smoothness on slices; the second is its defining lift-category test at t. Both statements are inherited by the pullback p/t. For $v' \in U'/t'$, smoothness gives a W-equivalence

$$(U/t)_{v'} \longrightarrow v'\backslash(U/t).$$

Its source is W-aspherical, so its target is too. W(5) converts this into the required statement that the target has exactly one connected component. Proposition 15 then proves that Q is cocartesian. Only the connectedness part of smoothness is used: as footnote 109 says, W_0-smoothness is sufficient.

For a local isomorphism q, the entire slice map q/t is an isomorphism, and so is p/t. In that case every factorization category $v'\backslash(U/t)$ has an initial object. This gives the second corollary without any localizer. The later formulation that local isomorphisms are smooth is Maltsiniotis

110. NB Ici t est un élément quelconque de $\mathrm{Ob}\, X$, t' son image dans X'.

(2005, Proposition 4.9), but the direct slice argument also explains the stronger ordinary conclusion needed here.

The arrows on complements in the statements of both corollaries are printed $T' \to T$. The map induced by the square is $T \to T'$, as in Proposition 15(c) and in the application on page 166. The condition is that this induced map be an isomorphism. Its inverse then exists, but no inverse map is part of the initial data. We retain the printed direction in the text and record the correction in the register.

Soit maintenant X un objet de Cat, et considérons un diagramme cocartésien dans $X^\wedge$:

$$(*) \qquad \begin{array}{ccc} G & \xrightarrow{\ i\ } & F \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ G' & \xrightarrow{\ i'\ } & F', \end{array}$$

où i est un monomorphisme. On sait que le caractère cocartésien du carré se vérifie 'argument par argument' par le caractère cocartésien de p. 111 [page 162]

$$(*) \qquad \begin{array}{ccc} G(x) & \xrightarrow{\ i(x)\ } & F(x) \\ {\scriptstyle p(x)}\downarrow & & \downarrow{\scriptstyle q(x)} \\ G'(x) & \xrightarrow{\ i'(x)\ } & F'(x), \end{array}$$

dans Ens, $\forall\, x$ dans X. Or un tel carré cocartésien dans Ens, avec $i(x)$ [un] monomorphisme, est aussi cartésien. Cela implique que le carré Q dans $X^\wedge$ est également cartésien.

Considérons, d'autre part, le foncteur canonique

$$\varphi_X : F \longmapsto X/F : X^\wedge \longrightarrow \mathrm{Cat}.$$

Il vaut mieux, d'ailleurs, le regarder comme un foncteur

$$\varphi_X : X^\wedge \longrightarrow \mathrm{Cat}/X,$$

et je rappelle, pour mémoire, que ce foncteur est pleinement fidèle, et que son image essentielle est formée des catégories X' sur X telles que

$$X' \longrightarrow X$$

soit un isomorphisme local, ou ce qui revient au même, que X' soit *fibrée* sur X à fibres discrètes : [page 163]

$$\varphi_X : X^\wedge \xrightarrow{\ \sim\ } \underbrace{\underline{\text{Fib disc}}\, X}_{\substack{\text{catégories fibrées} \\ \text{à fibres discrètes}}} .$$

Notons que toute flèche $X' \longrightarrow X''$ dans $\underline{\text{Fib disc}}\, X$ est un isomorphisme local (tautologique sur $X'/x' \longrightarrow X''/x''$), ce qui montre que si on a un diagramme

$$\begin{array}{ccc} X'/x' & \longrightarrow & X''/x'' \\ & {\scriptstyle \text{iso.}}\searrow \quad \swarrow{\scriptstyle \text{iso.}} & \\ & X/x & \end{array}$$

$$\begin{array}{ccc} X_1 & & X_2 \\ & \searrow \quad \swarrow & \\ & X_0 & \end{array}$$

dans $\underline{\text{Fib disc}}\, X$, le produit fibré $X_3 = X_1 \times_{X_0} X_2$ dans Cat est tel que $X_3 \longrightarrow X_2$ est un isomorphisme local, donc aussi $X_3 \longrightarrow X$. C'est-à-dire $\underline{\text{Fib disc}}(X)$ est stable par produits p. 112 [page 164]

fibrés. Ceci implique que les produits fibrés existent dans $\underline{\text{Fib disc}}\, X$, et que ce sont les produits fibrés dans Cat, ou dans Cat/X.

De même pour les produits finis dans $\underline{\text{Fib disc}}\, X$, ce sont les produits finis dans Cat/X. Bref

Lemme 1. *La sous-catégorie pleine* $\underline{\text{Fib disc}}\, X$ *de* Cat/X *est stable par* $\varprojlim$ *finies, donc les* $\varprojlim$ *existent dans* $\underline{\text{Fib disc}}\, X$ *et le foncteur d'inclusion*

$$\underline{\text{Fib disc}}\, X \longrightarrow \text{Cat}/X$$

y commute, et en particulier transforme carrés cartésiens de $\underline{\text{Fib disc}}\, X$ *en carrés cartésiens de* Cat/X*, ou ce qui revient au même, de* Cat*. De plus, en vertu de l'équivalence*

$$\varphi_X : X^\wedge \xrightarrow{\sim} \underline{\text{Fib disc}}\, X \hookrightarrow \text{Cat}/X,$$

le foncteur φ_X *de* $X^\wedge$ *dans* Cat/X *est exacte à gauche, en particulier il transforme carrés cartésiens de* $X^\wedge$ *en carrés cartésiens de* Cat/X*, ou encore de* Cat*.*

Notons aussi qu'étant exact à gauche, le foncteur φ_X de $X^\wedge$ dans Cat/X transforme monomorphismes en monomorphismes. D'autre part : [page 165]

Commentary · Later developments [ms. 164]

The exactness of the category of elements

Grothendieck's finite-limit lemma is the first part of a stronger known statement. The relative category-of-elements functor

$$j_X : \widehat{X} \longrightarrow \text{Cat}/X, \qquad F \longmapsto (X/F \to X),$$

preserves all small limits and colimits. This is Proposition 3.2.12 of Cisinski (2006a), in the published version, page 141. The absolute functor $i_X : F \mapsto X/F$ preserves colimits and pullbacks, and has the right adjoint stated in Corollary 3.2.13, page 142. We spell out the mechanism because it will also explain the pushout in Theorem 5.

An object of X/F is (x, a) with $a \in F(x)$. An arrow $(x, a) \to (y, b)$ is an arrow $u : x \to y$ such that $F(u)b = a$. Thus an n-simplex of its nerve is uniquely determined by a chain in X and the element at its last vertex:

$$N(X/F)_n \cong \coprod_{x_0 \to x_1 \to \cdots \to x_n} F(x_n).$$

All earlier elements are recovered by restriction. The final face uses the last restriction map of F; the other face and degeneracy maps change the underlying chain. The displayed bijections therefore define the nerve functor, not just its degreewise cardinalities.

Colimits of presheaves are evaluated pointwise, and coproducts commute with colimits. It follows that $N(X/F)$ preserves every small colimit in F. A cocone of nerves whose colimit is again a nerve is also a colimit cocone in categories: apply the fully faithful nerve to maps into an arbitrary target category. This proves the colimit assertion for i_X, and the cocones retain their maps to X, proving it for j_X as well. For limits over X, work over the fixed simplicial set NX. The fibre in degree n above a specified chain is $F(x_n)$, so limits are again calculated pointwise. Since the nerve creates limits, this proves the limit assertion for j_X.

For completeness, the absolute right adjoint is

$$R_X(C)(x) = \text{Fun}(X/x, C),$$

where the right side is the set of functors. For $u : x \to y$, restriction is precomposition with $X/x \to X/y$. A functor $H : X/F \to C$ assigns to $a \in F(x)$ the composite

$$X/x \longrightarrow X/F \xrightarrow{H} C, \qquad (z \xrightarrow{v} x) \longmapsto (z, F(v)a).$$

These assignments form a map $F \to R_X(C)$. Conversely, given such a map, evaluate its functor at 1_x to obtain the image of (x, a). An arrow $u : (x, a) \to (y, b)$ is sent to the arrow in the assigned functor on X/y from u to 1_y. Naturality gives the correct source and ensures preservation of identities and compositions. The two constructions are inverse. This proves the adjunction directly.

The relative target matters for products: $X/(F \times G)$ is the fibre product $(X/F) \times_X (X/G)$. It is generally not the ordinary product of the two total categories. The absolute functor sends the terminal presheaf to X, not to the terminal category. The manuscript correctly formulates finite exactness in Cat/X.

Lemme 2. *Les monomorphismes qui sont des isomorphismes locaux sont exactement les immersions ouvertes. Donc dans* Fib disc X*, les monomorphismes sont les immersions ouvertes, et le foncteur $\varphi_X : F \longmapsto X/F$ transforme monomorphismes en immersions ouvertes.*

Revenons alors au diagramme cocartésien $(*)$ (p. 161), et au diagramme correspondant dans Cat (et même dans Fib disc X)

$$\begin{array}{ccccc} X/G & \xrightarrow{X/i} & X/F & \dashleftarrow & T \\ {\scriptstyle X/p}\downarrow & & \downarrow{\scriptstyle X/q} & & \vdots \\ X/G' & \xrightarrow{X/i'} & X/F' & \dashleftarrow & T'. \end{array}$$

Comme $(*)$ est cartésien, le carré précédent est cartésien, par ce qui précède. Je veux prouver qu'il est également cocartésien (dans Cat/X, ou dans Cat, cela revient au même), et pour ceci [page 166] j'applique le corollaire 2 de la proposition 15 (p. 161), compte tenu que X/q est un isomorphisme local, et X/i' (étant un isomorphisme local `[et un]` monomorphisme) une immersion ouverte. Il suffit de prouver que, T' et T étant les sous-catégories fermées complémentaires des ouverts X/G' de X/F' et de X/G de X/F, que $T \longrightarrow T'$ est `[un]` isomorphisme.

`[Maintenant,` F `et` G`, et` F' `et` G'`, mais pas` p `et` q`, échangent leur rôles.]`

La vérification est immédiate : T est la catégorie des flèches $x \longrightarrow G$ dans $X^\wedge$ (de source x dans X) qui ne se factorisent pas par G `[plutôt par` F`]`, T' celle des flèches $x \longrightarrow G'$ qui ne se factorisent pas par F', le foncteur $T \longrightarrow T'$ étant le foncteur composition de $x \longrightarrow G$ avec $G \xrightarrow{q} G'$ p. 113

$$\begin{array}{ccc} F & \hookrightarrow & G \\ \downarrow & & \downarrow \\ F' & \hookrightarrow & G' \end{array}$$

(NB Le composé ne se factorise pas par F', car autrement, à cause du caractère cartésien de Q, $x \longrightarrow G$ se factoriserait par F.) Mais pour x donné, la donnée de $x \longrightarrow G$ ne se factorisant pas par F est celle d'un élément de $G(x) \backslash F(x)$, et à cause du caractère cocartésien de Q, [page 167]

$$(G(x) \backslash F(x)) \longrightarrow (G'(x) \backslash F'(x))$$

est bijectif, i.e. 'il revient au même' de se donner $x \longrightarrow G$ ne se factorisant pas par F, ou $x \longrightarrow G'$ ne se factorisant pas par F'.

Commentary · Exposition [ms. 167]

Why the complement calculation is enough

Grothendieck wants to transport a pushout of presheaves to a pushout of categories, where the homotopical criterion is already available. We use throughout the notation of the final theorem, $F \hookrightarrow G$ and $F' \hookrightarrow G'$. The source changes the letters immediately before this calculation; the editorial note marks that change, and no mathematical reversal is intended.

At each $x \in X$, the pushout of sets has the concrete description

$$G'(x) \cong F'(x) \amalg \big(G(x) \setminus F(x)\big).$$

The map q_x sends an element of $F(x)$ through p_x and leaves the complementary elements distinct. Hence $F'(x) \to G'(x)$ is injective and its inverse image in $G(x)$ is exactly $F(x)$. This proves

simultaneously that i' is a monomorphism and that the square of presheaves is cartesian. It also gives a bijection between the two objectwise complements.

A monomorphism $F \hookrightarrow G$ induces a full sieve $X/F \hookrightarrow X/G$: if (y, b) belongs to X/F and $u : (x, a) \to (y, b)$ is an arrow of X/G, then $a = G(u)b$ belongs to $F(x)$. Conversely, a monomorphism which is a local isomorphism is a full sieve. To see this, lift uniquely every arrow into an object in its image using the isomorphism on slices; injectivity on objects and arrows then identifies the lift with the given arrow. This is Lemma 2 with its categorical content made explicit.

It remains to check that the bijection of complementary objects respects all arrows in both directions. Let (x, a) and (y, b) be outside X/F. An arrow between their images in X/G' has an underlying arrow $u : x \to y$ satisfying

$$G'(u)q_y(b) = q_x(a).$$

By naturality its left side is $q_x G(u)b$. The element $G(u)b$ cannot belong to $F(x)$, since then its image would belong to $F'(x)$, whereas $q_x(a)$ does not. Both $G(u)b$ and a are therefore in the complement where q_x is injective. They are equal. This gives precisely one arrow in the original complement, with the same underlying u. Identities and compositions are preserved because both complement functors lie over X. The functor $T \to T'$ is thus an isomorphism of categories, not merely a bijection on objects. Proposition 15, Corollary 2, now proves the categorical pushout.

The stronger exactness result in the previous block gives an alternative: i_X preserves this pushout even without the monomorphism hypothesis. The monomorphism is needed for the homotopical conclusion, and for the simultaneous pullback assertion. Indeed, the nerve formula sends the square to a simplicial pushout along a monomorphism. Such a pushout computes the homotopy pushout of the nerves. Together with the Grothendieck-construction comparison, this proves that its canonical smooth-integral map is in W_∞, and hence in every fundamental localizer, by Cisinski (2006a, Corollary 4.2.19). Thus the W(7 bis) proviso in the homotopy-pushout clause of Theorem 5 can be removed. It must still be retained for the *reflection* implications in the following corollary.

Ainsi on a prouvé le

Théorème 5. *Soit X dans* Cat*, et*

$$Q : \quad \begin{array}{ccc} F & \xrightarrow{\ i\ } & G \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ F' & \xrightarrow{\ i'\ } & G' \end{array}$$

un carré cocartésien dans $X^\wedge$, avec i [un] *monomorphisme. Alors i' est* [un] *monomorphisme, le carré Q est aussi cartésien, et le carré correspondant dans* Cat$/X$ *ou dans* Cat

$$\begin{array}{ccc} X/F & \xrightarrow{X/i} & X/G \\ {\scriptstyle X/p}\downarrow & & \downarrow{\scriptstyle X/q} \\ X/F' & \xrightarrow{X/i'} & X/G' \end{array}$$

est à la fois cartésien et cocartésien. De plus, si W est un localiseur fondamental dans Cat*, satisfaisant* W(7 bis) (en plus de W(1,2,3))*, alors le carré X/Q dans* Cat *est W-cocartésien.* [page 168]

Ce dernier énoncé résulte de ce qui précédait et du corollaire 2 du théorème 4, compte tenu que X/q est un isomorphisme local, donc est W-lisse. p. 114

Commentary · Examples [ms. 168]

An attachment over the walking arrow

Theorem 5 can be seen without any large category of simplices. Let $X = [1] = (0 \to 1)$. A presheaf on X is a map of sets $F(1) \to F(0)$. Take $G(1) = \{r, s\}$, $G(0) = \{a, b, c\}$, with restrictions

$r \mapsto a$, $s \mapsto b$. Let F be the subpresheaf with $F(1) = \{r\}$ and $F(0) = \{a, b\}$, and let $F' = e$ be the terminal presheaf. The unique map $F \to e$ gives the pushout

$$G'(1) = \{*, s\}, \qquad G'(0) = \{*, c\}, \qquad * \mapsto *, \quad s \mapsto *.$$

The category X/G has five objects and two nonidentity arrows,

$$(0, a) \longrightarrow (1, r), \qquad (0, b) \longrightarrow (1, s),$$

with $(0, c)$ isolated. Its open subcategory X/F has three objects: the first arrow and the isolated object $(0, b)$. The category X/e is [1]. In the pushout, $(1, r)$ is identified with $(1, *)$, and both $(0, a)$ and $(0, b)$ with $(0, *)$. The resulting category has exactly the two arrows

$$(1, *) \longleftarrow (0, *) \longrightarrow (1, s)$$

and the isolated object $(0, c)$. This is X/G'. There are no further nonidentity compositions to add.

The two complementary closed subcategories are both the discrete category on $(1, s)$ and $(0, c)$. The new attachment changes the crossing arrow into $(1, s)$ but leaves the complement itself unchanged, exactly as Proposition 15 predicts. Their nerves give a homotopy pushout. On connected components the four corners have respectively $2, 3, 1, 2$ components, and the last set is the pushout of the first three component sets. This also checks concretely that the word "cartesian" for the presheaf square does not mean that either vertical map is an equivalence: the left vertical map merges two components, and the right one merges the corresponding two components after attachment.

Corollaire : ([111]) *On a* (moyennant W(7 bis)) *les équivalences*

$$\begin{aligned} i \in W_X \quad &\Longleftrightarrow \quad i' \in W_X \\ p \in W_X \quad &\Longleftrightarrow \quad q \in W_X, \end{aligned}$$

où

$$W_X \subseteq Fl(X^\wedge)$$

est défini par (cf. Pursuing Stacks …)

$$u \in W_X \qquad \Longleftrightarrow \qquad X/u : X/F \longrightarrow X/G \quad \textit{est dans } W.$$

Ainsi, dans une catégorie $X^\wedge$, les sommes amalgamées impliquant un monomorphisme se comportent de façon parfaite du point de vue homotopique, plus exactement pour les localiseurs W_X, pourvu seulement que W satisfasse à W(7 bis). Notamment, les monomorphismes dans $X^\wedge$ sont des 'W_X-cofibrations', en un sens similaire de celui de la définition 2 c) (pages 99, 100 [plutôt 109, 110]). [page 169]

[page 170 n'existe pas.]

Commentary · Present state [ms. 169]

From attachment stability to model structures

The final assertion concerns a class of cofibrations in the sense developed in this chapter: pushing a W_X-equivalence out along a monomorphism again gives a W_X-equivalence. This preservation property survives for ordinary homotopy types. The two reverse implications displayed in the corollary are different assertions and depend on the strong W(7 bis) hypothesis. The earlier failure of pushout reflection applies here as well after representing spaces by simplicial presheaves.

It would go beyond the text to infer that, for every small X, the class W_X is the weak-equivalence class of a model structure whose cofibrations are all monomorphisms. Already $X = e$ shows the missing condition. For $W = W_\infty$, a presheaf is a set and X/F its discrete category, so W_X consists of bijections. If a model structure on sets had these weak equivalences and all monomorphisms as cofibrations, every trivial fibration would be a bijection. Factoring a noninjective map as a

111. **NB** Si on veut seulement $i \in W_X \Longrightarrow i' \in W_X$, $p \in W_X \Longrightarrow q \in W_X$, il suffit que l'on ait W(7 bis) *faible*, i.e. $i_0 \in W \Longrightarrow i \in W$ dans l'énoncé de W(7 bis), p. 76 (Loc(6′a) avec les notations de XVI).

cofibration followed by a trivial fibration would make it injective, a contradiction. Attachment stability alone does not supply the factorization axiom.

The later theory identifies the additional hypotheses. For an accessible fundamental localizer and a W-local test category, the induced presheaf equivalences admit a cofibrantly generated model structure with monomorphisms as cofibrations; this is Cisinski (2006a, Corollary 4.2.18). In the ordinary case, the local test condition is characterized by the requirement that maps with the right lifting property against all monomorphisms be weak equivalences; see Cisinski (2006a, Theorem 4.1.19). The general existence theorem for accessible presheaf localizers, Theorem 1.4.3 of the same work, supplies the factorizations. The present calculation establishes the attachment mechanism on which that construction depends, while the test-category condition ensures that it models the intended homotopy theory.

Overview · XIIb-b

Chapter XII, section 5, manuscript pages 115–169.

These pages develop a concrete calculus for deciding when an ordinary gluing diagram of categories represents a homotopy gluing. Its central object is a comparison map. Given a strictly commuting square with initial corner X_0, adjacent corners X_1, X_2, and terminal corner Y, Grothendieck constructs a category $\mathcal{X}_Q$ from the three-category span and a canonical functor

$$\varphi_Q : \mathcal{X}_Q \longrightarrow Y.$$

The square is W-homotopically cocartesian when this particular functor belongs to the chosen weak-equivalence class W. The definition remembers the cocone, not only its four vertex homotopy types. The work that follows explains why the construction is independent of its two orientations, how smoothness can test the comparison on fibres, and why monomorphisms of presheaves provide a reliable supply of such squares.

The opening argument concerns a different but related exactness problem. Total W-asphericity here is the requirement that, for every $p : X \to Y$, the category of elements of the ordinary left Kan extension $p_!1_X$ be W-aspherical. It is the definition of this chapter, explicitly distinguished by the editors from the earlier use of the same phrase in *Pursuing Stacks*. W_0-properness, or W-properness under W(5), allows Grothendieck to compute

$$p_!1_X \cong \operatorname*{colim}_{i\in I} p_{i!}1_{X_i}$$

for a family $X \to I$. A terminal object of I reduces this colimit to the last fibre. The commentary supplies the generators-and-relations proof on components and the precise functor on comma categories requested in footnote 83. It also proves that total W_∞-asphericity is not invariant under weak homotopy equivalence. The properness hypothesis controls ordinary Kan extensions; equivalence of classifying spaces alone does not do that work.

The smooth integral of $X_1 \leftarrow X_0 \to X_2$ keeps the three sets of objects disjoint. Its mixed arrows run from the outer fibres to the middle fibre, with

$$\operatorname{Hom}_{\mathcal{X}_Q}(a, x) = \operatorname{Hom}_{X_i}(a, \alpha_i x) \qquad (a \in X_i,\ x \in X_0).$$

Its universal property therefore includes natural transformations $f_i\alpha_i \Rightarrow f_0$. They need not be invertible. Strict commutativity of the given square supplies identity transformations and hence the canonical φ_Q. Dividing the integral into two full closed pieces gives a genuine categorical pushout and pullback. Each piece retracts onto its outer fibre by an adjunction. The nerve of this closed cover proves directly that the total category represents the homotopy pushout of classifying spaces. The general theorem is Thomason's; the bibliography distinguishes verification of the original metadata from verification of an independent primary proof (Thomason, 1979; Cegarra, 2020).

Even the smallest examples explain why this construction is needed. For the span $e \leftarrow \{a, b\} \to e$, the integral is a four-object category whose nerve is a circle. Its ordinary categorical pushout is a point. The ordinary pushout of the same diagram in the homotopy category is also a point: it retains equality of components but loses the two paths implementing compatibility. The integral retains those paths as transition arrows. This is the concrete content, on these pages, of the insistence on forming diagram categories before localization.

The excision hypotheses require particular care. Proposition 13 and its cube corollary are valid conditional assertions under the full W(7 bis) and W(7) printed in the manuscript. Those axioms include reflection statements stronger than the usual preservation of weak equivalences by homotopy pushout. They fail for W_∞. The commentary proves this with a connected acyclic finite complex having nontrivial fundamental group. Its suspension is contractible, so the union of its two cones and both cones are contractible although their

intersection is not. A map of this closed-cover square to the point square violates the converse cube implication. The usual forward gluing theorem survives. A normalized-chain calculation also explains exactly why the complete three-way implication works for integral homology equivalences. The earlier chapter's claim about full W(7) for W_∞ is therefore not a valid justification of the converses in the present portion.

The proper integral reverses the transition arrows. Grothendieck compares the two constructions by the functorial resolution

$$C \longleftarrow \Sigma(C) \longrightarrow C^{\mathrm{op}}.$$

Both projections are aspherical, and the same comparison can be integrated. Proposition 14 proves agreement of the four versions obtained from smooth or proper integration and from the span or its opposite. The commentary writes out the chosen twisted-arrow convention and completes the deferred transitivity verification. The natural comparison with the opposite operation is involutive; its naturality makes the square of four integration comparisons commute. The indexing category must keep its two paths distinct until they reach Y. Replacing that free diamond by a commutative square would erase precisely the information the proof is using.

The question on manuscript pages 145–146 asks whether a bad ordinary pushout can become a good homotopy cocone after mapping to another target. We answer it with finite posets. A collapsible disk with seven triangles maps to the tetrahedral two-sphere so that all associated comma categories are nonempty and connected. Its face poset E embeds as a sieve in a contractible mapping-cylinder poset B. The categorical pushout

$$P = B \amalg_E e$$

has two incomparable minimal vertices below the face poset of that sphere. Its nerve is their join with the subdivided sphere, hence has classifying space S^3. The span $B \leftarrow E \to e$ has contractible integral. Consequently the comparison to P is not a weak equivalence, whereas its composite with $P \to e$ is. The proof includes the categorical pushout universal property; a separate exact finite calculation checks the collapses, comma connectivity, and rational homology. This is a worked development, with no claim of priority. The same disk-to-sphere map supplies the promised counterexample to homotopy invariance of total asphericity.

Theorem 4 turns from construction to recognition. Its forward assertion says that smoothness of the three maps f_i implies smoothness of φ_Q. The reverse assertion for the middle map retains strong W(7 bis). Two slice calculations identify the strict fibres relevant to local smoothness with integrals of lift categories. Footnote 107 correctly observes that the apparent square in the original proof is not strictly commutative. The repair uses the split fibration of the integral over the fork and its aspherical fibres. This proves the forward direction without the strong excision axiom. An explicit contraction removes the same unnecessary hypothesis from the open-cover corollaries. The final unconditional sentence after Corollary 6, however, omits essential outer smoothness assumptions; a four-object lift category with an isolated component gives a finite counterexample.

The last part returns to ordinary category theory. A full sieve $U \subset X$ and its complement T are glued by the presheaves $\mathrm{Hom}_X(-, t)$ on U. Proposition 15 says that a square along $U \subset X$ is a pushout exactly when it identifies the complementary categories and transports these crossing-arrow presheaves by left Kan extension. The connected factorization categories in its statement are the fibres of that comparison of presheaves. This gives a full proof of the criterion and explains why an agreement on objects and strata would be insufficient.

For a presheaf F on X, the formula

$$N(X/F)_n = \coprod_{x_0 \to \cdots \to x_n} F(x_n)$$

then makes the final gluing theorem transparent. It proves preservation of colimits by the category-of-elements construction; the relative construction into Cat/X also preserves all small limits, the known strengthening recorded by Cisinski (2006a, Proposition 3.2.12 and Corollary 3.2.13). A pushout of presheaves along a monomorphism becomes a simplicial pushout along a monomorphism. Thus the positive homotopy-pushout clause of Theorem 5 holds for every fundamental localizer. Its subsequent reflection implications still require the strong hypothesis. Model structures require further conditions, supplied later by accessibility and local test categories; attachment stability alone is insufficient.

The later derivator definition identifies φ_Q with the terminal component of the coherent left-Kan-extension counit (Groth, 2013, Definition 3.9). The comparison with ∞-categories requires another localization: a total category models the categorical colimit after its transport arrows are inverted, while classifying spaces invert all arrows (Lurie, 2009, Corollary 3.3.4.3). These formulations clarify the target of the present calculations without replacing their elementary categorical proofs. The equivalence of the two integration conventions and the strict-cocone question are resolved, as are the specified coherence and local-smoothness gaps. The opening request for a sufficiently large class of cofibrations closed under the stated interval operation is not settled here in its full generality. We record that limitation without declaring it a present-day open problem.

ed. 115

VI Critère de W_∞-asphéricité pour les $\Omega^n(X,x)$.

1 Cogitations sur W_n.

On va définir, pour $n \in \mathbf{N}$,

$$W_n \subseteq \mathrm{Fl}(\mathrm{Cat})$$

par les conditions suivantes (où $f : X \longrightarrow Y$ est une flèche dans Cat).

$f \in W_0 \iff$ a) $\pi_0(f)$ bijectif.

$\iff$ b) Pour tout préfaisceau d'ensembles F *constant* sur Y, $H^0(Y,F) \longrightarrow H^0(X, f^*F)$ est bijectif.

$\iff$ c) Le foncteur $F \longmapsto f^*F$ des préfaisceaux d'ensembles *constants* sur Y vers les faisceaux d'ensembles constants sur X est pleinement fidèle.

`[Les termes de faisceau ou de préfaisceau sont utilisés ici indifféremment.]`

NB Si F_0 est un ensemble, $F_{0\,Y}$ le faisceau d'ensembles constant défini par F sur Y, on a

$$H^0(Y, F_{0\,Y}) \simeq \mathrm{Hom}_{\mathrm{Ens}}(\pi_0(Y), F_0) \qquad \text{(fonctoriel en } Y)$$
$$\mathrm{Hom}_{Y^\wedge}(F_{0\,Y}, G_{0\,Y}) \simeq \mathrm{Hom}_{\mathrm{Ens}}(\pi_0(Y), \mathrm{Hom}_{\mathrm{Ens}}(F_0, G_0)) \qquad \text{(fonctoriel en } Y),$$

ce qui implique que a) $\Longrightarrow$ c) $\overset{\text{tautologiquement}}{\underset{\substack{\text{en prenant}\\ \mathrm{Hom}_{Y^\wedge}(e_Y, F)}}{\Longrightarrow}}$ b) $\Longrightarrow$ a).

$f \in W_1 \iff$ a) $\pi_0(f)$ bijectif, et pour tout $x \in \mathrm{Ob}\, X$, $\pi_1(f,x)$: $\pi_1(X,x) \longrightarrow \pi_1(Y, f(x))$ est bijectif. (NB Il suffit de le vérifier pour *un* x dans chaque composante connexe de X.)

$\iff$ a′) $\Pi(X) \xrightarrow{\Pi f} \Pi(Y)$ est une équivalence de catégories.

$\iff$ b) $H^0(Y,F) \longrightarrow H^0(X, f^*F)$ bijectif pour tout faisceau d'ensembles *localement constant* sur Y, et $H^1(Y,F) \longrightarrow H^1(X, f^*F)$ bijectif si de plus F est un faisceau en groupes.

$\iff$ b′) Comme b), mais pour le H^1 on se borne à F *constant*, et on exige $H^1(f)$ *surjectif* seulement.

$\iff$ c) Le foncteur $F \longmapsto f^*F$ de la catégorie des faisceaux d'ensembles localement constants sur Y vers celle des faisceaux localement constants sur X est une équivalence de catégories.

Commentary · Exposition [ms. 171]

What the first two tests measure

Grothendieck is trying to recognize finite homotopy information without leaving the category of small categories. The two initial cases explain why locally constant coefficients, rather than arbitrary presheaves, are the appropriate witnesses. Write $BX = |NX|$ for the classifying space of X. A locally constant set-valued presheaf is a functor on the fundamental groupoid $\Pi(BX)$, with the variance reversed if one retains the presheaf convention. In this block all changes of variance are absorbed by inversion in the groupoid. The word "constant" on p. 171 means globally constant, whereas "locally constant" permits monodromy. For a disconnected category these are substantially different conditions.

For a set A, a section of the constant presheaf A_X chooses one element of A on each connected component. Thus $H^0(X, A_X) = \mathrm{Map}(\pi_0 X, A)$. A natural transformation $A_X \to B_X$ similarly chooses one map $A \to B$ per component. These formulas prove all three tests for W_0. In the converse direction, if precomposition with $\pi_0 f$ is bijective for every target set, Yoneda gives that $\pi_0 f$ is a bijection. The empty category is included: the map from a two-element set to its set of sections on the empty category cannot be bijective.

There is a useful elementary explanation of the apparently weak condition b′) for W_1. After using constant sets to identify components, work with connected X, Y and put $\alpha : H = \pi_1(X, x) \to G = \pi_1(Y, f(x))$. Sections of the local system corresponding to a G-set A are A^G, and sections after pullback are A^H. Their equality for every A forces α to be surjective. Indeed, let $K = \alpha(H)$ and take the transitive G-set G/K. The coset K is fixed by H; if every H-fixed element is G-fixed, then $K = G$. Constant nonabelian H^1 has the familiar description

$$H^1(X, L_X) = \mathrm{Hom}(H, L)/L,$$

where L acts by conjugation. Surjectivity for $L = H$ says that the class of the identity of H is represented by $\rho\alpha$ for some $\rho : G \to H$. Conjugating ρ makes $\rho\alpha = 1_H$, so α is injective as well. If there are several components, choose the identity representation on the chosen component and trivial representations on the others. This proves b′)⇒a), including the componentwise assertion.

An equivalence of fundamental groupoids conversely identifies every category of local systems, its global sections, and its torsors. This proves a)⇒b), c). To see directly that c) also forces the groupoid equivalence, full faithfulness recovers global sections as maps from the terminal object and hence forces α to be surjective by the same coset argument; essential surjectivity makes the regular H-set the restriction of a G-set, so $\ker\alpha$ acts trivially on a faithful H-set and is trivial. The torsor interpretation is the first step of the comparison between cohomology and homotopy types recalled in Lurie (2009, Preface, pp. vii–viii). Nothing here requires a choice of a universal covering category: the fundamental groupoid already contains precisely the needed information.

NB Le groupe $\pi_1(X, x)$ est défini via la théorie du groupoïde fondamental. On sait qu'il est en bijection canonique avec $\pi_0(\Omega(X, x))$, où $\Omega(X, x) = \underline{\mathrm{Ch}}(X; x, x)$ (ce qui permet d'avoir une loi de composition monoïdale sur $\Omega(X, x)$, donnant la loi de groupe sur le π_0), ou au choix $\Omega(X, x) = \underline{\mathrm{Ch}}_\infty(X; x, x)$ (plus commode dans certaines situations, mais ne donnant pas directement la loi de composition dans $\pi_0(\Omega(X, x))$).

Je vais poser, pour $n \in \mathbf{N}$,

$$\pi_n(X, x) = \pi_0(\Omega^n(X, x)),$$

Ω^n désignant l'itéré n-ième du foncteur $(X, x) \longmapsto \Omega(X, x)$ de la catégorie $\mathrm{Cat}_\bullet$ des objets ponctués de Cat dans elle-même. Je préfère ici travailler avec la théorie $\underline{\mathrm{Ch}}$ au lieu de $\underline{\mathrm{Ch}}_\infty$. Tôt ou tard il faudra donner un énoncé de comparaison …

Théorème 1 ([112]). *Soit $f : X \longrightarrow Y$ dans* Cat*, et soit $n \in \mathbf{N}$, $n \geq 2$, S une partie de* $\mathrm{Ob}\, X$ *telle que le composé $S \longrightarrow \mathrm{Ob}\, X \longrightarrow \pi_0(X)$ soit* `[un]` *épimorphisme. Les conditions suivantes sont équivalentes.*

112. Sans doute *faux*. On doit avoir a) $\Longrightarrow$ b), mais b) $\Longrightarrow$ a) `[est]` sans doute faux déjà pour $n = 2$ (sauf le cas X, Y 1-connexes). Cf. énoncé rectifié `[p. 178]`.

a) $\pi_i(f,x)$ *isomorphe pour tout* $x \in \mathrm{Ob}\, X$ *et tout* $i \in [0,n]$.

a′) *Comme a), mais avec* $x \in S$.

b) *On a*

$$\begin{array}{lll} H^0(Y,F) & \xrightarrow{\sim} & H^0(X,f^*F) \quad \textit{pour } F \textit{ faisceau d'ensembles} \\ & & \textit{localement constant sur } Y. \\ H^1(Y,F) & \xrightarrow{\sim} & H^1(X,f^*F) \quad \textit{si de plus } F \textit{ faisceau en groupes.} \\ H^i(Y,F) & \xrightarrow{\sim} & H^i(X,f^*F) \quad \textit{si de plus } F \textit{ faisceau abélien, } i \in [2,n]. \end{array}$$

ms. page 173

Commentary · Exposition [ms. 172]

Loops, finite types, and the scope of the proposed theorem

The iterated path construction is being asked to do two jobs. First it supplies the groups $\pi_i(X,x)$ intrinsically in Cat; subsequently it must show that these groups are the usual homotopy invariants of BX. The later identification of the minimal fundamental localizer with ordinary weak homotopy equivalences removes the distinction between W_ω and W_∞ in the modern interpretation; see Cisinski (2004, Theorem 2.2.11). It should not be used to erase Grothendieck's effort to obtain the result from the categorical path construction itself.

Theorem 1 contains three separate assertions. The equivalence a)⇔a′) is the basepoint transport statement established below. The implication a)⇒b) is correct, and the argument on pp. 180–185 supplies its proof after the twisted-coefficient evaluation map is made explicit. The converse b)⇒a) is false in general. The first failure, however, is in degree 3, not in degree 2 as footnote 112 suggests. The degree-two case survives even with nontrivial fundamental group. We prove this distinction below, because it materially changes the interpretation of the ensuing "rectification".

It is also necessary to distinguish an equivalence of n-types from a map with n-connected homotopy fibres. For the former, $\pi_0 f$ is bijective and $\pi_i f$ is an isomorphism for $1 \le i \le n$. For the latter one needs, in addition, surjectivity on π_{n+1}. Grothendieck identifies this additional condition correctly on p. 179, but calls the fibre condition the "good localizer" on p. 187. That last sentence cannot stand as a definition of a class of weak equivalences: the fibre condition fails the two-out-of-three axiom. The distinction does disappear for a map to a point, which explains why the argument of Theorem 2 is unaffected.

NB L'équivalence de a) et a′) devrait être triviale, mais pour cela il faut avoir défini les $\pi_n(X,x)$, pour x variable dans $\mathrm{Ob}\, X$, comme système local sur X, chose que je n'ai pas faite encore. Je vais essayer de le faire dans un courant d'air. Tout d'abord, les $\Omega(X,x)$ sont les fibres d'une W_ω-fibration parfaite ([113]), s'insérant dans le carré cartésien

$$\begin{array}{ccc} \underline{\mathrm{Ch}}(X) & \longleftarrow & \Omega(X,-) \\ {\scriptstyle p_X=(\sigma_X,\beta_X)}\downarrow & \nearrow_{i_X} & \downarrow \\ X \times X & \xleftarrow{\mathrm{diag}_X} & X. \end{array}$$

113. **NB** W_ω est le plus petit localiseur de Cat (satisfaisant W(1, 2 bis, 3)).

ed. 117 On sait alors que l'on a un foncteur

$$(*) \qquad \begin{aligned} \Pi X &\longrightarrow \mathrm{Hot}_{W_\omega} \\ x &\longmapsto \mathrm{hot}_{W_\omega}(\Omega(X,x)). \end{aligned}$$

Or on a, pour $i \geq 1$,

$$\pi_i(X,x) = \pi_{i-1}(\underbrace{\Omega(X,x)}_{\text{objet ponctué}}).$$

Cela donne le système local cherché des π_i, si seulement on avait un foncteur un peu plus précis que $(*)$, savoir

$$\Pi X \longrightarrow \mathrm{Hot}_{\bullet W_\omega} \qquad \text{(catégorie } W_\omega\text{-homotopique } \textit{ponctuée})$$

([114]). Or la flèche $i_X : X \longrightarrow \underline{\mathrm{Ch}}X$ relevant p_X donne une section canonique de $\Omega(X,-)$ sur X - celle justement qui associe à tout $x \in X$ le point marqué 1_x de $\Omega(X;x,x)$ ('lacet vide en x'). La question est donc celle-ci : ms. page 174

> On a une W-fibration $\Omega \longrightarrow X$, avec une section donné σ. Cela définit-il un foncteur canonique
>
> $$X \longrightarrow \mathrm{Hot}_{\bullet W},$$
>
> transformant toute flèche en `[un]` isomorphisme?

L'idée naturelle est de prendre

$$x \longmapsto \mathrm{hot}_{\bullet W}(\Omega/x)$$

en ponctuant Ω/x par le point marqué $\sigma(x)$ de $\Omega_x \hookrightarrow \Omega/x$. L'ennui, c'est que les morphismes de transition $\Omega/x \longrightarrow \Omega/x'$ (pour $x \xrightarrow{u} x'$ dans X) ne sont pas compatibles avec les points marqués. Mais on a une flèche (savoir $\sigma(u)$) allant de l'image $\sigma(x)/x'$ du point marqué de Ω/x vers le point marqué $\sigma(x')/x'$ de Ω/x'. Ceci doit suffire pour définir la flèche ms. page 175

$$(\Omega/x, \sigma(x)/x) \longrightarrow (\Omega/x', \sigma(x')/x')$$

comme flèche dans $\mathrm{Hot}_{\bullet W}$, avec transitivité pour une composée $x \xrightarrow{u} x' \xrightarrow{v} x''$ dans X. Je vais
ed. 118 pour l'instant me borner à une indication, quitte à faire des vérifications circonstanciées par ms. page 176 la suite. Au besoin, j'utiliserai dès maintenant que pour $i \in \mathbf{N}$, $i \geq 1$,

$$\pi_i(f,x) : \pi_i(X,x) \longrightarrow \pi_i(Y, f(x))$$

peuvent s'interpréter comme provenant d'un homomorphisme de systèmes locaux

$$\underset{\sim i}{\pi}(X,-) \longrightarrow f^*(\underset{\sim i}{\pi}(Y,-))$$

sur X. La condition a) du théorème 1 s'interprète en disant que cet homomorphisme est un *isomorphisme* pour $i \in [1,n]$, et la condition a') se borne alors à rappeler qu'il suffit de tester qu'il en est ainsi pour *un* point de chaque composante connexe de X.

---

114. Mais il faut aussi vérifier que les $\pi_n(X,x)$ $(n \geq 1)$ sont des foncteurs sur $\mathrm{Hot}_{\bullet W_\infty}$, i.e. transforment W_∞-équivalences en itou. Cela résulte de W(4a) pour W_∞, qui implique que $(X,x) \mapsto \Omega(X,x)$ se factorise par $\mathrm{Hot}_{\bullet W_\infty}$ (en tant que foncteur à valeurs dans $\mathrm{Hot}_{\bullet W_\infty}$).

Commentary · Development (commentators') [ms. 175]

Making pointed transport explicit

Grothendieck needs to transport a marked object along an arrow even when the underlying transition functor does not preserve that object strictly. The discrepancy is useful data: the arrow supplied by the section tells us exactly which change of basepoint to make. The following construction fills in the indicated verification using only arrow categories and localization. We checked the natural-homotopy and adjunction lemmas in Cisinski (2004, §1.1, especially Proposition 1.1.9 and Corollary 1.1.10); we did not locate a discussion of this particular pointed comma-category formula in the consulted sources. The result is an elementary completion of the manuscript's construction, with no assertion of priority.

Pointed transport lemma. [ours] Suppose W contains every functor admitting a left or a right adjoint and satisfies two-out-of-three. In the localization of pointed categories at functors whose underlying functors lie in W, an arrow $a : d \to e$ of a category D defines a canonical isomorphism

$$t_a : (D, d) \longrightarrow (D, e).$$

It is natural in functors $D \to D'$, satisfies $t_{1_d} = 1$, and satisfies $t_{ba} = t_b t_a$ for composable arrows a, b.

Proof. Regard a as the marked object of $D^{[1]}$. The two evaluation functors give a pointed span

$$(D, d) \xleftarrow{e_0} (D^{[1]}, a) \xrightarrow{e_1} (D, e).$$

The constant-diagram functor is left adjoint to e_0 and right adjoint to e_1, so both evaluations belong to W. Define $t_a = [e_1][e_0]^{-1}$. For the identity arrow the constant-diagram functor is a pointed common section, proving the unit assertion. For a composable pair, mark $D^{[2]}$ by the diagram $d \xrightarrow{a} e \xrightarrow{b} h$. Evaluation at every vertex belongs to W. For the endpoints this again follows from adjunctions. For the middle vertex use the natural transformation $e_0 \Rightarrow e_1$ and the following elementary consequence of the assumptions: naturally related functors belong to W simultaneously. Indeed, represent a natural transformation by $H : A \times [1] \to B$. The projection $A \times [1] \to A$ has an adjoint and lies in W; each endpoint section lies in W by two-out-of-three. Thus $Hi_0 \in W$ if and only if $H \in W$, if and only if $Hi_1 \in W$. Restriction to the three edges commutes with vertex evaluation and is therefore in W by two-out-of-three. On this common pointed source,

$$[e_2][e_0]^{-1} = \big([e_2][e_1]^{-1}\big)\big([e_1][e_0]^{-1}\big).$$

This is the composition assertion. Applying a functor to arrow diagrams commutes strictly with all evaluations and restrictions, proving naturality. □

Now let $q : E \to X$ be the fibration under discussion, with section σ. For $u : x \to x'$ write $u_* : E/x \to E/x'$ for postcomposition. Its marked source maps to $u_*\sigma(x)$, and the section gives an arrow

$$a_u : u_*\sigma(x) \longrightarrow \sigma(x')$$

in E/x'. Define the pointed transition to be $t_{a_u}[u_*]$. For $v : x' \to x''$, the equality $a_{vu} = a_v\, v_*(a_u)$, naturality of t, and the composition formula prove the functor law. When the comma transitions belong to W, these maps are isomorphisms and the functor factors through ΠX. The pointed inclusions $E_x \to E/x$ identify it with the family of strict fibres whenever those inclusions belong to W. Applied to the loop fibration, this gives the local systems of higher homotopy groups and proves the equivalence of the one-basepoint and every-basepoint formulations. It gives ordinary transport in the pointed homotopy category; a coherent family of pointed spaces contains further information, which is not claimed to follow from this ordinary functor alone.

L'énoncé du théorème 1 garde un sens pour $n = 1$, et dans ce cas a été 'rappelé' précédemment (et est ± tautologique). Cela va nous permettre de procéder par récurrence sur n, en supposant que le théorème est prouvé pour $n - 1$. Cela signifie que l'on peut supposer que les conditions a) *et* b) sont satisfaites par f pour $i \in [1, n-1]$, et se borner à prouver que, sous ces conditions, la condition a) (ou a′), pour $i = n$, équivaut à la condition b) pour $i = n$.

Donc il faut prouver simplement ceci : ms. page 177

Lemme ([115]). *Supposons que* $\pi_i(f, x)$ `[est un]` *isomorphisme pour* $i \in [0, n-1]$ *et b)*

115. Sans doute faux.

satisfait pour $i \in [0, n-1]$, où $n \in \mathbf{N}$, $n \geq 2$, est fixé. Alors les conditions suivantes sont équivalentes :

a) $\pi_n(f,x) : \pi_n(X,x) \longrightarrow \pi_n(Y, f(x))$ `[est un]` *isomorphisme pour tout $x \in \operatorname{Ob} X$.*

b) $H^n(Y,F) \xrightarrow{\sim} H^n(X, f^*F)$ `[est un]` *isomorphisme pour tout faisceau abélien localement constant sur Y.*

Notons que f induit une flèche dans $\mathrm{Cat}_\bullet$,

$$\Omega(f,x) : \Omega(X,x) \longrightarrow \Omega(Y, f(x)),$$

d'où

$$\begin{array}{ccc} \pi_i(\Omega(X,x)) & \longrightarrow & \pi_i(\Omega(Y,f(x))) \\ \wr| & & \wr| \\ \pi_{i+1}(X,x) & \longrightarrow & \pi_{i+1}(Y,f(x)), \end{array}$$

s'identifiant à $\pi_{i+1}(f,x)$:

$$\pi_i(\Omega(f,x)) \simeq \pi_{i+1}(f,x).$$

ed. 119 L'hypothèse a) du lemme implique que $\pi_i(\Omega(X,x)) \xrightarrow{\sim} \pi_i(\Omega(Y,y))$ pour $i \in [0, n-1]$. Il s'agit ici des π_i basés en les points unités. On devra sans doute prouver que, du fait qu'il s'agit d'un morphisme de monoïdes dans Cat (satisfaisant certaines conditions?) ça reste vrai pour les π_i en *tout* point ξ de $\Omega(X,n)$. Par l'hypothèse de récurrence, on saura donc que $\Omega(X,x) \longrightarrow \Omega(Y,y)$ induit un isomorphisme pour la cohomologie à coefficients localement ms. page 178
constants, jusqu'en dimension $n-1$ inclus.

Finalement, je me suis ± convaincu que l'énoncé du théorème 1 est faux tel quel. Voici un énoncé que j'éspère vrai, et que je vais essayer de prouver dans un esprit 'utilitaire', en utilisant tout ce que je sais en homotopie et cohomologie (et pas seulement ce que j'ai développé 'from scratch' dans le modélisateur Cat).

Théorème 1 rectifié. *Considérons, pour un entier $n \geq 2$ donné, les conditions suivantes sur une flèche $f : X \longrightarrow Y$ dans* Cat *(ou une application continue d'espaces topologiques, ou un morphisme dans $\mathbf{\Delta}^\wedge$ etc. etc.) :*

a_n) Si Z est une 'fibre homotopique' de f (NB il y en a essentiellement une par composante connexe de Y), alors Z est n-connexe, i.e. (p. ex) $\pi_i(Z) = 0$ pour $i \in [0,n]$. ms. page 179

Commentary · Examples [ms. 178]

The first genuine failure and the role of loop multiplication

The withdrawn induction fails because ordinary cohomology in degree n need not see all of π_n when lower homotopy is already present. A concrete example makes the failure exact. Take

$$f : S^2 = \mathbf{CP}^1 \longrightarrow \mathbf{CP}^\infty = K(\mathbf{Z}, 2).$$

Both spaces are simply connected. Their integral cellular chain complexes have $\mathbf{Z}$ in degree 0 and degree 2, and no groups in degrees 1 and 3; $\mathbf{CP}^\infty$ has additional even-dimensional cells starting in degree 4. Thus for every abelian group M, the map induces isomorphisms on $H^i(-;M)$ for $0 \leq i \leq 3$: the nonzero groups in this range are $H^0 = M$ and $H^2 = M$. Nonabelian H^1 is trivial on both spaces and every local system is constant. Yet

$$\pi_3(S^2) = \mathbf{Z} \longrightarrow \pi_3(K(\mathbf{Z},2)) = 0$$

is not an isomorphism. The source group is detected by the Hopf fibration, and the target calculation follows from $S^1 \to S^\infty \to \mathbf{CP}^\infty$; both computations appear in Hatcher (2002, Examples 4.50–4.51). This disproves Theorem 1 and the lemma on p. 177 for $n = 3$, even with simply connected source and target. Applying the category-of-simplices construction to singular simplicial models gives an actual functor of small categories with the same failure; the nerve/category-of-simplices equivalence is recorded in Cisinski (2004, Lemma 2.1.15).

> The proposed passage from the unit component of a loop space to all components is nevertheless sound. If M is a topological monoid with $\pi_0 M$ a group, multiplication by any $m \in M$ is a homotopy equivalence. Choose m' representing its inverse component. Paths from mm' and $m'm$ to the unit show that multiplication by m' is a homotopy inverse, using associativity. A homomorphism of such monoids commutes with these translations. Hence its effect on homotopy groups in every component is determined by its effect at the unit, together with the bijection on components. Realization of a monoidal category has this property when its monoid of components is a group, as it is for Grothendieck's loop category. The monoidal argument repairs the specific verification requested at the top of p. 178; it does not repair the false cohomological converse used by the abandoned induction.

b_n) $\pi_0(f)$ *est bijectif, et* $\forall\ x \in X$, $\pi_i(f,x) : \pi_i(X,x) \longrightarrow \pi_i(Y, f(x))$ *est* `[un]` *isomorphisme pour* $i \in [1,n]$. *(***NB** *Il suffit de le dire pour* un *point* x *de chaque composante connexe de* X*.)*

c_n) $H^i(Y,F) \longrightarrow H^i(X, f^*F)$ `[est un]` *isomorphisme pour* F *faisceau localement constant sur* Y *(avec* F *abélien si* $i \geq 2$, F *faisceau en groupes si* $i = 1$*).*

On a alors

$$a_n \implies b_n \implies ({}^{116})\ c_n \implies ({}^{117})\ a_{n-1}$$

(et je présume que chacune de ces implications est stricte).

Démonstration. $\mathrm{a}_n \Longrightarrow \mathrm{b}_n$ est conséquence immédiate de la suite exacte d'homotopie pour une Hot-fibration $\bar{X} \xrightarrow{\bar{f}} Y$ qui factorise $X \xrightarrow{f} Y$ en $f = \bar{f} \circ i$, $i \in W_\infty$. En fait, a_n *équivaut* à b_n + la surjectivité des $\pi_{n+1}(X,x) \longrightarrow \pi_{n+1}(Y, f(x))$, laquelle bien sûr ne résulte *pas* de b_n, i.e. de la bijectivité des $\pi_i(f,x)$ pour $i \leq n$ (prendre des $K(\pi, n+1)$). Donc l'implication est bien stricte.

ed. 120 $\mathrm{b}_n \Longrightarrow \mathrm{c}_n$. On peut supposer que f est une Hot-fibration (et même Hot-parfait si ça nous chante …). On sait déjà que pour ms. page 180

$$(*) \qquad H^i(Y,F) \longrightarrow H^i(X, f^*F)$$

tout est O.K. si $i \in \{0,1\}$. Donc on peut supposer F abélien. Si ça nous avance, on peut supposer, par récurrence, (que l'implication $\mathrm{b}_{n-1} \Longrightarrow \mathrm{c}_{n-1}$ est connue, donc) que $(*)$ est `[un]` isomorphisme pour $i < n$. Reste à le voir pour $i = n$. On est ramené bien sûr, comme $\pi_0(f)$ est bijectif, au cas où X, Y sont 0-connexes, donc il y a essentiellement une seule fibre Z. La suite exacte d'homotopie nous apprend que

$$\pi_i(Z,z) = 0 \qquad \text{pour } i \leq n-1 \ (Z \text{ est } (n-1)\text{-connexe})$$

et de plus

$$\pi_n(Z,z) \longrightarrow \pi_n(X,z) \qquad \text{est nul}$$

(car $\pi_n(X,z) \longrightarrow \pi_n(Y,y)$ `[est un]` isomorphisme donc `[un]` monomorphisme), donc

$$\pi_{n+1}(Y,y) \longrightarrow \pi_n(Z,z) \qquad \texttt{[est un]}\ \text{épimorphisme.}$$

Comme Z est $(n-1)$-connexe (donc aussi 1-connexe), on a

$$(*) \qquad H^i(Z,G) = 0\ , \qquad \text{si } 0 < i < n\ ,$$

pour G localement constant (donc constant) sur Z.

---

116. si X, Y 1-connexes, c'est vraiment prouvé, sinon, il y a des vérifications à faire (qui ont l'air soritales …).

117. **NB** Même si X, Y 1-connexes, il n'est pas clair que $\mathrm{c}_n \Longrightarrow \mathrm{b}_n$, car il faut montrer que $\pi_n(Z) \longrightarrow \pi_n(X)$ est nul, et on trouve seulement que le composé avec $\pi_n(X) \longrightarrow H_n(X)$ est nul. Je présume qu'il y a des contre-exemples.

Commentary · Exposition [ms. 179]

Three conditions and the extra degree

The corrected theorem separates fibre connectivity, homotopy isomorphisms, and cohomological isomorphisms. This separation is the main conceptual gain of the first section. In condition c_n the printed text has omitted the range of i; the intended range is $0 \le i \le n$, as both proof and notation require. We use singular local coefficients on classifying spaces, or on CW replacements when discussing spaces. A statement about arbitrary topological spaces with their ordinary sheaf cohomology would require additional hypotheses and is not supplied by the argument here.

For a homotopy fibre Z over $y = f(x)$, the exact homotopy sequence gives

$$\pi_{n+1}(X,x) \longrightarrow \pi_{n+1}(Y,y) \longrightarrow \pi_n(Z,z) \longrightarrow \pi_n(X,x) \longrightarrow \pi_n(Y,y).$$

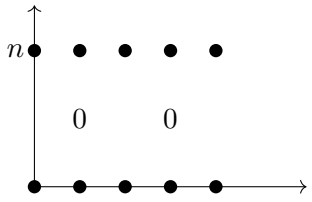
Together with the preceding terms, this proves

$$a_n \iff b_n \text{ and } \pi_{n+1}(X,x) \twoheadrightarrow \pi_{n+1}(Y,y)$$

for one basepoint in every component, with nonempty connected fibres understood. In contemporary terminology a_n says that f is $(n+1)$-connected when a k-connected map is defined to have $(k-1)$-connected fibres. Authors also use a convention shifted by one; specifying the fibres avoids that ambiguity.

The map $* \to K(A, n+1)$, for $A \neq 0$, satisfies b_n but not a_n, since its homotopy fibre is $K(A,n)$. At the other end, $S^n \to *$ has $(n-1)$-connected fibre, but fails c_n: with $M = \mathbf{Z}$, its degree-n cohomology map is $0 \to \mathbf{Z}$. These examples prove strictness of the first and last arrows in the chain. The middle arrow is strict for $n = 3$ by the preceding example, but it is an equivalence for $n = 2$. Thus the conjecture that *each* implication is strict for every $n \ge 2$ is false. This does not affect the implication chain itself.

The lower boundary in the fibre statement matters. A bijection on components and isomorphisms on π_i through degree n yield only $(n-1)$-connected fibres; the remaining group $\pi_n Z$ can be the quotient of $\pi_{n+1}Y$ by the image of $\pi_{n+1}X$. It is precisely this group that enters the next low-degree exact sequence. The proof succeeds by showing that its restriction map from the cohomology of X is zero, rather than by claiming that the group itself vanishes.



ms. page 181

Écrivons la suite spectrale de Leray pour $f : X \longrightarrow Y$ et $f^*F = F_X$:

$$H^*(X, f^*F) \Longleftarrow E_2^{pq} = H^p(Y, H^q(Z, f^*F)),$$

où '$H^q(Z)$' doit être vu comme un système local sur Y. Donc par $(*)$ on a

$E_2^{pq} = 0$ si $0 < q < n$,

,

donc on trouve la suite exacte

$$0 \longrightarrow H^n(Y,F) \longrightarrow H^n(X,F_X) \xrightarrow{\alpha} H^0(Y, \underbrace{H^n(Z, \overbrace{F_Z}^{M_Z})}_{= \mathrm{Hom}(\pi_n(Z,z),M) \text{ par [1e] th. de Hurewicz}}) \longrightarrow H^{n+1}(Y,F).$$

ed. 121 Ici je fixe un point x de X, Z désigne la fibre de f en $y = f(x)$, et M celle de F en y, $M = F_y$. Le groupe $\pi_1(Y)$ y opère, d'ailleurs $\pi \overset{\text{déf}}{=} \pi_1(X,x) \simeq \pi_1(Y,y)$ aussi. Le $H^0(Y, H^n(Z, F_Z))$ peut s'interpréter, sauf erreur, comme

$$\mathrm{Hom}_\pi(\pi_n(Z,x), M),$$

en tenant compte de l'opération de $\pi = \pi_1(X, x)$ sur $\pi_n(Z, x)$ également. (À vérifier.) Il faut interpréter la flèche

$$H^n(X, F_X) \longrightarrow \mathrm{Hom}_\pi(\pi_n(Z, x), M),$$

via l'application composée [où $z = x$, vu comme point de Z]

$$(*) \qquad \pi_n(Z, z) \longrightarrow \pi_n(X, x) \longrightarrow H_n(X, \mathbf{Z}).$$

Si F est *constant* sur Y (p. ex. si Y [est] 1-connexe), donc de valeur M, on a les flèches canoniques

$$(*') \qquad H^n(X, F_X) = H^n(X, M) \longrightarrow \mathrm{Hom}(H_n(X, \mathbf{Z}), M) \longrightarrow \mathrm{Hom}(\pi_n(Z, z), M)(^{118})$$

[lire : Hom_π],

et sûrement (en dehors de toute hypothèse de type b_n ou autre) l'application canonique directe 'de localisation sur Y', suivi de …, ms. page 182

$$(**) \qquad H^n(X, F_X) \longrightarrow H^0(Y, H^n(Z, F_Z)) \longrightarrow \mathrm{Hom}_\pi(\pi_n(Z), M)$$

n'est autre que la composée des applications canoniques ci-dessus. Dans le cas actuel où on suppose b_n, la deuxième flèche dans $(**)$ est [un] isomorphisme, donc la composée 'n'est autre' que la flèche de localisation elle-même. D'autre part $\pi_n(Z, z) \longrightarrow \pi_n(X, x)$ dans $(*)$ est nul, donc aussi $\pi_n(Z, z) \longrightarrow H_n(X, \mathbf{Z})$, donc aussi la flèche composée $(*')$ qui s'en déduit. Revenons alors à la suite exacte de Leray (page précédente), on trouve que $H^n(Y, F) \xrightarrow{\sim} H^n(X, F_X)$.

Commentary · Exposition [ms. 181]

The exact sequence behind the cohomological implication

The use of a path replacement now lets Grothendieck import the classical fibration argument into his categorical model. Assume b_n, reduce to a connected component, and replace f by a fibration with fibre Z. Then Z is $(n-1)$-connected, and the homotopy sequence also says that $\pi_n Z \to \pi_n X$ is zero. For an abelian local system F on Y with fibre M at y, the restriction $F|_Z$ is constant. The cohomological Serre–Leray spectral sequence has

$$E_2^{p,q} = H^p(Y; \mathcal{H}^q(Z; M)) \quad \Longrightarrow \quad H^{p+q}(X; f^*F).$$

Here $\mathcal{H}^q(Z; M)$ includes both the transport of the fibre and that of M; replacing it by an untwisted constant group would lose the content of the argument. The historical spectral sequence is Serre (1951, Chapter II, §8, Proposition 6); for the indexing and filtration in the untwisted presentation see Hatcher (2004, Theorem 1.14).

Since $H^q(Z; M) = 0$ for $0 < q < n$, the only contributions in total degrees at most n are the bottom row and $E_2^{0,n}$. No differential reaches the bottom row before d_{n+1} from $(0, n)$ to $(n+1, 0)$. Reading the filtration therefore gives the natural exact sequence

$$\begin{aligned} 0 \longrightarrow H^n(Y; F) \longrightarrow H^n(X; f^*F) \xrightarrow{\alpha} \mathrm{Hom}_{\mathbf{Z}[\pi]}(\pi_n Z, M) \\ \longrightarrow H^{n+1}(Y; F) \longrightarrow H^{n+1}(X; f^*F), \end{aligned}$$

where $\pi = \pi_1 Y = \pi_1 X$. Only exactness through the penultimate group is needed. The identification of $E_2^{0,n}$ uses the natural Hurewicz isomorphism $\pi_n Z \cong H_n Z$ and the universal coefficient theorem, followed by taking monodromy invariants. The fibre is simply connected, so no ambiguity from inner automorphisms survives in its degree-n group. The map α is restriction to a fibre, viewed as an invariant homomorphism.

There is an efficient chain-level way to finish the twisted case. If T is connected with fundamental group π, a local system G with fibre M is represented by a left $R = \mathbf{Z}[\pi]$-module. A cocycle representing $c \in H^n(T; G)$ is an R-linear map

$$z : C_n(\widetilde{T}) \longrightarrow M, \qquad z\partial = 0.$$

118. grâce à la composition avec $(*)$.

Evaluation on cycles gives a homomorphism $H_n(\widetilde{T}) \to M$; changing z by a coboundary has zero effect on cycles. Composing with the equivariant Hurewicz homomorphism produces

$$\varepsilon_G : H^n(T; G) \longrightarrow \mathrm{Hom}_R(\pi_n(T, t), M), \qquad n \geq 2.$$

This is the desired spherical evaluation. Its additivity follows from the homomorphism property of Hurewicz, or from the pinch map of the sphere; its equivariance follows directly from R-linearity. Naturality follows by lifting a pointed map to universal covers and applying the chain map. The local-coefficient chain model is described in Hatcher (2002, §3H, pp. 327–334); the verification above supplies the particular application the manuscript leaves open.

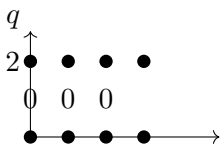
For $j : Z \to X$, choose the lift $Z \to \tilde{X}$ corresponding to the marked point. Because Z is simply connected and $(n-1)$-connected, naturality of evaluation and Hurewicz identify α with

$$H^n(X; f^*F) \xrightarrow{\varepsilon_{f^*F}} \mathrm{Hom}_R(\pi_n X, M) \xrightarrow{j^*} \mathrm{Hom}_R(\pi_n Z, M).$$

The last map is zero because $j_* : \pi_n Z \to \pi_n X$ is zero. Hence $\alpha = 0$, and exactness proves that $H^n(Y; F) \to H^n(X; f^*F)$ is an isomorphism. In lower degrees it is already an isomorphism by the zero rows of the spectral sequence. Degrees 0 and nonabelian 1 are controlled by the fundamental groupoid. This completes $b_n \Rightarrow c_n$ for all the coefficients actually stated, without an assumption of simple connectivity.

Comment récupérer le cas où F n'est *pas* constant? Dans le cas $n = 2$, cela marchait, en passant aux revêtements universels $\tilde{X}$, $\tilde{Y}$ de X, Y (par rapport aux points x, y choisis), et en écrivant les suites spectrales

$$\begin{array}{ccccc} H^*(Y, F) & \Longleftarrow & E_2^{pq} & = & H^p(\pi, H^q(\tilde{Y}, F_{\tilde{Y}})) \\ \downarrow & & \downarrow & & \\ H^*(X, F_X) & \Longleftarrow & E_2'^{pq} & = & H^p(\pi, H^q(\tilde{X}, F_{\tilde{X}})). \end{array}$$



L'hypothèse b_n est conservée en passant de $f : X \longrightarrow Y$ à $\tilde{f} = \tilde{f}_x : \tilde{X} \longrightarrow \tilde{Y}$, donc on sait
ed. 122 que

ms. page 183

$$(*) \qquad E_2^{pq} \xrightarrow{\sim} E_2'^{pq} \qquad \texttt{[est un]} \text{ isomorphisme si } q \leq n.$$

Dans le cas $n = 2$, utilisant que

$$E_2^{p1} = E_2'^{p1} = 0 \qquad \text{car } H^1(\tilde{X}) = H^1(\tilde{Y}) = 0,$$

,

on trouve deux suites exactes

$$\begin{array}{ccccccccc} 0 & \longrightarrow & H^2(\pi, H^0(\tilde{Y})) & \longrightarrow & H^2(Y) & \longrightarrow & H^0(\pi, H^2(\tilde{Y})) & \longrightarrow & H^3(\pi, H^0(\tilde{Y})) \\ & & \downarrow \text{iso} & & \downarrow & & \downarrow \text{iso} & & \downarrow \text{iso} \\ 0 & \longrightarrow & H^2(\pi, H^0(\tilde{X})) & \longrightarrow & H^2(X) & \longrightarrow & H^0(\pi, H^2(\tilde{X})) & \longrightarrow & H^3(\pi, H^0(\tilde{X})), \end{array}$$

et un homomorphisme de l'une dans l'autre, qui permet de conclure par le lemme des 5 que $H^2(Y, F) \longrightarrow H^2(X, F_X)$ est `[un]` isomorphisme. Mais pour n quelconque, la relation $(*)$ sur les termes E_2 (pour $q \leq n$) ne me semble pas impliquer la relation similaire pour les E_n supérieures, et de là pour les termes E_∞, ce qui permettrait de conclure.

Je reviens donc à la suite exacte p. 181, avec F faisceau *tordu.* J'ai envie de trouver une application canonique

$$H^n(X, G) \longrightarrow \overbrace{\mathrm{Hom}_\pi(\pi_n(X, x), G_x)}^{\text{Homs } \textit{additifs} \text{ bien sûr, i.e. de } \mathbf{Z}[\pi]\text{-modules}},$$

où G est un faisceau abélien localement constant quelconque sur X, et $\pi = \pi_1(X,x)$. Si j'interprète $\pi_n(X,x)$ par des classes d'homotopie d'applications ponctuées ms. page 184

$$(S^n, x_0) \xrightarrow{\varphi} (X,x)$$

j'ai bien, pour une telle application φ,

$$\varphi^* : H^n(X,G) \longrightarrow H^n(S^n, \overbrace{\varphi^*G}^{\simeq (G_x)_{S^n}}) \simeq G_x$$

(tenant compte que S^n est 1-connexe, et que sa n-cohomologie à valeurs dans un faisceau constant M est M.) Sûrement l'application

$$H^n(X,G) \longrightarrow G_x$$

ed. 123 ainsi définie ne dépend que de la classe d'homotopie ponctuée de φ, d'où

$$\pi_n(X,x) \times H^n(X,G) \longrightarrow G_x,$$

et il faut de plus prouver a) que c'est compatible avec les opérations de $\pi = \pi_1(X,x)$, et b) que c'est additif en $\pi_n(X,x)$, pour avoir l'application cherchée

$$H^n(X,G) \longrightarrow \mathrm{Hom}_\pi(\pi_n(X,x), G_x).$$

Si j'admets ceci, il n'y a qu'un pas pour admettre aussi que la flèche qui nous intéresse vraiment (dans la suite exacte p. 181) ms. page 185

$$H^n(X,F_X) \longrightarrow \mathrm{Hom}_\pi(\pi_n(Z,z), \underbrace{M}_{=F_y})$$

n'est autre que la composée de la flèche précédente (page précédente) pour $G = F_X$, avec

$$\mathrm{Hom}_\pi(\pi_n(X,x), M) \longrightarrow \mathrm{Hom}_\pi(\pi_n(Z,x), M)$$

déduite de

$$\pi_n(Z,x) \longrightarrow \pi_n(X,x).$$

Or cette flèche est nulle, par l'hypothèse b_n. Donc la flèche α dans la suite exacte page 181 est nulle, donc $H^n(Y,F) \longrightarrow H^n(X,F_X)$ est `[un]` isomorphisme, q.e.d. (mais il y a pas mal de travail de vérification à faire …).

Commentary · Development (commentators') [ms. 183]

Completing the universal-cover comparison

Grothendieck briefly abandons the universal-cover method because he does not see how its comparison of E_2 rows controls later pages. The method can be completed directly at the level of complexes. It is useful to record the argument, since the needed range is finite and one should not invoke an unrestricted comparison theorem without checking its boundary. We use the ordinary truncation of complexes and the local-coefficient complex in Hatcher (2002, §3H). We did not find this particular completion of p. 183 in the consulted literature; its ingredients are standard homological algebra.

Finite-range descent lemma. [ours] Let π be a group and let $u : C \to D$ be a map of nonnegative cochain complexes of $\mathbf{Z}[\pi]$-modules which induces isomorphisms on cohomology in degrees $0 \le q \le n$. Then

$$H^k(R\Gamma(\pi, C)) \longrightarrow H^k(R\Gamma(\pi, D))$$

is an isomorphism for $0 \le k \le n$.

Proof. The smart truncation $\tau_{\le n}C$ agrees with C below n, has $\ker(d : C^n \to C^{n+1})$ in degree n, and is zero above n. The natural inclusion fits into the truncation triangle

$$\tau_{\le n}C \longrightarrow C \longrightarrow \tau_{\ge n+1}C.$$

Derived invariants carry a complex whose cohomology vanishes below $n+1$ to one with the same lower bound. Indeed, choose an injective resolution starting in degree $n+1$, or inspect the first-quadrant spectral sequence with terms $H^p(\pi, H^q(-))$: all its potentially nonzero terms have $p \ge 0$ and $q \ge n+1$. Applying $R\Gamma$ to the triangle and taking its long exact cohomology sequence shows that

$$H^k(R\Gamma(\pi, \tau_{\le n}C)) \xrightarrow{\sim} H^k(R\Gamma(\pi, C)), \qquad k \le n,$$

because the adjacent terms of degrees $k-1$ and k for $\tau_{\ge n+1}C$ both vanish. The same holds for D. Finally $\tau_{\le n}u$ is a quasi-isomorphism, and derived invariants preserve quasi-isomorphisms. The two truncation comparisons prove the assertion. □

Apply the lemma to the equivariant cochain complexes of the universal covers with constant fibre M and its given π-action. Derived invariants compute the cohomology with the corresponding local coefficients on the quotient: one may use a free resolution of $\mathbf{Z}$ over $\mathbf{Z}[\pi]$ and the usual total double complex. Indeed, each group of covering chains is free over $\mathbf{Z}[\pi]$, so each cochain term is a product of coinduced modules and is acyclic for the invariants functor. Its ordinary invariant complex is the local-coefficient cochain complex. The simply connected case of $b_n \Rightarrow c_n$ gives the required cohomology isomorphisms of the cover complexes through degree n, and the lemma gives the desired twisted comparison on X and Y. Thus the alternative proposed on p. 182 does work. The spherical-evaluation proof remains closer to the geometric reason the edge map vanishes.

$\mathrm{c}_n \Longrightarrow \mathrm{a}_{n-1}$. On peut procéder par récurrence sur n. (NB L'enoncé a un sens même pour $n = 1$, où il est prouvé, et même $\mathrm{c}_1 \Longrightarrow \mathrm{b}_1$, et $\mathrm{b}_1 \Longrightarrow \mathrm{a}_0$, plus généralement $\mathrm{b}_n \Longrightarrow \mathrm{a}_{n-1}$, immédiat par `[la]` suite exacte d'homotopie.) Donc on sait déjà, en plus de l'hypothèse c_n, qu'on a a_{n-2}, i.e. Z est $(n-2)$-connexe. Il faut prouver qu'il est même $(n-1)$-connexe, i.e. $\pi_{n-1}(Z) = 0$. Le cas $n = 2$ demande peut-être une attention particulière, car on ne sait pas même encore que Z est 1-connexe. Mais on sait que c_2 implique c_1, qui équivaut `[?]` à b_1, donc on a ms. page 186

$$\pi_1(X, x) \longrightarrow \pi_1(Y, y) \qquad \text{isomorphisme,}$$

donc

$$\pi_1(Z, x) \longrightarrow \pi_1(X, x) \qquad \texttt{[est]}\ \textit{nul,}$$

donc

$$\pi_2(Y, y) \longrightarrow \pi_1(Z, x) \qquad \texttt{[est un]}\ \text{épimorphisme,}$$

ce qui implique tout au moins que $\pi_1(Z, x)$ est *abélien.* Il faut le voir comme un π-module, et prouver sa nullité comme tel (moyennant c_2).

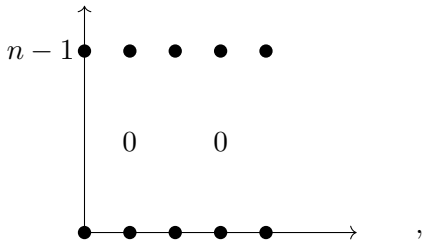
Commentary · Exposition [ms. 185]

Recovering the first missing homotopy group

For the converse direction Grothendieck changes the use of the spectral sequence: instead of annihilating the edge map, he chooses coefficients in which the first possible fibre group can test itself. This is why all local systems must be admitted. A single constant coefficient group need not detect a nontrivial module with monodromy.

Assume c_n. The degree-0 and degree-1 conditions give $\pi_0 X = \pi_0 Y$ and identify $\pi_1 X$ with $\pi_1 Y = \pi$. Induction gives that the homotopy fibre Z is $(n-2)$-connected. For $n \ge 3$ its first possible nonzero group $A = \pi_{n-1}Z$ is abelian and Hurewicz identifies it with $H_{n-1}Z$. For $n = 2$ one must first justify the same assertion differently: exactness gives a surjection $\pi_2 Y \twoheadrightarrow \pi_1 Z$, since $\pi_1 X \to \pi_1 Y$ is an isomorphism. Thus $\pi_1 Z$ is abelian, and its abelianization map to $H_1 Z$ is already an isomorphism. In both cases transport makes A a π-module; the possible ambiguity in degree one is inner conjugation in an abelian group and therefore vanishes.

For the local system determined by a π-module M, the first nonzero fibre row gives



$$0 \longrightarrow H^{n-1}(Y;M) \longrightarrow H^{n-1}(X;f^*M) \longrightarrow \mathrm{Hom}_{\mathbf{Z}[\pi]}(A,M) \longrightarrow H^n(Y;M) \longrightarrow H^n(X;f^*M).$$

For $n=2$, the degree-one groups in this display use abelian coefficients, a case included in c_n. The first comparison is surjective and the last is injective. Exactness therefore forces $\mathrm{Hom}_{\mathbf{Z}[\pi]}(A,M)=0$. Every π-module occurs as a coefficient system on Y, so take $M=A$. The identity of A must vanish, and hence $A=0$. This proves $c_n \Rightarrow a_{n-1}$, with the endpoint case checked rather than hidden under an appeal to Hurewicz.

This proof uses less than full c_n at its final step: after the lower-degree induction, surjectivity in degree $n-1$ and injectivity in degree n suffice. The full hypothesis is a convenient uniform formulation, not an optimal list of separate tests. The source has found the correct mechanism; the qualifications about coefficients and the degree-one fibre group complete its sketch.

ed. 124 Passons au cas général. On a pour F localement constant abélien sur Y

$$H^*(X,F_X) \Longleftarrow \underbrace{E_2^{pq} = H^p(Y,H^q(Z,F_Z))}_{\substack{=0 \text{ si } 0<q<n-1 \\ \text{car } Z \text{ est } (n-2)\text{-connexe}}},$$

D'où

$$0 \longrightarrow H^{n-1}(Y,F) \longrightarrow H^{n-1}(X,F_X) \longrightarrow \underbrace{H^0(Y,H^{n-1}(Z,F_Z))}_{\substack{\mathrm{Hom}_\pi(\pi_{n-1}(Z,x),F_x) \\ \text{par Hurewicz}}} \longrightarrow H^n(Y,F) \longrightarrow H^n(X,F_X).$$

L'hypothèse c_n implique qu'on a ms. page 187

$$\mathrm{Hom}_\pi(\pi_{n-1}(Z,x), \underbrace{M}_{=F_x}) = 0$$

et ceci *quel que soit le π-module M,* puisque $\pi = \pi_1(X,x) \xrightarrow{\sim} \pi_1(Y,y)$. Cela implique (en prenant p. ex. $M = \pi_{n-1}(Z,x)$!) que $\pi_{n-1}(Z,x)=0$. (Mais en faisant attention, dans le cas $n=2$, qu'on sait déjà que $\pi_1(Z,x)$ est abélien).

Donc le théorème rectifie page 178 a bien l'air vrai. Il est un peu triste, puisque dans chacune des implications

$$a_n \implies b_n \implies c_n \implies a_{n-1}$$

on perd un chouia, et en fin de compte on sort avec la magnifique implication

$$a_n \implies a_{n-1}.$$

De toutes façons, il est ± clair que le "bon" localiseur W_n, celui qui doit définir les "n-types d'homotopie" comme objets de Hot_{W_n}, est défini par la condition a_n.

ms. page 188

2 Critère de W_n-asphéricité.

Je vais essayer de faire mieux quand Y est réduit à un point. Cette fois, je
ed. 125 veux être strict, et donner (si je peux) des démonstrations complètes dans le cadre où je me place à présent, celui du modéliseur Cat, et en n'utilisant que ce que je sais y démontrer directement à présent, sans me référer à la théorie semi-simpliciale ou topologique.

Commentary · Development (commentators') [ms. 187]

Degree two and the localizer correction

Two brief remarks in the manuscript deserve a more precise disposition. The suggestion of a degree-two counterexample is stronger than the examples support, and the choice of the fibre condition as the localizer confuses a useful generating class with its saturation. Both can be settled without changing the successful implication arguments.

The degree-two converse. [ours] For maps of classifying spaces, the condition c_2 implies b_2. Consequently b_2 and c_2 are equivalent without a simple-connectivity hypothesis.

Proof. The degree-one argument already identifies fundamental groupoids, so work on one component and write $R = \mathbf{Z}[\pi]$. Let

$$I = \mathrm{Hom}_{\mathbf{Z}}(R, \mathbf{Q}/\mathbf{Z}), \qquad (r\varphi)(s) = \varphi(sr).$$

This is a left R-module and hence a permitted local system on Y. Evaluation at $1 \in R$ gives a natural adjunction isomorphism

$$\mathrm{Hom}_R(C_*(\widetilde{Y}), I) \cong \mathrm{Hom}_{\mathbf{Z}}(C_*(\widetilde{Y}), \mathbf{Q}/\mathbf{Z}),$$

and likewise for X. Its inverse sends a homomorphism λ to the map $c \mapsto (r \mapsto \lambda(rc))$. Since $\mathbf{Q}/\mathbf{Z}$ is injective as an abelian group, evaluation on homology gives

$$H^2(Y; I) \cong \mathrm{Hom}_{\mathbf{Z}}(H_2\widetilde{Y}, \mathbf{Q}/\mathbf{Z}).$$

The isomorphism is natural in the lifted map $\widetilde{f}$. Hypothesis c_2 therefore says that the dual of $H_2(\widetilde{f})$ is an isomorphism. Dualization into $\mathbf{Q}/\mathbf{Z}$ is exact and detects nonzero abelian groups: a nonzero element generates a cyclic subgroup with a nonzero homomorphism to $\mathbf{Q}/\mathbf{Z}$, and injectivity extends this homomorphism to the whole group. Applying this observation to kernel and cokernel shows that $H_2(\widetilde{f})$ itself is an isomorphism. The universal covers are simply connected, so the natural Hurewicz isomorphisms $\pi_2\widetilde{X} \cong H_2\widetilde{X}$ and $\pi_2\widetilde{Y} \cong H_2\widetilde{Y}$ prove that $\pi_2 f$ is an isomorphism. □

The algebraic ingredients are the standard injective-cogenerator argument, checked in The Stacks Project Authors (2026f, Tags 01D8 and 08WE), together with Hatcher (2002, Theorem 4.32). We did not find a source addressing footnote 112 specifically; this is our application of those familiar tools to its question. It is not a new form of the Hurewicz theorem. The same argument shows that the degree-j part of c_n detects the map on H_j of universal covers. For $j = 2$ these homology groups are exactly π_2; for $j = 3$ the Hopf class in the earlier example explains why the conclusion changes.

Now consider the last sentence of p. 187. If $A \neq 0$, the maps

$$* \xrightarrow{s} K(A, n+1) \xrightarrow{r} *$$

satisfy $rs = 1$. The fibre of r is n-connected and the fibre of rs is contractible, but the fibre of s is $K(A, n)$, which is not n-connected. Thus the class defined by a_n fails two-out-of-three. The class defined by b_n, equivalently the maps made into equivalences by nth Postnikov truncation, is the correct weak-equivalence class for n-types. The modern truncation adjunction is given in Lurie (2009, Proposition 5.5.6.18).

There is a charitable precise reading of Grothendieck's intuition.

Saturation of the fibre class. [ours] In spaces, a_n *generates* the same localization as b_n.

Proof. Every Postnikov map $X \to P_nX$ has n-connected fibres: it is an isomorphism on π_i through n, and the target has zero π_{n+1}. Given a b_n-map $f : X \to Y$, its natural square with $P_nf : P_nX \to P_nY$ has vertical maps in a_n, and its lower map is a weak homotopy equivalence, hence also lies in a_n. Two-out-of-three puts f in the saturation of a_n. Conversely, b_n is saturated and contains a_n. This proves the equality. □

The proof is a direct application of the standard truncation adjunction just cited; the formulation addresses the specific localizer sentence, without a priority claim. It leaves the literal definition on p. 187 marked as false. For $X \to *$, the two conditions agree already before saturation, so the next theorem needs no change of indexing.

Théorème 2 (?). *Soit X dans* Cat, $n \in \mathbf{N}$ *un entier* ≥ 1. *Alors les conditions suivantes sont équivalentes :*

a_n) X est 0-connexe, et si x est dans X, $\pi_i(X,x) = 0$ pour $i \in [1,n]$ (condition qui ne dépend pas du choix de x), i.e. les $\Omega^i(X,x)$ pour $i \in [1,n]$ sont 0-connexes.

b_n) Pour tout groupe G, $G \longrightarrow H^0(X, G_X)$ est un isomorphisme, et $H^1(X, G_X) = 0$. De plus, si G est abélien, on a aussi $H^i(X, G_X) = 0$, pour $i \in [1,n]$.

Démonstration. Pour $n = 1$ cette équivalence est ± tautologique et a été rappelée (sous une forme légèrement différente) au début (p. 71). On procède par récurrence. On peut donc supposer que $n \geq 2$, que X satisfait a_{n-1}, b_{n-1}, et prouver qu'alors a_n, b_n sont équivalentes, i.e. $\pi_n(X,x) = 0$ équivaut à $H^n(X,M) = 0$ pour tout groupe abélien M.

On utilise la W_∞-fibration (parfaite) ms. page 189

$$\begin{array}{ccc} E = \underline{\mathrm{Ch}}(X; x, -) & & E \ W_\infty\text{-asphérique} \\ \big\downarrow & & \\ X & & \end{array}$$

de fibre Z en x égale à $\Omega(X,x)$.

Commentary · Context [ms. 188]

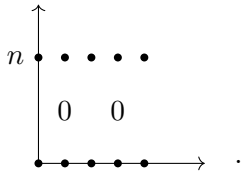
Why the path fibration is the right final test

Grothendieck now asks the categorical path construction to reproduce an argument whose classical power came from the contractible total space of based paths. Serre's thesis developed precisely this exchange between the homology of a space, that of its loop space, and their homotopy groups; see Serre (1951, Chapter IV, §5, Proposition 7). The point of repeating the argument in Cat is not a new calculation of the groups. It is to show that the categorical paths already carry enough geometry to recognize the ordinary weak homotopy type, before appealing to a comparison with topological paths.

For $E = \underline{\mathrm{Ch}}(X; x, -) \to X$, the total category is W_∞-aspherical and the fibre is $Z = \Omega(X,x)$. Under the induction hypothesis, both base and fibre have long vanishing ranges. The spectral sequence then has only its bottom row and one possible first fibre row. The vanishing of the total cohomology forces those two rows to communicate by transgression. This is the reason the proof over a point is sharper than the preceding relative theorem: there is no independent cohomology of a nontrivial target that can absorb the first obstruction.

The condition in degree zero should be read literally for every group. Taking a nontrivial group G, the diagonal map $G \to G^{\pi_0 X}$ is bijective only when $\pi_0 X$ has one element. It excludes the empty category as well. Once X is connected, the condition $H^1(X, G_X) = *$ for every group G forces $\pi_1 X = 1$: choose $G = \pi_1 X$ and the conjugacy class of its identity representation. This is why abelian coefficients alone would not prove the initial case; a perfect nontrivial fundamental group could otherwise survive.

Supposons a_n) pour X, donc a_{n-1}) pour $\Omega(X,x)$. Par hypothèse de récurrence, on a donc



$$H^i(Z, M) = 0 \qquad \text{pour } i \in [1, n-1],$$

M groupe abélien. Donc dans la suite spectrale de Leray,

$$H^*(E, M) \Longleftarrow E_2^{pq} = H^p(X, H^q(Z, M))$$

on a

$$E_2^{pq} = 0 \qquad \text{si } q \in [1, n-1],$$

ed. 126 On a donc la suite exacte

$$0 \longrightarrow H^n(X, M) \longrightarrow H^n(E, M)$$

et comme E est W_∞-asphérique, on a $H^n(E, M) = 0$, donc $H^n(X, M) = 0$.

Inversement, supposons b_n), prouvons a_n). On sait déjà qu'on a a_{n-1}), donc a_{n-2} pour $\Omega(X, x)$, ce qui implique

$$H^i(Z, M) = 0 \qquad \text{pour } i \in [1, n-2],$$

donc

$$E_2^{pq} = 0 \qquad \text{si } q \in [1, n-2].$$

On a donc la suite exacte

ms. page 190

$$0 \longrightarrow \underbrace{H^{n-1}(X, M)}_{=0} \longrightarrow \underbrace{H^{n-1}(E, M)}_{=0} \longrightarrow H^0(X, H^{n-1}(Z, M)) \longrightarrow \underbrace{H^n(X, M)}_{=0} \longrightarrow H^n(E, M),$$

donc

$$H^0(X, \quad \underbrace{H^{n-1}(Z, M)}_{\substack{\text{système local} \\ \textit{constant} \text{ sur } X, \\ \text{car } X \text{ est 1-connexe}}} \quad) = 0,$$

donc

$$H^{n-1}(Z, M) = 0,$$

ce qui, par hypothèse de récurrence, implique $\pi_{n-1}(Z, z) = 0$, donc $\pi_n(X, x) = 0$, q.e.d.

Corollaire. *Pour que X soit W_∞-asphérique, i.e. pour qu'on ait $G \xrightarrow{\sim} H^0(X, G)$, $H^1(X, G) = 0$* `[pour]` *tout groupe* `[G]`*, et $H^i(X, G) = 0$ si $i \geq 2$ pour G abélien, il faut et il suffit que* 1°) *X soit 0-connexe, et (x étant un point de X)* 2°) *les $\Omega^i(X, x)$* `[soient]` *0-connexes pour $i \geq 1$.*

Commentary · Exposition [ms. 190]

The loop criterion, including its degree-two endpoint

Theorem 2 is proved by the displayed induction, with one small verification at its lower endpoint. Suppose first that X is n-connected. Then $Z = \Omega X$ is $(n-1)$-connected, so the induction hypothesis annihilates $H^q(Z; M)$ for $1 \leq q < n$. In the path-fibration spectral sequence this gives an injection

$$H^n(X; M) \hookrightarrow H^n(E; M) = 0.$$

The lower-degree groups have already vanished, and the degree-zero and torsor conditions follow from connectedness and simple connectivity. This proves the forward implication exactly in the form stated.

Conversely, assume the cohomological conditions through degree n. The induction hypothesis makes X $(n-1)$-connected and Z $(n-2)$-connected. For $n \geq 2$, X is simply connected, so the fibre-cohomology local systems on X are constant. The low-degree exact sequence for $E \to X$ gives

$$H^0(X; \mathcal{H}^{n-1}(Z; M)) = 0, \qquad \text{hence} \qquad H^{n-1}(Z; M) = 0$$

for every abelian M. If $n \geq 3$, Z is simply connected. Its nonabelian degree-one conditions and all its lower abelian cohomology conditions are already satisfied; the induction hypothesis applied to Z therefore gives $\pi_{n-1} Z = 0$.

For $n = 2$, one cannot immediately apply that same sentence: Z is only known to be connected, and the displayed computation gives vanishing of $H^1(Z; M)$ only for abelian groups M. The loop multiplication supplies the missing information. The two compositions of loops in the connected loop

space, concatenation of based loops and the multiplication induced from the loop-space multiplication, have the same unit and satisfy the interchange law. The Eckmann–Hilton argument makes $\pi_1 Z$ abelian. Thus

$$H^1(Z; M) = \mathrm{Hom}(\pi_1 Z, M),$$

and choosing $M = \pi_1 Z$ forces $\pi_1 Z = 0$. Equivalently, this is the familiar fact that $\pi_1 \Omega X = \pi_2 X$ is abelian. It closes the induction without requiring an additional theorem about nonabelian cohomology of Z.

The corollary follows by allowing every finite n. Connectedness of X together with connectedness of every iterated loop category says that all homotopy groups of BX vanish. Since a realization of a nerve has CW type, Whitehead's theorem makes BX weakly equivalent, indeed homotopy equivalent, to a point; see Hatcher (2002, Theorem 4.5). Here "aspherical" means weakly contractible, not merely the modern usage $\pi_i = 0$ for $i > 1$. For example $B\mathbf{Z} \simeq S^1$ has no higher homotopy groups, but its first loop category has components indexed by $\mathbf{Z}$, so it fails this criterion immediately.

The later minimal-localizer theorem identifies this test with Grothendieck's original axiomatic weak equivalences. Its local characterization also makes the loop method visible in the final proof: Cisinski (2004, Theorem 2.3.6, especially 2.3.6.3–2.3.6.4) passes from a weakly aspherical object to its loops and then uses vanishing of homotopy groups. Thus the categorical construction has reached its intended target. The distinction between different choices of categorical paths has become a question of canonical comparison, which is exactly the subject of the following pages.

3 Sur la philosophie des fibres homotopiques.

Le critère d'asphéricité (pour W_∞) que je viens d'obtenir, grâce aux foncteur $\underline{\mathrm{Ch}}(X)$ (ou au choix, $\underline{\mathrm{Ch}}_\infty(X)$) et ses dérivés $\Omega(X, x)$ et les itérés, enlève tout doute (s'il pouvait en rester encore) que les 'espaces de chemins' que j'ai construit (assez péniblement!) sont bel et bien 'les bons'. Je voudrais maintenant me rendre compte de façon la plus précise possible de leur 'canonicité', dans quelle mesure ces constructions sont indépendant d'un choix (p.ex. celui entre la théorie $\underline{\mathrm{Ch}}$, et $\underline{\mathrm{Ch}}_\infty$).

Tout revient, finalement, à des questions de factorisation d'une flèche quelconque

$$f : X \longrightarrow Y$$

ed. 127 de Cat en

$$X \xrightarrow{i_f} \bar{X} \xrightarrow{\bar{f}} Y,$$

avec

$$i_f \in W, \qquad \bar{f} \in W\text{-fib}$$

(le fait que $\bar{f}$ puisse même être choisie W_ω-parfait, ne me paraissant pas essentiel ici).

C'est bien de cela qu'il s'agit pour construire
un objet 'chemins dans X'

$$\underline{\mathrm{Ch}}(X),$$

ms. page 192

en factorisant l'application diagonale

$$X \xrightarrow{\mathrm{diag}_X} X \times X,$$

et aussi quand on construit $\Omega(X, x)$ comme fibre en x d'une W-fibration

$$E(X, x) \longrightarrow (X, x)$$

qui factorise l'inclusion

$$\{x\} \longrightarrow X$$

(donc $E(X, x)$ étant W-asphérique).

Commentary · Context [ms. 191]

From a model for paths to an intrinsic operation

The question of canonicity belongs to Grothendieck's original reason for introducing derivators. In *Pursuing Stacks*, §69, he recalls the inadequacy of a single derived category for some of the diagrammatic constructions arising from the SGA 5 trace formalism. He proposes retaining derived categories for all diagram shapes, with their variance in the indexing category. The two three-object shapes for spans and cospans already encode homotopy fibres and cofibres (Grothendieck, 1983, §69, printed pp. 1–3). The move on these pages, from a particular category of paths to a property of localized slices, is a local instance of that larger programme.

The letter to Thomason of 2 April 1991 makes the distinction especially explicit. Its first numbered discussion treats W as the essential homotopical datum and fibrations or cofibrations as additional means of proving existence and calculating operations; it then describes the intrinsic class of pullback-preserving W-fibrations (Grothendieck, 1991a, point 1, pp. 3–4). This is a retrospective clarification of the position being explored here, not evidence that every provisional axiom of the present pages has already been checked. In particular, the retract qualification discussed below remains necessary under the literal two-out-of-three assumptions. The calculation of paths serves the intrinsic operation by providing enough useful representatives on which the operation becomes ordinary pullback.

On peut être plus ou moins exigeant, et regarder, soit pour un 'but' Y (ou plutôt un S) fixé dans Cat, une factorisation fonctorielle

$$C : \mathrm{Cat}/S \longrightarrow \underline{\mathrm{Fib}}_W S \hookrightarrow \mathrm{Cat}/S$$

du morphisme structural $X \longrightarrow S$ d'un objet, en

$$X \xrightarrow{i_X} C(X) \longrightarrow S,$$

i.e. on se donne le foncteur C, *plus*
le morphisme fonctoriel ms. page 193

$$i_C : \mathrm{id}_{\mathrm{Cat}/S} \longrightarrow C$$

avec

$$(i_X : X \longrightarrow C(X)) \in W \qquad \forall\ X \text{ dans } \mathrm{Cat}/S,$$

soit être encore plus exigeant et faire varier en même temps la source et le but de $f : X \longrightarrow Y(= S)$, et demander un foncteur

$$i_f \in W, \qquad p_f \in W\text{-fib}$$

pour toute flèche f dans Cat.

Commentary · Exposition [ms. 192]

A replacement must remember its comparison map

Grothendieck now asks what the lengthy construction of paths has bought him beyond a convenient calculation. The preceding connectivity criterion identifies its homotopical effect; it does not yet identify the construction independently of its presentation. The change of viewpoint is to regard a path category as a factorization of a structural map. A factorization of the diagonal gives paths, and a factorization of a point inclusion gives based paths. Once the second factor has the required base-change property, its ordinary fibres can serve as homotopy fibres. The same question can therefore be asked without mentioning intervals or zigzags.

For a fixed base put $\mathcal{A} = \mathrm{Cat}/S$, and let $\mathcal{F} \subseteq \mathcal{A}$ be the full subcategory of the permitted fibrations over S. The data are a functor $C : \mathcal{A} \to \mathcal{F}$ and a natural transformation $i : \mathrm{id}_{\mathcal{A}} \to jC$, where j is inclusion and every i_X belongs to W_S. The transformation is part of the data. An arbitrary choice of an equivalent object for every X would neither provide the arrows $C(f)$ nor specify which comparison is to be called canonical. Naturality supplies both controls at once. Indeed,

$$C(f)i_X = i_Y f$$

and two-out-of-three show that $f \in W_S$ if and only if $C(f) \in W_S$. Thus the homotopicality of C is a consequence of its coaugmentation, not an extra axiom.

There are two levels of functoriality in the text. A replacement on $\mathcal{A}$ controls variation of the object over one base. A replacement on the arrow category also controls maps between bases, although it need not commute with ordinary pullbacks. The latter distinction matters: a functorial factorization of arrows does not, merely by being functorial, identify $C(X \times_S T)$ with $C(X) \times_S T$. Derived base change will be obtained from a localization argument. It is not asserted to be an identity between these raw constructions.

This is the same elementary geometry that underlies Brown's mapping-path factorization. In a category of fibrant objects, a factorization of the diagonal of Y yields a factorization of $f : X \to Y$ by pulling that path object back along f. Brown requires no functorial choice of path objects for this argument (Brown, 1973, Part I, §1, pp. 420–422). Grothendieck deliberately asks for a more explicit choice here so that comparison maps can be written in the original category. The two approaches answer different parts of the same problem: existence of the derived construction and a convenient formula for computing it.

ms. page 194

Dans les deux points de vue, dans quel sens a-t-on *unicité* d'une telle construction?

Prenons d'abord le premier point de vue, factorisation des flèches à but fixé S, donc `[c'est une]` question dans Cat/S. J'ai oublié une propriété importante, mais elle résulte de ce qui a été dit : le foncteur

$$X \longmapsto C(X) : \qquad \begin{array}{ccc} \mathrm{Cat}/S & \longrightarrow & \mathrm{Cat}/S \\ & \searrow \quad \nearrow & \\ & \underline{\mathrm{Fib}}_W S & \end{array}$$

transforme `[les]` *flèches* `[de]` W *en itou*, comme on voit sur le diagramme commutatif

$$\begin{array}{ccc} X & \xrightarrow{i_X} & C(X) \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle C(f)} \\ Y & \xrightarrow{i_Y} & C(Y), \end{array}$$

où i_X, i_Y sont dans W, donc

$$f \in W \qquad \Longleftrightarrow \qquad C(f) \in W.$$

Soit

$$(C', i')$$

ms. page 195

un deuxième foncteur, $\mathrm{Cat}/S \longrightarrow \mathrm{Cat}/S$,

muni d'un morphisme

$$i' : \mathrm{id}_{\mathrm{Cat}/S} \longrightarrow C'$$

qui est dans W argument par argument, et tel que C' se factorise par $\underline{\mathrm{Fib}}_W S$. On peut comparer C et C' moyennant $C \circ C'$, car

$$\begin{array}{ccccc} & & C \circ C' & & \\ & {\scriptstyle C*i'} \nearrow & & \nwarrow {\scriptstyle i*C'} & \\ C = C \circ \mathrm{id} & & & & C' = \mathrm{id} \circ C', \end{array}$$

ed. 129 i.e. on a, pour tout X dans Cat/S,

$$\begin{array}{ccccc} & & C(C'(X)) & & \\ & {\scriptstyle C(i'_X)} \nearrow & & \nwarrow {\scriptstyle i_{C'(X)}} & \\ C(X) & & & & C'(X), \end{array}$$

le deux flèches étant dans W (celle de gauche parce que $C(W) \subseteq W$). Ce sont des flèches dans $\underline{\mathrm{Fib}}_W S$, et si on suppose que W satisfait W(4b), elles induisent des W-équivalences en chaque fibre. Cela montre donc déjà

qu'à isomorphisme (peut-être non-canonique) près, le foncteur composé défini par C, ms. page 196

$$X \longmapsto C(X) \longmapsto (s \longmapsto \mathrm{hot}_W(C(X)_s))$$

$$\begin{array}{ccccc} \mathrm{Cat}/S & \longrightarrow & \underline{\mathrm{Fib}}_W S & \longrightarrow & \underline{\mathrm{Hom}}(S^\circ, \mathrm{Hot}_W), \\ & \searrow & & \nearrow & \\ & & {\scriptstyle \varphi_C} & & \end{array}$$

ne dépend pas du choix particulier de C, i.e. deux tels foncteurs 'fibres homotopiques' (correspondant à deux choix C, C') sont toujours isomorphes. Mais au lieu d'utiliser $C \circ C'$ pour définir un tel isomorphisme, on aurai pu utiliser $C' \circ C$, ou quelque autre procédé. On aimerait comprendre s'il y a unicité véritable, une caractérisation intrinsèque de ces isomorphismes $\varphi_C \xrightarrow{\sim} \varphi_{C'}$, indépendamment de telle construction ou de telle autre.

Je présume que $C \circ C'$ est lui aussi muni de

$$\mathrm{id}_{\mathrm{Cat}/S} \longrightarrow C \circ C',$$

et même a priori de deux façons possible

ms. page 197

$$\begin{array}{ccccc} & & C(C'(X)) & & \\ & {\scriptstyle C(i'_X)} \nearrow & & \nwarrow {\scriptstyle i_{C'(X)}} & \\ C(X) & & & & C'(X) \\ & {\scriptstyle i_X} \nwarrow & & \nearrow {\scriptstyle i'_X} & \\ & & X, & & \end{array}$$

soit par $C(i'_X) \circ i_X$, soit par $i_{C(X)} \circ i'_X$, heureusement elles sont égales, car pour toute flèche $X \xrightarrow{i'} X'$ dans Cat/S, le carré

Commentary · Exposition [ms. 196]

Two replacements and one normalized comparison

The composite replacement is a useful device because it compares two constructions without asking either to map directly to the other. Write the two coaugmentations as $i : \mathrm{id} \to C$ and $i' : \mathrm{id} \to C'$. For every X the diagram gives

$$C(X) \xrightarrow{C(i'_X)} CC'(X) \xleftarrow{i_{C'(X)}} C'(X).$$

Both arrows are weak equivalences: the first because C preserves W_S, and the second because it is a component of i. Their passage to fibrewise equivalences uses the additional fibre axiom invoked in the text. This last step must be retained. A weak equivalence of total objects over a base need not induce weak equivalences of their ordinary fibres when the objects have not been suitably replaced.

There is already a precise answer to the question about the order CC' versus $C'C$. Let $q : \mathcal{A} \to \mathcal{A}[W_S^{-1}]$ be localization. The required comparison between the two localized endofunctors is

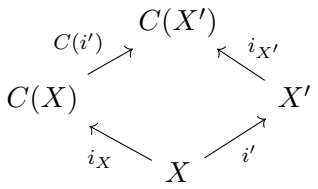
$$\theta_{C,C'}(X) = q(i'_X)q(i_X)^{-1}.$$

It is the unique comparison compatible with the specified maps from $q(X)$. Naturality of i, applied to i'_X, gives

$$C(i'_X)i_X = i_{C'(X)}i'_X.$$

After localization this proves

$$q(i_{C'(X)})^{-1}q(C(i'_X)) = q(i'_X)q(i_X)^{-1}.$$



The common-refinement construction therefore gives exactly the normalized comparison. Reversing the order of the replacements gives the same answer. For three replacements the cocycle identity is literal:

$$\theta_{C',C''}\theta_{C,C'} = \theta_{C,C''}.$$

The apparent ambiguity disappears as soon as compatibility with the coaugmentations is made explicit.

When this calculation is transported to the category of fibres, one uses the full faithfulness of the localization comparison proved below. In that category the formula is not an instruction to apply an ordinary fibre functor to i_X: its source X need not be fibrant. Instead, it characterizes the comparison after passing through the equivalence of localized categories. This is the categorical content of the word "canonical" here. It does not say that the underlying functors admit no other automorphisms after their specified comparison maps have been forgotten.

ed. 130

est commutatif (par fonctorialité de $i_X : X \longrightarrow C(X)$), et on applique ceci au cas de $X' = C'(X)$, $i' = i'_X$.

Cette remarque nous encourage à faire un saut dans l'abstraction, et d'introduire la catégorie ms. page 198

$$(*) \qquad \mathcal{C} = \mathcal{C}_S = \begin{cases} \text{catégorie des couples } (C, i), \text{ avec} \\ C : \mathrm{Cat}/S \longrightarrow \mathrm{Cat}/S \text{ se factorisant par } \underline{\mathrm{Fib}}_W S, \\ i : \mathrm{id}_{\mathrm{Cat}/S} \longrightarrow C \text{ tel que } i_X \in W \ \forall\ X \text{ dans } \mathrm{Cat}/S, \end{cases}$$

une flèche

$$(C, i) \longrightarrow (C', i')$$

étant une flèche

$$C \xrightarrow{u} C' \qquad (\text{dans } \underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{Cat}/S))$$

rendant commutatif le carré `[lire : le diagramme]`

$$\begin{array}{ccc} & \mathrm{id}_{\mathrm{Cat}/S} & \\ {\scriptstyle i}\swarrow & & \searrow{\scriptstyle i'} \\ C & \xrightarrow{\quad u \quad} & C'. \end{array}$$

En d'autres termes, $\mathcal{C}$ est défini comme une sous-catégiorie pleine de

$$\mathrm{id}_{\mathrm{Cat}/S} \backslash \underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{Cat}/S),$$

à savoir celle dont les objets (C, i) satisfont les deux conditions $(*)$ plus haut (impliquant l'une et l'autre le localiseur W).

Ces conditions impliquent ceci ms. page 199

a) $\forall\ X$ dans Cat/S, $(u_X : C(X) \longrightarrow C'(X)) \in W$, puisque

$$\begin{array}{ccc} & X & \\ {\scriptstyle i_X \in W}\swarrow & & \searrow{\scriptstyle i'_X \in W} \\ C(X) & \xrightarrow{\quad u_X \quad} & C'(X), \end{array}$$

ed. 131 et

b) si W satisfait W(4b), de sorte que $u_X \in W_S^{\mathrm{f}}$, alors ce définit un *isomorphisme* entre $\varphi_C(X)$ et $\varphi_{C'}(X)$

$$\begin{array}{ccc} s & \longmapsto & \mathrm{hot}_W(C(X)_s) \\ & & \downarrow u_{X,s} \\ s & \longmapsto & \mathrm{hot}_W(C'(X)_s). \end{array}$$

Mieux encore, dans ce cas, le foncteur composé

$$\mathcal{C} \times \mathrm{Cat}/S \longrightarrow \underline{\mathrm{Fib}}_W S \longrightarrow \mathrm{HOT}_W^{\mathrm{lc}}(S)$$

donne naissance à

$$\mathcal{C} \longrightarrow \underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{HOT}_W^{\mathrm{lc}}(S))$$

qui transforme toute flèche de $\mathcal{C}$ en `[un]` *isomorphisme,* donc se factorise par le groupoïde fondamental de $\mathcal{C}$,

$$\Pi\mathcal{C} \longrightarrow \underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{HOT}_W^{\mathrm{lc}}(S)).$$

Quant au foncteur envisagé tantôt ms. page 200

$$\begin{array}{ccc} \mathcal{C} & \longrightarrow & \underbrace{\underline{\mathrm{Hom}}\,(\mathrm{Cat}/S, \underline{\mathrm{Hom}}(S^\circ, \mathrm{Hot}_W))}_{\simeq \underline{\mathrm{Hom}}((\mathrm{Cat}/S)\times S^\circ, \mathrm{Hot}_W)} \\ C & \longmapsto & ((X,s) \longmapsto \mathrm{hot}_W(C(X)_s)\,), \end{array}$$

il se déduit du précédent en composant avec

$$\begin{array}{ccc} \mathrm{HOT}_W(S) & \longrightarrow & \underline{\mathrm{Hom}}(S^\circ, \mathrm{Hot}_W), \\ & \searrow \quad \nearrow & \\ & \underline{\mathrm{Hom}}(\Pi S^\circ, \mathrm{Hot}_W) & \end{array}$$

plus exactement, avec le foncteur qui s'en déduit

$$\underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{HOT}_W(S)) \longrightarrow \underline{\mathrm{Hom}}(\mathrm{Cat}/S, \underline{\mathrm{Hom}}(S^\circ, \mathrm{Hot}_W)).$$

On voit poindre ici un principe plausible de canonicité d'isomorphismes, en ce qui concerne les foncteurs

$$C_W : \mathrm{Cat}/S \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(S)$$

définis par les $C \in \mathrm{Ob}\,\mathcal{C}$, par la relation

$$\Pi\mathcal{C} \approx \text{ catégorie ponctuelle, i.e. } \mathcal{C} \text{ est 1-connexe.}$$

De plus, les arguments utilisés jusqu'ici sont de nature à tel point formelle, que les aspects
ed. 132 spécifiques du Modéliseur Cat semblent n'y jouer pratiquement aucun rôle, ou un rôle très ms. page 201
effacé.

Commentary · Exposition [ms. 200]

The category of choices is contractible

Grothendieck's category $\mathcal{C}$ packages the compatibility just used. Its arrows are natural transformations of replacement functors that commute with their coaugmentations. Every such arrow is pointwise in W_S, by two-out-of-three. Hence any construction which sends these weak equivalences to isomorphisms factors through $\Pi\mathcal{C}$. The remaining question is whether this groupoid has exactly one arrow between any two objects. The natural common refinements give more: provided a replacement exists, the nerve of $\mathcal{C}$ is contractible.

Here is a direct proof. Fix $(R, r) \in \mathcal{C}$ and define

$$T(C, i) = \big(CR, (Cr)i\big).$$

The displayed unit is also $(iR)r$, by naturality of i. The composite CR takes values in $\mathcal{F}$, and its coaugmentation is a weak equivalence. Thus T is an endofunctor of $\mathcal{C}$. On an arrow $u : C \to D$ put $T(u) = uR$. There are natural transformations

$$\mathrm{id}_{\mathcal{C}} \xrightarrow{\alpha} T \xleftarrow{\beta} \mathrm{const}_{(R,r)}, \qquad \alpha_C = Cr, \quad \beta_C = iR.$$

Both are arrows under the identity functor because $(Cr)i = (iR)r$. To check their naturality, use, respectively, naturality of u at r_X and the equation $ui = j$ for a map $(C, i) \to (D, j)$. These are equalities before localization.

A natural transformation $F \to G$ gives a functor $\mathcal{D} \times [1] \to \mathcal{E}$, hence a homotopy between the maps of nerves induced by F and G; this is the elementary nerve calculation used in Quillen (1973, §1, Proposition 2). The two transformations above consequently homotope the identity of $|N\mathcal{C}|$ to a constant map. With the usual change of universe if necessary, $|N\mathcal{C}|$ is contractible. In particular, $\Pi\mathcal{C}$ is equivalent to the terminal groupoid. Any two zigzags of comparisons between the same replacements induce the same isomorphism in a target in which all arrows of $\mathcal{C}$ become invertible.

This argument also locates the imprecision in the word *filtrante* on the next page. A common target for two objects is only one of the conditions for a filtered category; parallel arrows must also become equal after postcomposition. The common-refinement square does not establish that second condition. Nor do the natural maps into a binary product, even with all the displayed coherence, establish it in general. For example, the category of nonempty finite ordered sets and order-preserving injections has ordered concatenation and natural inclusions from both factors. It is not filtered: the two injections from a singleton into a two-element ordered set remain distinct after every injection. Nevertheless its nerve is contractible by the same argument. This example refutes the inference being used, not a separately proved assertion that this particular $\mathcal{C}$ fails to be filtered. Contractibility supplies precisely the canonicity needed here, so no strict equalization claim is required.

Le carré de la page 197 montre surtout que la catégorie $\mathcal{C}$ est filtrante - (C, i), (C, i') s'envoient l'un et l'autre dans (C'', i''), avec $C'' = C \circ C'$, et $i'' = (C * i') \circ i = (i * C') \circ i'$. Il

y a même une loi de composition dans $\mathcal{C}$, nullement commutative ni unitaire c'est sûr, mais sûrement associative, et (si cette composition est notée $*$) avec des morphismes fonctoriels

$$\xi \xrightarrow{\alpha_{\xi,\xi'}} \xi * \xi' \xleftarrow{\beta_{\xi,\xi'}} \xi'$$

qui assurent le caractère filtrant croissant de $\mathcal{C}$. Ces flèches semblent remplacer en quelque sorte l'unité bilatère absente, et on s'attend à ce qu'elles aient les mêmes excellentes propriétés que si on avait une telle unité, concernant les composés doubles $(\xi * \xi') * \xi'' \simeq \xi * (\xi' * \xi'')$,

ms. page 202

$$(\xi * \xi') * \xi'' \xrightarrow{\sim} \xi * (\xi' * \xi'').$$

Il y a deux façons d'envoyer un produit binaire

$$\xi * \xi', \qquad \xi' * \xi'', \qquad \xi * \xi''$$

dans le produit ternaire, et bien elles doivent dans chacun des trois cas, être égales. Et de même il y a, ceci admis, encore deux façons d'envoyer ξ dans le produit ternaire, en factorisant soit par $\xi * \xi'$, soit par $\xi * \xi''$, et de même pour les deux autres foncteurs ξ', ξ''; et là encore, ces deux façons doivent être égales, dans chacun de ces trois cas - donc $3 + 3 = 6$ égalités en tout à écrire et à vérifier - on a vu pire!

La philosophie calculatoire devrait être celle-ci : Si on a un produit n-uple

$$\xi_1 * \xi_2 * \cdots * \xi_n$$

(où je me dispense de mettre des parenthèses ...), pour tout produit m-uple partiel ($m \in [1, n-1]$)

ms. page 203

$$\xi_{i_1} * \xi_{i_2} * \cdots * \xi_{i_m} \qquad (i_1 < i_2 < \cdots < i_m),$$

en utilisant à tour de bras les isomorphismes d'associativité et les $\alpha_{\xi,\xi'}$, $\beta_{\xi,\xi'}$, il n'y a pourtant qu'une seule façon de l'envoyer dans le produit n-uple. J'ai bien l'impression que ça doit être vrai. (Est-ce que ça implique déjà que $\mathcal{C}$ est 1-connexe?)

En fait, il y a bien une unité bilatère, mais elle n'est pas dans $\mathcal{C}$, mais dans la catégorie plus grande

$$\mathrm{id}_{\mathrm{Cat}/S} \backslash \underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{Cat}/S),$$

qui elle, comme toute catégorie

$$\mathrm{id}_{\mathcal{X}} \backslash \underline{\mathrm{Hom}}(\mathcal{X}, \mathcal{X}),$$

ed. 133 est une catégorie monoïdale, i.e. avec produit associatif *et* unitaire. Les flèches $\alpha_{\xi,\xi'}$, $\beta_{\xi,\xi'}$ sont les flèches qui résultent de la présence de cette unité (vu que $\mathcal{C}$ est une sous-catégorie pleine), et alors il doit devenir clair qu'on a les compatibilités dites.

ms. page 204

Mais même une catégorie monoïdale, est elle 1-connexe? Par exemple B_G, pour G un groupe disons, est bien une catégorie monoïdale et même 'groupale', une G-catégorie (tout ce qu'il y a de strict), et pourtant elle n'est *pas* 1-connexe!

Commentary · Exposition [ms. 203]

Insertion of units accounts for all six equalities

The associativity discussion is an effort to make the comparison procedure usable without remembering a particular sequence of refinements. It can be completed inside the ordinary monoidal category of endofunctors. An object of the coslice $\mathrm{id}_{\mathcal{A}} \backslash \mathrm{Fun}(\mathcal{A}, \mathcal{A})$ is a pointed endofunctor (C, i). Set

$$(C, i) * (D, j) = (CD, (Cj)i) = (CD, (iD)j).$$

The equality is naturality of i. Horizontal composition of natural transformations makes this a bifunctor. Its associativity is strict when functor composition is taken strictly, and its unit is $(\mathrm{id}, \mathrm{id})$.

That unit is also initial in the coslice: the unique arrow to (C, i) is i itself. Although the unit need not lie in the replacement subcategory, its arrows supply α and β there.

For an ordered list $(C_1, i_1), \dots, (C_n, i_n)$ and a subset $J \subseteq \{1, \dots, n\}$, insert an identity endofunctor in every position not in J. The map from this partial composite to $C_1 \cdots C_n$ is the horizontal composite of the identity transformations in the retained positions and the transformations $i_k : \mathrm{id} \to C_k$ in the omitted positions. This gives a specified map for every inclusion of ordered subsets. Its compatibility with a second insertion follows from the interchange law for horizontal and vertical composition of natural transformations. In components that law is just the naturality square which permits two adjacent insertions to change order. Any two orders of insertion differ by adjacent interchanges, so they give the same map. This proves the three binary-to-ternary and the three unary-to-ternary equalities requested in the manuscript, and proves the general ordered-subword assertion at the same time.

The concern raised using B_G has a valid lesson but needs a restriction on G. The one-object category with automorphism group G is a strict monoidal category of this form only when G is abelian. Indeed, the tensor product and composition share the same unit and obey interchange, so

$$a \otimes b = (a \circ 1) \otimes (1 \circ b) = (a \otimes 1) \circ (1 \otimes b) = a \circ b;$$

interchanging the two factorizations gives $a \circ b = b \circ a$. Conversely, an abelian group defines such a strict monoidal category by using its group operation for tensor product. Taking $G = \mathbf{Z}$ therefore gives a valid example with nontrivial fundamental group. What contracts the replacement category is the natural pair of maps into $C * R$, not monoidality alone. The source's broad assertion about an arbitrary group is left as printed and is registered separately from the repaired example.

Bien sûr, on peut court-circuiter la question de la 1-connexité de $\mathcal{C}$, en notant qu'après tout on a déjà a priori un objet privilégié dans

$$\underline{\mathrm{Hom}}(\mathrm{Cat}/S, \mathrm{HOT}^{\mathrm{lc}}_W(S)),$$

i.e. un foncteur canonique

$$\mathrm{Cat}/S \longrightarrow \mathrm{HOT}^{\mathrm{lc}}_W(S),$$

savoir le foncteur composé

$$(*) \qquad \mathrm{Cat}/S \underbrace{\longrightarrow}_{\substack{\text{localisation} \\ \text{par } W_S}} (\mathrm{Cat}/S)W_S^{-1} \longrightarrow \underbrace{\mathrm{HOT}^{\mathrm{lc}}_W(S)}_{\overset{\text{déf}}{=}(\underline{\mathrm{Fib}}_W S)(W_S^{\mathrm{f}})^{-1}} \quad ,$$

où la deuxième flèche est définie comme le quasi-inverse de

$$(**) \qquad (\underline{\mathrm{Fib}}_W S)(W_S^{\mathrm{f}})^{-1} \longrightarrow (\mathrm{Cat}/S)W_S^{-1}$$

déduit de l'inclusion ms. page 205

$$(\underline{\mathrm{Fib}}_W S, W_S^{\mathrm{f}}) \hookrightarrow (\mathrm{Cat}/S, W_S).$$

Le fait que $(*)$ soit une équivalence, se prouve justement par le fait de l'existence d'un foncteur $C : \mathrm{Cat}/S \longrightarrow \mathrm{Cat}/S$ et d'un $i : \mathrm{id}_{\mathrm{Cat}/S} \longrightarrow C$, ayant les propriétés qu'on sait, i.e. du fait que $C \neq \emptyset$. De plus, la donnée d'un objet C de $\mathcal{C}$ donne un moyen commode d'expliciter le quasi-inverse dudit foncteur. Mais ce quasi-inverse a une existence canonique et indépendante du choix d'un C, i.e. d'un mode de calcul. Le fait que le foncteur composé φ dans $(*)$ puisse se 'relever' (à isomorphisme près) en un foncteur

$$C : \mathrm{Cat}/S \longrightarrow \underline{\mathrm{Fib}}_W S$$

entre $\varphi(X) = \mathrm{hot}_{W,S}(X)$ et $\mathrm{hot}_{W,S}(C(X))$ et que l'isomorphisme puisse s'expliciter, lui aussi, par une flèche X-fonctorielle

$$i_X : X \longrightarrow C(X), \qquad i_X \in W, \qquad \text{ms. page 206}$$

ed. 134 dans Cat/S lui-même (et non seulement dans le localisé (Cat/S)W_S^{-1}), est une vertu particulière du [mot illisible], qui ne doit pas pour autant faire oublier le caractère intrinsèque des flèches (∗), indépendamment de tout mode de calcul.

Commentary · Exposition [ms. 205]

Why the inclusion becomes an equivalence

Grothendieck's second answer to the canonicity problem identifies the category being computed. We give the localization argument explicitly, since its hypotheses explain both its strength and its limits. Let $(\mathcal{A}, W)$ be a category with weak equivalences satisfying two-out-of-three, let $j : \mathcal{F} \hookrightarrow \mathcal{A}$ be full, and suppose $C : \mathcal{A} \to \mathcal{F}$ is equipped with $i : \mathrm{id}_{\mathcal{A}} \to jC$ whose components lie in W. Give $\mathcal{F}$ the induced weak equivalences. Then

$$\overline{j} : \mathcal{F}[W^{-1}] \longrightarrow \mathcal{A}[W^{-1}]$$

is an equivalence. Indeed, naturality and two-out-of-three show that C preserves weak equivalences, so it induces $\overline{C}$. The transformation i induces an isomorphism $\mathrm{id} \simeq \overline{j}\,\overline{C}$. Its restriction to $\mathcal{F}$ has all its components in $\mathcal{F}$, because that subcategory is full, and gives $\mathrm{id} \simeq \overline{C}\,\overline{j}$. These two natural isomorphisms prove the assertion. This is the same replacement mechanism used earlier in the commentary, notably on Chapter VI, manuscript p. 112; here it proves an equivalence with the entire localized slice.

For the particular functor (∗∗) the weak equivalences on $\underline{\mathrm{Fib}}_W S$ have been written W_S^{f} rather than as the induced W_S. One therefore also uses their agreement on this subcategory: the fibre axiom supplies the implication from total to fibrewise equivalence, while the converse is the relevant local-to-global property. Nonemptiness of $\mathcal{C}$ alone, without this compatibility of weak-equivalence classes, is not the whole statement. Once the compatibility is available, the preceding proof applies exactly as written.

The printed sentence on manuscript p. 205 calls (∗) an equivalence. The equivalence proved by the argument is (∗∗); (∗) starts in the unlocalized category and includes a localization functor. This is an edition-level slip, not a defect in the replacement argument. For example, even over the terminal base, localization identifies distinct natural-homotopic maps of categories, so the original localization functor cannot generally be fully faithful.

There is also a precise uniqueness statement for the inverse. If $J : \mathcal{B} \to \mathcal{H}$ is an equivalence, and $P, P' : \mathcal{H} \to \mathcal{B}$ are supplied with counits $\epsilon : JP \xrightarrow{\sim} \mathrm{id}$ and $\epsilon' : JP' \xrightarrow{\sim} \mathrm{id}$, full faithfulness of J gives a unique natural isomorphism $\vartheta : P \to P'$ satisfying

$$\epsilon'\, J\vartheta = \epsilon.$$

Its image under J is $(\epsilon')^{-1}\epsilon$, which proves existence, uniqueness, naturality, and the cocycle law. Thus the intrinsic object is the inverse equipped with its comparison to the given equivalence. A formula using paths is one realization of that object. In the more general setting of derivable categories, Cisinski (2010, Proposition 1.8) obtains the analogous equivalence between a category and its fibrant subcategory even when the chosen replacements are organized by a cleavage rather than by a strict functor into the original category.

‖ La clef de la situation, et des questions de canonicité, me semble être dans le fait que (∗∗) est une équivalence de catégories - et il faut avouer que, tout familier et quasiment banal qu'il soit finalement devenu pour moi, c'est là un fait tout à fait remarquable et nullement évident a priori. (Mais sans doute peut-on l'avoir aussi par les fourbis généraux à la Quillen-Thomason, sans se battre avec un formalisme de chemins …) Les 'isomorphismes canoniques' qu'on peut établir entre une 'théorie C ' et une 'théorie C' ' (via deux constructions différentes, p. ex., de catégories de chemins, ou via l'approche de Quillen-Thomason, sans chemins) doivent toujours revenir à ceux

qu'on peu définir via la comparaison de la 'théorie C ' d'une part, la 'théorie C' ' de l'autre, avec ce que nous donne directement la flèche composée (∗) (p. 204). Finalement, il me semble que *l'existence* d'une théorie des 'fibres homotopiques' (ou 'W-homotopiques') d'une flèche $X \longrightarrow S$ dans Cat, résulte de l'équivalence (∗∗) (p. 204), et cette théorie pourrait sans

ms. page 207

doute dans une certaine mesure se développer à partir de là, sans choix d'un foncteur C ni d'une structure de catégorie de modèles au sens de Quillen.

Commentary · Examples [ms. 206]

A homotopy fibre which an ordinary kernel misses

The replacement construction is already visible in elementary homological algebra, where its comparison maps and the information lost by taking a raw fibre can both be written down. This gives a different example from the groupoid calculations in the commentary on earlier chapters. Let C, D be cochain complexes of abelian groups, with differential of degree 1, and let $f : C \to D$ be a cochain map. Take W to be the quasi-isomorphisms. Degreewise surjections preserve quasi-isomorphisms under pullback: pulling such a surjection $E \to D$ back along a map $A \to B$ over D gives a map between the short exact sequences with common kernel $\ker(E \to D)$ and quotient map $A \to B$. The long exact cohomology sequences prove the assertion. Thus these surjections belong to the class of W-fibrations used below.

Define a complex

$$E(f)^n = C^n \oplus D^{n-1} \oplus D^n, \qquad d(c, h, y) = (d_C c,\ y - f(c) - d_D h,\ d_D y).$$

The equation $d^2 = 0$ follows from $d_D f = f d_C$. The maps

$$j(c) = (c, 0, f(c)), \qquad p(c, h, y) = y, \qquad r(c, h, y) = c$$

are cochain maps, $pj = f$, and $rj = \mathrm{id}_C$. The degree -1 map

$$H(c, h, y) = (0, 0, h)$$

satisfies $dH + Hd = \mathrm{id}_{E(f)} - jr$. Consequently j is a cochain-homotopy equivalence, in particular a quasi-isomorphism, while p is degreewise surjective. We have obtained the required factorization $C \xrightarrow{j} E(f) \xrightarrow{p} D$ with its comparison map explicit.

The strict fibre of p over the zero map $0 \to D$ is

$$F(f)^n = C^n \oplus D^{n-1}, \qquad d(c, h) = (d_C c, -f(c) - d_D h).$$

With the convention $\mathrm{Cone}(f)^n = D^n \oplus C^{n+1}$ and differential $(y, c) \mapsto (d_D y + f(c), -d_C c)$, this is canonically isomorphic to $\mathrm{Cone}(f)[-1]$ after reordering the summands. The sign is forced by the shift; it is not an additional convention about homotopy fibres. The short exact sequence $0 \to D[-1] \to F(f) \to C \to 0$ gives the familiar exact sequence relating the cohomology of the fibre, C, and D.

For a concrete calculation, let $C = D = \mathbf{Z}[0]$ and let f be multiplication by an integer $m \geq 2$. The ordinary kernel is zero. The homotopy fibre is the two-term cochain complex

$$\mathbf{Z} \xrightarrow{-m} \mathbf{Z}$$

in degrees 0 and 1. It has $H^0 = 0$ and $H^1 = \mathbf{Z}/m\mathbf{Z}$. The replacement has retained the failure of surjectivity which the ordinary kernel discards. This example is classical: Brown lists complexes in an abelian category, with quasi-isomorphisms and surjections, among his categories of fibrant objects (Brown, 1973, Part I, §1, Example 3, p. 421). The calculation explains why Grothendieck insists on replacing the structural map before taking its fibre.

4 Axiomatisation des 'fibres W-homotopiques'.

La reflexion de hier me fait revenir sur l'axiomatique dans des 'catégories de modèles'

$$(\mathcal{M}, W)$$

([119]) plus générales que Cat, dans l'esprit de VI (cf. théorème-scholie 2, p. 108-113). Pour le moment, on va supposer seulement $\mathcal{M}$ stable par produits fibrés (on n'a pas besoin d'objet final). On introduit l'ensemble

$$\mathrm{Fib}_W \subseteq \mathrm{Fl}(\mathcal{M})$$

des W-*fibrations* (sous-entendu 'ultrafortes'!) par la condition

ms. page 208

$f : X \longrightarrow Y$ est dans Fib_W si et seulement si le foncteur changement de base par X,

$$\begin{array}{rcl} Y' & \longmapsto & X' = X \times_Y Y' \\ \mathcal{M}/Y & \longrightarrow & \mathcal{M}/X \end{array}$$

ed. 135

transforme W_X dans W_Y, où $W_X \subseteq \underline{\mathrm{Fl}}(\mathcal{M}/X)$ `[est]` défini par
$u \in W_X \iff \sigma(U) \in W$ ($\sigma : \mathcal{M}/X \longrightarrow \mathcal{M}$ le foncteur 'source', ou 'oubli de X').

([120]). Posons, pour tout S dans $\mathcal{M}$,

$$\mathrm{Ho}^!_W(S) = (\mathcal{M}/S)W_S^{-1},$$

qui joue le rôle d'une catégorie de W-types d'homotopie relatifs *localement constants* sur S. On aimerait décrire une loi contravariante en S pour $\mathrm{Ho}^!_W(S)$, i.e. pour

$$f : S' \longrightarrow S$$

flèche quelconque dans $\mathcal{M}$, définir

$$(*) \qquad f^*_W : \mathrm{Ho}^!_W(S) \overset{?}{\to} \mathrm{Ho}^!_W(S').$$

La difficulté est, bien sûr, que le foncteur changement de base

$$f^* : \mathcal{M}/S \longrightarrow \mathcal{M}/S'$$

n'est *pas* en général compatible avec les localiseurs W_S, $W_{S'}$. La notion de W-fibration sert donc en premier lieu à dégager la condition la plus évidente sur une flèche $f : S' \longrightarrow S$ dans $\mathcal{M}$, pour que le foncteur changement de base soit compatible avec les localiseurs W_S, $W_{S'}$ (c'est *ça* la définition), donc induit $(*)$ sur les localisées.

ms. page 209

Commentary · Later developments [ms. 208]

The intrinsic fibrations are sharp maps

The purpose of the new definition is to extract from $(\mathcal{M}, W)$ the largest class of maps along which ordinary pullback is homotopical. For $f : X \to Y$ the correctly typed condition is

$$f^* : (\mathcal{M}/Y, W_Y) \longrightarrow (\mathcal{M}/X, W_X).$$

The edition reverses W_X and W_Y in the sentence following the displayed pullback functor; the direction of that functor fixes the intended reading. Unpacked, the definition says that whenever $a : A \to B$ is in W and is a map over Y, the map

$$X \times_Y A \longrightarrow X \times_Y B$$

is again in W. The quantification over all objects over Y is essential. Testing only pullbacks of weak equivalences whose target is exactly Y would omit part of the requirement.

119. W satisfait l'axiome de saturation faible : les isomorphismes `[sont]` dans W, et si deux parmi f, g, gf `[sont]` dans W, le troisième aussi.

120. **NB** Donner ici la proposition: Fib_W *stable par composition et par changement de base, et contient les isomorphismes, stable par facteurs directs.*

In a model category, this is precisely the condition called *sharp* by Rezk (1998, §2). His Proposition 2.2 says that all model fibrations are sharp exactly when the model category is right proper. His Proposition 2.7 further identifies sharp maps, in a right proper model category, with those maps all of whose ordinary pullback squares are homotopy cartesian. These hypotheses distinguish three statements which can otherwise look indistinguishable: a map can be a fibration for a chosen model structure, preserve weak equivalences by pullback, or compute all homotopy pullbacks strictly. The first is extra structure, the second depends only on $(\mathcal{M}, W)$, and the equivalence with the third needs the stated properness hypothesis. Rezk attributes the sharp-map idea to Hopkins; we are comparing equivalent conditions, not asserting a historical line of transmission from this manuscript.

The basic stability properties require little machinery. If $f : X \to Y$ and $g : Y \to Z$ preserve weak equivalences by pullback, so does gf, because $(gf)^*$ is canonically f^*g^*. To see stability under a pullback $f' : X \times_Y T \to T$, regard a weak equivalence over T also as a map over Y; its pullback by f' is the same underlying map as its pullback by f. Isomorphisms plainly have the property. The statement about retracts in footnote 120 is different: it needs retract closure of W. Under that hypothesis, pulling back a retract diagram makes the map to be tested a retract of a map in W, proving the result. Under only the weak saturation explicitly listed in footnote 119, the retract assertion fails, as the following finite example shows.

Le *'problème des fibres homotopiques'* est justement de définir $(*)$ pour *toute* flèche dans $\mathcal{M}$, pas seulement pour les W-fibrations, de tellle façon que les $\mathrm{Ho}^!_W(S)$ forment, pour S variable, les fibres d'une catégorie fibrée remarquable sur $\mathcal{M}$. Quand $\mathcal{M}$ admet un objet final, de sorte que l'on peut regarder les flèches

$$p : e \longrightarrow S \qquad (p \text{ comme 'point'})$$

dans $\mathcal{M}$ comme des 'points' de S, la 'fibre W-homotopique' d'un objet quelconque X/S de $\mathcal{M}/S$ en ledit point sera par définition l'élément de

$$\mathrm{Ho}_W = \mathrm{Ho}_W(\mathcal{M}) \simeq \mathrm{Ho}^!_W(e)$$

défini par

$$p^*(\mathrm{ho}^!_{W/S}(X/S)),$$

ed. 136 où ms. page 210

$$\mathrm{ho}^!_{W/S} : \mathcal{M}/S \longrightarrow \mathrm{Ho}^!_W(S) \overset{\text{déf}}{=} (\mathcal{M}/S)(W_S)^{-1}$$

est le foncteur de localisation canonique.

Commentary · Development (commentators') [ms. 209]

The retract condition needs a hypothesis

The minimal axioms are being separated here so that the fibre theory will apply beyond familiar model categories. A small counterexample helps to keep that economy honest. We use the usual meaning of a direct factor of a morphism, namely a retract in the arrow category. The observation below addresses only the retract clause of footnote 120; composition, pullback, and isomorphism stability remain valid under the assumptions stated in the text.

Finite-set counterexample to the retract clause. [ours] Let $\mathcal{M}$ be the category of finite sets, and let W consist of all maps $A \to B$ for which $|A| \equiv |B| \pmod 2$. Then $\mathcal{M}$ has pullbacks and W contains all isomorphisms and satisfies two-out-of-three. Nevertheless the class Fib_W defined on manuscript p. 208 is not closed under retracts.

Proof. The axioms for W follow by applying equality in $\mathbf{Z}/2\mathbf{Z}$ to the cardinalities of the three objects in a composable pair. Set $S = \{0, 1\}$. Let E have one element over 0 and three over 1, and write $p : E \to S$ for its structural map. For every finite set $T \to S$,

$$|E \times_S T| = |T_0| + 3|T_1| \equiv |T| \pmod 2.$$

Thus if $A \to B$ over S belongs to W, its pullback along p also belongs to W. This proves $p \in \mathrm{Fib}_W$.

Let E' have one element over 0 and two over 1, and let $p' : E' \to S$. Include E' into E by choosing two of the three elements over 1. Define a retraction $E \to E'$ which is the identity on the chosen elements and sends the remaining element to either of the two elements over 1. Together with the identity of S, these maps exhibit p' as a retract of p in the arrow category. But the map $\varnothing \to S$, considered as a map from the empty object to the identity object of $\mathcal{M}/S$, lies in W, since both cardinalities are even. Its pullback along p' is $\varnothing \to E'$, whose target has cardinality 3. This map is not in W. Hence $p' \notin \mathrm{Fib}_W$. □

This counterexample also makes clear what repairs the statement. One may assume W is retract closed, as in a model category; strong saturation is more than sufficient. Alternatively, one can omit the retract clause, which is not needed for the formal base-change construction on the following pages. We checked the axioms in Brown's Part I, Cisinski's §1, and Rezk's sharp-map discussion; those sources do not provide this particular example. The argument is supplied here as a local clarification of the manuscript, without a claim of priority.

Pour tout S dans $\mathcal{M}$, soit

$$\underline{\mathrm{Fib}}_W S \subseteq \mathcal{M}/S$$

la sous-catégorie pleine formée des objets X/S de $\mathcal{M}/S$ tels que $X \longrightarrow S$ soit W-fibrant. On va définir une variante

$$\mathrm{Ho}^{\mathrm{lc}}_W(S)$$

de $\mathrm{Ho}^{!}_W(S)$, comme

$$\mathrm{Ho}^{\mathrm{lc}}_W(S) \overset{\text{déf}}{=} (\underline{\mathrm{Fib}}_W S)(W^{\mathrm{u}}_S)^{-1},$$

où

> $W^{\mathrm{u}}_S \subseteq \underline{\mathrm{Fl}}(\underline{\mathrm{Fib}}_W S)$ est le localiseur formé des flèches $u : X \longrightarrow Y$ qui sont 'universellement sur S dans W', i.e. telles que pour toute flèche $S' \longrightarrow S$ de $\mathcal{M}$ de but S, la flèche déduite par changement de base,
>
> $$u' : X' = X \times_S S' \longrightarrow Y' = Y \times_S S'$$
>
> est dans $W_{S'}$.

On a 'fait ce qu'il fallait' pour que $\mathrm{Ho}^{\mathrm{lc}}_W(S)$ soit contravariant en S pour des flèches *quelconques* $f : S' \longrightarrow S$ de $\mathcal{M}$, elles définissent

$$(**) \qquad f^{*\,\mathrm{lc}}_W : \mathrm{Ho}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{Ho}^{\mathrm{lc}}_W(S'),$$

puisque les W-fibrations sont stables par changement de base, et que par suite $f^* : \mathcal{M}/S \longrightarrow \mathcal{M}/S'$ induit

$$f^*_{\underline{\mathrm{Fib}}_W} : \underline{\mathrm{Fib}}_W S \longrightarrow \underline{\mathrm{Fib}}_W S'$$ ms. page 211

qui, par définition de W^{u}_S et $W^{\mathrm{u}}_{S'}$, est compatible avec les localiseurs

$$f^*_{\underline{\mathrm{Fib}}_W} : (\underline{\mathrm{Fib}}_W S, W^{\mathrm{u}}_S) \longrightarrow (\underline{\mathrm{Fib}}_W S', W^{\mathrm{u}}_{S'}),$$

et passe donc aux catégories des fractions en une flèche $(*)$.

On peut se demander pourquoi ne pas être plus généreux, et définir $\mathrm{Ho}^{\mathrm{lc}}_W(S)$ comme $(\mathcal{M}/S)(W^{\mathrm{u}}_S)^{-1}$, en définissant W^{u}_S dans $\mathcal{M}/S$ de la même façon que tantôt dans $\underline{\mathrm{Fib}}_W S$ - ce qui ne coûte pas plus cher. Une première réponse est d'expérience le localiseur W^{u}_S dans $\mathcal{M}/S$ tout entier s'avère pratiquement inutilisable, d'une part parce que l'appartenance à W^{u}_S (pour une flèche entre objets de $\mathcal{M}/S$ qui ne sont pas très particuliers, p.ex. W-fibrés sur S) est invérifiable (sauf pour des isomorphismes et des choses comme ça …), et que d'autre part la ed. 137 catégorie de fractions est prohibitivement grosse et ne peut servir (semble-t-il) à rien. Une autre réponse, c'est qu'on veut que la catégorie obtenue réponde bien à l'intuition de types d'homotopie relatifs *localement constants* sur S - et on veut donc que pour un changement de base quelconque $f : S' \longrightarrow S$ par un ms. page 212

Commentary · Exposition [ms. 211]

Two localizations with different immediate advantages

Grothendieck keeps two constructions in view because each makes one half of the desired theory immediate. Write

$$\mathcal{H}_S = (\mathcal{M}/S)[W_S^{-1}], \qquad \mathcal{L}_S = (\mathrm{Fib}_W S)[(W_S^{\mathrm{u}})^{-1}].$$

The first accepts every object over S. Its ordinary inverse-image functor is initially available only for a base map in Fib_W. The second accepts only objects whose structural map is a W-fibration, but its inverse images exist for every base map. The universal quantifier defining W_S^{u} is precisely what makes this second assertion formal.

For $f : T \to S$, ordinary pullback sends $\mathrm{Fib}_W S$ into $\mathrm{Fib}_W T$, as just proved. If $u \in W_S^{\mathrm{u}}$ and $g : U \to T$, the iterated pullback $g^* f^* u$ is isomorphic to $(fg)^* u$, hence belongs to W. Therefore $f^* u \in W_T^{\mathrm{u}}$. The universal property of localization supplies a functor

$$P_f : \mathcal{L}_S \longrightarrow \mathcal{L}_T.$$

The canonical isomorphisms between iterated ordinary pullbacks survive localization and give $P_g P_f \simeq P_{fg}$. Their associativity follows from the universal property of the pullback: both routes identify an iterated pullback with the same object, carrying the same projections. Thus the result is naturally a pseudofunctor, or equivalently a fibred category. No strictly functorial global choice of pullbacks is needed.

One can also see exactly what must be checked to define the fibre at a generalized point. Fix $X \to S$ in $\mathrm{Fib}_W S$. Sending $T \to S$ to the absolute homotopy type of $X \times_S T$ is a covariant functor on $\mathcal{M}/S$; a map $T' \to T$ induces the corresponding map between total pullbacks. If that map of generalized points is in W_S, its image is in W by the defining property of $X \to S$. The functor consequently inverts weak equivalences between generalized points. This assertion is compatible with replacing X by a morphism in W_S^{u}, since evaluation at every T then gives a weak equivalence. It therefore makes sense for all $\xi \in \mathcal{L}_S$, not only for a chosen representative.

This explains the two separate roles of the subcategory and the localizer. Restricting to $\mathrm{Fib}_W S$ controls variation of the generalized point by a weak equivalence. Restricting the arrows to W_S^{u} controls variation of the representative by a weak equivalence after any base change. Omitting either condition loses one of these immediate guarantees. The manuscript's remark that the unrestricted universal localization is too large is a methodological judgment; it is not a theorem saying that every such localization is mathematically useless. What has been proved is the precise pair of invariance properties above.

S' dans $\mathcal{M}/S$, d'où un foncteur composé

$$\mathcal{F}_S(W_S^{\mathrm{u}})^{-1} \xrightarrow{f_W^{*\,\mathrm{lc}}} \mathcal{F}_{S'}(W_{S'}^{\mathrm{u}})^{-1} \longrightarrow \mathrm{Ho}_W$$
$$\mathcal{F}_S(W_S^{\mathrm{u}})^{-1} \xrightarrow[\varphi_{S'}]{} \mathrm{Ho}_W$$

([121]) déduit des foncteurs de catégories avec localiseurs

$$(\mathcal{F}_S, W_S^{\mathrm{u}}) \xrightarrow{f^*} (\mathcal{F}_{S'}, W_{S'}^{\mathrm{u}}) \xrightarrow{\text{oubli de } S'} (\mathcal{M}, W)$$

(foncteur composé $\varphi_{S'}$ qui peut être vu comme le foncteur *'fibre homotopique en l'objet S' sur S'*, cet objet étant visualisé comme un 'point' de S 'à valeurs dans S' ' suivant le yoga fonctoriel général …), le foncteur

$$\begin{aligned} S' &\longmapsto \varphi_{S'}(\xi) \qquad \text{pour } \xi \text{ dans } \mathcal{F}_S(W_S^{\mathrm{u}})^{-1} \\ \mathcal{M}/S &\longrightarrow \mathrm{Ho}_W \end{aligned}$$

transforme flèches dans W_S en isomorphismes : la 'fibre W-homotopique' en S'/S d'un objet de $\mathcal{F}_S(W_S^{\mathrm{u}})^{-1}$ (vu comme W-type d'homotopie *localement constant* sur S) doit être 'la même', si S' remplacé par S'' avec $S'' \longrightarrow S'$ donné et dans W_S. C'est pour cela qu'il est raisonnable ms. page 213

de prendre $\mathcal{F}_S$ 'assez petit' (savoir $\underline{\mathrm{Fib}}_W S$, qui est exactement ajusté pour cela), plutôt que de prendre $\mathcal{M}/S$ tout entier.

On peut donc dire que la catégorie $\underline{\mathrm{Fib}}_W S$, et le localiseur W_S^{u} ont été construits ad-hoc, le plus simplement possible, pour donner lieu à un localisé $\mathrm{Ho}_W^{\mathrm{lc}}(S)$ qui réponde à l'intuition de W-types d'homotopie relatifs localement constants des deux façons suivantes :

1°) Il y a spontanément une loi contravariante en S, pour des flèches quelconques $S' \longrightarrow S$ dans Cat (on a défini W_S^{u} juste exprès en conséquence).

2°) que la notion de 'fibre W-homotopique en S'/S' d'un objet ξ de $\mathrm{Ho}_W^{\mathrm{lc}}$ satisfasse à la condition précédente, i.e. une flèche $S'' \longrightarrow S'$ dans $\mathcal{M}/S$ qui est dans W_S définisse un *isomorphisme* (dans Ho_W) des fibres homotopiques

$$\underbrace{\xi_{S''}}_{\varphi_{S''}(\xi)} \longrightarrow \underbrace{\xi_{S'}}_{\varphi_{S'}(\xi)}$$

(et on a choisi $\mathcal{F}_S = \underline{\mathrm{Fib}}_W(S)$ juste exprès pour ça).

ed. 138 On a donc une excellente notion de fibres W-homotopiques pour des X W-fibrés sur S - cette fois excellente pour des changements de base *quelconque* - et il n'y a aucun mérite à ça puisqu'on a tout défini exprès pour ça!

Pour le dire autrement, on a défini *deux* notions de W-types d'homotopie relatifs sur S, ms. page 214
l'une de façon à donner un tel type d'homotopie $\mathrm{ho}_{W,S}^{!}(X)$ pour *tout* objet de $\mathcal{M}/S$, mais il n'y a a priori une bonne notion de changement de base que pour les changements de base $S' \longrightarrow S$ qui sont W-fibrés, l'autre, qui correspond plus directement à l'intuition d'un W-type d'homotopie localement constant sur S, n'associe un tel type $\mathrm{ho}_{W,S}^{\mathrm{lc}}(X)$ qu'aux X de $\mathcal{M}/S$ qui sont W-fibrés sur S, en revanche cette notion admet une bonne notion d'image inverse et de 'fibre W-homotopique' pour des changements de base quelconques.

Une 'bonne' théorie des fibres W-homotopiques doit réunir en une seule les deux notions précédentes, de sorte que les avantages des deux s'ajoutent, et les désavantages s'éliminent! Elle s'obtient à l'aide d'un axiome draconien sur la situation (alors que jusqu'à maintenant on n'a rien utilisé sur $W \subseteq \underline{\mathrm{Fl}}(\mathcal{M})$, si ce n'est tout au plus la saturation faible, en plus de l'existence des produits fibrés) :

ⓐ (*Axiome de la fibre homotopique.*) Pour tout objet S dans $\mathcal{M}$, le foncteur canonique ms. page 215

$$\mathrm{Ho}_W^{\mathrm{lc}}(S) \longrightarrow \mathrm{Ho}_W^{!}(S)$$

déduit de l'inclusion

$$(\underline{\mathrm{Fib}}_W(S), W_S^{\mathrm{u}}) \longrightarrow (\mathcal{M}/S, W_S)$$

est une *équivalence de catégories.*

Cet axiome implique que dans $\underline{\mathrm{Fib}}_W S$, W_S^{u} et le localiseur induit par W_S (que je désigne encore par W_S par abus de notation) ont même saturé fort. En fait, il est naturel de compléter l'axiome précédent par le suivant.

ⓑ (Axiome adjoint de l'axiome de la fibre homotopique.) Sur $\underline{\mathrm{Fib}}_W S$, les localiseurs W_S^{u} et W_S coïncident, i.e. on a ceci :

> Soient X, Y dans $\underline{\mathrm{Fib}}_W S$, $X \xrightarrow{u} Y$ un S-morphisme tel que $u \in W_S$, alors $u \in W_S^{\mathrm{u}}$ (i.e. le morphisme $u' : X' \longrightarrow Y'$ déduit par tout changement de base $S' \longrightarrow S$ est encore dans W).

Je présume que a) sera rarement satisfait sans que b) le soit (et inversement d'ailleurs), et ms. page 216
que la démonstration de a) et b) se fera pratiquement en une seule haleine.

121. $\mathcal{F}$ désigne ici une sous-catégorie fibrée de $\mathcal{M}/\mathcal{M} = \underline{\underline{\mathrm{Fl}}}(\mathcal{M})$ sur $\mathcal{M}$, substitut éventuel de celle formée de $\underline{\mathrm{Fib}}_W S$ ou de $\mathcal{M}/S$ tout entier.

Commentary · Exposition [ms. 215]

Transporting base change and separating the two axioms

The comparison axiom now combines the two advantages. Let

$$J_S : \mathcal{L}_S \longrightarrow \mathcal{H}_S$$

be induced by inclusion. Axiom a says that J_S is an equivalence. Choose an inverse R_S together with the unit and counit of an adjoint equivalence. For an arbitrary $f : T \to S$, define derived inverse image by

$$f^!_W = J_T P_f R_S : \mathcal{H}_S \longrightarrow \mathcal{H}_T.$$

This is the operation denoted f^*_W in the manuscript; the temporary exclamation mark here only distinguishes it from raw pullback. For composable $U \xrightarrow{g} T \xrightarrow{f} S$, the comparison

$$J_U P_g R_T J_T P_f R_S \xrightarrow{\sim} J_U P_g P_f R_S \xrightarrow{\sim} J_U P_{fg} R_S$$

uses $R_T J_T \simeq \mathrm{id}$ and the ordinary pullback comparison. The triangle identities of the chosen adjoint equivalences and the associativity of pullback give the unit and pentagon identities. Equivalently, these identities can be checked after the fully faithful equivalences J_S, where they reduce to those same identities. A different choice of inverses gives the unique normalized comparison described above, so the resulting fibred theory is independent of that choice up to the corresponding coherent equivalence.

Axiom a also has a useful immediate consequence which is weaker than axiom b. If u between W-fibrant objects belongs to W_S, then J_S sends its image in $\mathcal{L}_S$ to an isomorphism. An equivalence reflects isomorphisms, so u belongs to the strong saturation of W^{u}_S on $\mathrm{Fib}_W S$. Since $W^{\mathrm{u}}_S \subseteq W_S$, the two classes have the same strong saturation there. This is exactly the intermediate observation in the text. It does not, under bare two-out-of-three, identify the two original classes of arrows.

There is a clean case in which axiom b follows. Suppose W itself is strongly saturated: a morphism belongs to W exactly when it is inverted by $\mathcal{M} \to \mathcal{M}[W^{-1}]$. Then W^{u}_S is strongly saturated in $\mathrm{Fib}_W S$. Indeed, if u becomes invertible after localization at W^{u}_S, every evaluation functor

$$X \longmapsto X \times_S T \longmapsto \mathcal{M}[W^{-1}]$$

for $T \to S$ sends u to an isomorphism. Strong saturation gives $u_T \in W$ for every T, which is the definition of $u \in W^{\mathrm{u}}_S$. Thus axiom a implies axiom b under this extra hypothesis. Without it, the statement in the manuscript should retain its saturation formulation; the author's expectation that the two axioms will usually be verified together is not a formal converse.

The construction gives a derived base-change theory, but it does not by itself assert all the axioms of a derivator on arbitrary diagram categories. Those require further control of diagrams, pointwise detection, and homotopy Kan extensions. The distinction preserves the considerable content of the comparison axiom without crediting it with statements that are proved elsewhere.

Si $\mathcal{M} = \mathrm{Cat}$, W un localiseur fondamental, alors la notion adaptée ici de W-fibration (lire : 'ultraforte', dans la terminologie spécifique développée dans Cat) est à tel point forte, qu'elle
ed. 139 implique déjà pratiquement b) (moyennant W(4a′), il est vrai, cf. p. 53), et a) n'est guère vérifiable que si on a W(4a) ([122]) (loc. cit.). Donc ici c'est 'l'axiome des fibrations' sur W, sous sa forme forte W(4a), qui est la clef de voûte d'une bonne théorie des fibres homotopiques.

Une telle théorie (revenant au cas général) revient à dire, pour l'essentiel, qu'il y a 'assez' de W-fibrations ('ultrafortes') pour pouvoir décrire *tout* objet d'un $\mathcal{M}/S$, à W_S-équivalence près, comme un objet W-fibrant sur S. Dans les cas à ma connaissance, on a de plus ceci : on a pour tout S dans $\mathcal{M}$ une sous-catégorie $\mathcal{F}_{0\,S}$ de $\underline{\mathrm{Fib}}_W S$ (je pense par exemple à $\underline{\mathrm{Parf}}_W S$, ms. page 217
voire $\underline{\mathrm{Parf}}_{W_\omega} S$, dans le cas où $\mathcal{M} = \mathrm{Cat}$), telle que pour toute sous-catégorie pleine $\mathcal{F}$ de $\mathcal{M}/S$ telle que

$$\mathcal{F}_{0\,S} \subseteq \mathcal{F} \subseteq \mathcal{M}/S$$

(a fortiori, pour une $\mathcal{F}$ pleine telle que $\underline{\mathrm{Fib}}_W S \subseteq \mathcal{F} \subseteq \mathcal{M}/S$), les inclusions induisent des

122. Non, il me semble que W(4b) doit suffire …

équivalences de catégories

$$\mathcal{F}_{0\,S}(W_S)^{-1} \xrightarrow{\sim} \mathcal{F}(W_S)^{-1} \xrightarrow{\sim} \underbrace{(\mathcal{M}/S)(W_S)^{-1}}_{\overset{\text{déf}}{=}\mathrm{Hot}^{!}_{W}(S)}.$$

Le choix de $\mathcal{F}_{0\,S}$ ne semble pas pouvoir se fixer de façon 'la meilleure possible', une fois pour toutes dans le contexte axiomatique adopté ici. C'est un élément de structure supplémentaire dans $\mathcal{M}$ (en plus du localiseur W), au même titre que la donnée des classes de Q-fibrations et Q-cofibrations, à la Quillen. J'ignore si les axiomes a), b) ci-dessus (axiome de la fibre homotopique) impliquent déjà la variante de ⓐ :

ms. page 218

Commentary · Later developments [ms. 216]

What the weaker model formalisms establish

The new axioms are close to Brown's economy of assumptions, but they organize it differently. Brown begins with specified fibrations and weak equivalences on a category whose objects are fibrant, and assumes the path-object and pullback axioms needed for a calculus of homotopy. Here the fibrations are extracted from W itself by asking for homotopical base change; the existence of enough suitable representatives is imposed afterwards. One should therefore compare the actual hypotheses before using a theorem about one formalism in the other.

Cisinski's derivable categories give a precise later setting for this programme. Definition 1.1 separates weak equivalences, fibrations, and factorization toward fibrant objects. Proposition 1.8 proves that restricting to fibrant objects does not change the homotopy category. Theorem 2.21 then constructs a weak left derivator on finite direct categories, with the additional diagram axiom stated there (Cisinski, 2010). This is a useful progression for reading the present section: comparison of a single localization comes first; coherent diagram calculus requires further work. None of these results says that an arbitrary category equipped only with a two-out-of-three class automatically has homotopy fibres.

For ordinary spaces or simplicial sets with weak homotopy equivalences, a right proper model presentation supplies a familiar way to meet the requirements. Model fibrations are sharp, and ordinary pullback of a sharp map computes homotopy pullback. Weak equivalences between such representatives remain weak equivalences after derived base change. These are the roles of properness and replacement in the usual theory, rather than unexplained special properties of a path formula. In the generality of the manuscript, the corresponding assertions are the explicit axioms a and b, unless a chosen factorization theorem proves them.

The fibrewise ordinary diagram $s \mapsto \mathrm{hot}_W(X_s)$ still forgets coherence. In manuscript p. 200 the functor through ΠS° is being used for the locally constant subcategory: the missing superscript lc on the displayed $\mathrm{HOT}_W(S)$ should be understood in that context. It is not a factorization of every varying relative type through the fundamental groupoid. The commentary on earlier chapters already treats the difference between an ordinary diagram in a homotopy category and a coherent family (notably on Chapter VI, manuscript pp. 7 and 74). The equivalence of localized slice categories here concerns the coherent family; evaluation in ordinary homotopy types is one invariant of it.

ⓒ Pour toute sous-catégorie pleine $\mathcal{F}$ de $\mathcal{M}/S$ telle que

$$\underline{\mathrm{Fib}}_W S \subseteq \mathcal{F} \subseteq \mathcal{M}/S$$

les inclusions induisent des équivalences

$$\underbrace{(\underline{\mathrm{Fib}}_W S)(W_S)^{-1}}_{\substack{=\,\mathrm{Ho}^{\mathrm{lc}}_W(S)\\ \text{moyennant a)}}} \xrightarrow{\sim} \mathcal{F}(W_S)^{-1} \xrightarrow{\sim} \underbrace{(\mathcal{M}/S)(W_S)^{-1}}_{=\mathrm{Ho}^{!}_W(S)}.$$

Mais je présume que pratiquement, quand on pourra vérifier ⓐ, on pourra vérifier ⓒ également ([123]).

ed. 140

123. Cf. page 240 ff. Il faudrait ici développer un peu plus le formalisme de $\mathrm{Ho}^{\mathrm{lc}}_W(S)$ et les fibres homotopiques, sous l'hypothèse ⓐⓑ plus haut.

5 Axiomatique des W-types d'homotopie relatifs non localement constants $\mathrm{Ho}^{\mathcal{L}}_W(S)$.

On n'a rien dit jusqu'à ce point d'éventuels W-types d'homotopie relatifs (sur un objet S de $\mathcal{M}$) qui ne seraient *pas* "localement constants". Il en était question pourtant dans loc. cit. (VI, théorème-scholie 2, partie II du théorème pages 109-113.) Je profite de l'occasion pour revenir là dessus. Il faut introduire, dans chaque $\mathcal{M}/S$, un deuxième localiseur

$$W^0_S \subseteq \mathrm{Fl}(\mathcal{M}/S), \qquad W^0_S \subseteq W_S$$

(plus fin que W_S), ce qui permettra de définir ms. page 219

$$\mathrm{Ho}_W(S) \overset{\text{déf}}{=} (\mathcal{M}/S)(W^0_S)^{-1}.$$

Qu'il n'y ait pas de choix *canonique* qui s'impose ici, déduit de la seule structure $(\mathcal{M}, W)$, est claire sur l'exemple de (Cat, W), auquel cas on trouve *deux* choix symétriques, transformés l'un en l'autre par l'involution

$$X \longmapsto X^\circ : (\mathrm{Cat}, W) \xrightarrow{\sim} (\mathrm{Cat}, W),$$

à savoir W^{g}_S et W^{d}_S. Le choix de l'un ou de l'autre, disons (pour fixer les idées) de W^{g}_S, est associé à une notion d'*isomorphisme local* (ou de 'coisomorphisme local' dans le cas de W^{d}_S) que je voudrais axiomatiser. Il semble bien que pour les principales catégories de modèles pour Hot (et pour ses variantes), on dispose de façon assez naturelle d'une telle notion d'isomorphisme local (sans l'embarras, le plus souvent, d'un automorphisme involutif fournissant une notion symétrique …).

Commentary · Present state [ms. 218]

Intermediate categories and the extra information in a replacement

The last question of this section asks for more than essential surjectivity. It asks whether one may admit any collection of additional representatives without changing the localized category. A functorial replacement proves exactly this strengthened assertion, and it is useful to isolate the short proof. Let $\mathcal{F}_0 \subseteq \mathcal{A}$ be full, and suppose a coaugmented replacement $C : \mathcal{A} \to \mathcal{F}_0$, $i : \mathrm{id} \to C$, has components in W. For every full intermediate category

$$\mathcal{F}_0 \subseteq \mathcal{E} \subseteq \mathcal{A},$$

restricting C and i to $\mathcal{E}$ gives a replacement into $\mathcal{F}_0$. The localization proof on p. 205 then applies both to $\mathcal{F}_0 \subseteq \mathcal{E}$ and to $\mathcal{F}_0 \subseteq \mathcal{A}$. Consequently

$$\mathcal{F}_0[W^{-1}] \xrightarrow{\sim} \mathcal{E}[W^{-1}] \xrightarrow{\sim} \mathcal{A}[W^{-1}].$$

Fullness ensures that the components of the restricted coaugmentation really are arrows of $\mathcal{E}$; no closure of $\mathcal{E}$ under limits or factorizations is needed. When $\mathcal{F}_0 = \mathrm{Fib}_W S$ and axiom b identifies the weak-equivalence classes, this is axiom c in the text. If the replacement lands in a smaller full category of perfect objects, the stronger assertion preceding c follows as well.

The point is that a replacement supplies comparisons inside every such intermediate category. An abstract equivalence after localization has forgotten where its representing zigzags live. One therefore cannot justify c merely by factoring an equivalence of categories through the intermediate localization: a composite of two functors can be an equivalence without either factor being an equivalence. The source recognizes precisely this issue when it distinguishes axioms a and b from its question about c.

Our conclusion about the source's unanswered implication is deliberately narrower than a general claim of openness. The implication from the bare axioms a and b to c is not proved in these pages, and the literature checked here does not settle that exact formulation. The argument above establishes c under the explicit functorial-replacement hypothesis already available in the categorical

construction. Grothendieck returns to the issue at manuscript p. 240 and following in this same chapter, with factorization hypotheses and a qualification on p. 241 that every object should be W-fibrant over the terminal object; that later discussion is commented with those pages. Brown's and Cisinski's theorems provide other sufficient structures, not a proof that the extra structure follows from a and b alone. Thus the practical expectation on p. 218 has a complete proof in the replacement setting, while its unrestricted logical formulation is kept separate.

On supposera donc, comme dans loc. cit. p. 94-96, donné une classe

$$\mathcal{L} \subseteq \mathrm{Fl}(\mathcal{M})$$

de morphismes, jounant le rôle de 'flèches de localisation' ou 'd'isomorphismes locaux', satisfaisant les conditions suivantes. ms. page 220

Commentary · Exposition [ms. 219]

What the finer relative theory remembers

Grothendieck now wants a family to retain the direction in which its fibres vary. The preceding fibre theory has deliberately made transport invertible. A general coefficient system on a category need not have this property: a specialization can create a component, identify two components, or alter a higher homotopy group. Localizing the total category over the base at all total-space equivalences loses such information. The additional class W_S^0 is introduced to preserve it.

There are consequently two distinct localizations to keep in view. The category $(\mathrm{Cat}/S)[W_S^{-1}]$ describes a homotopy type equipped with a map to the homotopy type of S. In the ordinary homotopy theory, its derived fibres form a locally constant coherent family over $|NS|$. A directional diagram, by contrast, is a functor from NS, or from NS^{op} according to the chosen variance, to spaces. Its transition maps need not be equivalences. It is the localization of the whole diagram category at objectwise equivalences that records this datum; a diagram in the ordinary category of homotopy types need not retain its coherence. The distinction is the one already made in the commentary on Chapter VI, pp. 64–74, and not a new objection to the fibre construction.

The notation W_S^{g} has a concrete test inherited from Chapter VI, manuscript p. 41: a map $u : X \to Y$ over S belongs to this class precisely when

$$X/s \longrightarrow Y/s \quad \text{belongs to } W \qquad (s \in \mathrm{Ob}\, S).$$

Here $X/s = X \times_S (S/s)$. Replacing these over-categories by the under-categories $s\backslash X$ gives W_S^{d}. Taking opposite categories exchanges the two tests, together with the base S and its opposite. It does not give an equivalence between the two theories over a fixed, unmodified S. The phrase that neither choice is canonically imposed should be read as a statement about the absence of a preferred orientation in the specified data, not as a theorem that no invariant construction of any kind is possible (Grothendieck, 1990b, Chapter VI, manuscript pp. 41–42).

The axioms on $\mathcal{L}$ make the test intrinsic to a chosen class of base changes. Since id_S is an admissible test, membership in $W_S^{\mathcal{L}}$ implies membership in W_S. Testing against every base change is stronger, giving $W_S^{\mathrm{u}} \subseteq W_S^{\mathcal{L}}$. All three agree on the good locally constant representatives by the preceding fibre axiom. Their agreement there says nothing about their agreement on the whole slice: the whole purpose of the finer theory is to retain objects outside that subcategory.

(∗) $\mathcal{L}$ contient les isomorphismes, est stable par composition, et par changement de base.

On pose, pour S dans $\mathcal{M}$,

$$\mathcal{L}_S \subseteq \mathcal{M}/S \qquad \text{sous-catégorie pleine des } S'/S \text{ telle que } S' \longrightarrow S \texttt{ [soit]} \text{ dans } \mathcal{L}.$$

On définit alors pour tout S dans $\mathcal{M}$

$$W_S^{\mathcal{L}} \subseteq \mathrm{Fl}(\mathcal{M}/S)$$
$$(X \xrightarrow{u} Y) \in W_S^{\mathcal{L}} \iff \forall\, S' \in \mathcal{L}_S,\ (u_{S'} : X \times_S S' \longrightarrow Y \times_S S') \text{ est dans } W.$$

ed. 141 C'est donc une variante du localiseur W_S^{u}, où maintenant on ne prend comme changements de base que les flèches '$\mathcal{L}$-localisantes', i.e. $\in \mathcal{L}$. On a donc

$$W_S^{\mathrm{u}} \subseteq W_S^{\mathcal{L}} \subseteq W_S$$

en tant que parties de $\mathrm{Fl}(\mathcal{M}/S)$, et de même dans toute sous-catégorie pleine $\mathcal{F}$ de $\mathcal{M}/S$. Dans le cas de $\underline{\mathrm{Fib}}_W S$, moyennant l'axiome (b) ci-dessus ($W_S^{\mathrm{u}} = W_S$ dans $\underline{\mathrm{Fib}}_W S$), les trois localiseurs coïncident.

On pose

$$\mathrm{Ho}_W^{\mathcal{L}}(S) \text{ (ou } \mathrm{Ho}_W(S)) \overset{\text{déf}}{=} (\mathcal{M}/S)(W_S^{\mathcal{L}})^{-1},$$

et on a donné dans loc. cit. (partie II du théorème-scholie) un résultat intéressant sur cet invariant, pour S fixé. Mon propos présent est de voir ce qui se passe pour S variable. ms. page 221
Visiblement, une notion de W-type d'homotopie relatif sur un objet quelconque S de $\mathcal{M}$ n'est satisfaisante, que si elle permet des images inverses par des flèches *quelconques*

$$f : S' \longrightarrow S$$

dans $\mathcal{M}$, qui doivent définir absolument

$$f_W^{*\mathcal{L}} \text{ ou } f_W^* : \mathrm{Ho}_W^{\mathcal{L}}(S) \longrightarrow \mathrm{Ho}_W^{\mathcal{L}}(S').$$

On est donc confronté à la même perplexité que tantôt - et ce n'est *pas,* cette fois, l'introduction de $\underline{\mathrm{Fib}}_W(S)$ qui va sauver la situation, car

$$(\underline{\mathrm{Fib}}_W S)(\underbrace{W_S^{\mathcal{L}}}_{\substack{=W_S \\ =W_S^{\mathrm{u}}}})^{-1} \longrightarrow (\mathcal{M}/S)(W_S^{\mathcal{L}})^{-1}$$

n'a aucune envie, cette fois, d'être une équivalence de catégories, mais bien plutôt une inclusion (pleinement fidèle) des W-types d'homotopie relatifs constants sur S, dans les W-types d'homotopie quelconques. Il faut visiblement un axiome qui remplace l'axiome 'de la fibre homotopique'.

ms. page 222

Commentary · Examples [ms. 221]

An endomorphism which becomes invertible only after changing the fibre

A single irreversible transition already explains why the new theory is needed. Consider the category $B\mathbf{N}$ with one object and endomorphism monoid $(\mathbf{N}, +)$. Let a covariant diagram of spaces assign a circle to its object and the degree-two map $d : S^1 \to S^1$ to its generating endomorphism. This diagram cannot be locally constant: multiplication by 2 on $\pi_1(S^1) = \mathbf{Z}$ is not invertible. Objectwise weak equivalences of diagrams preserve this obstruction.

Its homotopy colimit is the mapping torus

$$T_d = (S^1 \times [0,1])/((z,1) \sim (d(z),0)).$$

One can obtain this model directly from the bar construction for the free monoid on one generator: the higher simplices express compositions of that generator, and collapse onto the mapping-cylinder description. Van Kampen, using the circle in the fibre and the loop round the parameter as generators, gives

$$\pi_1(T_d) = \langle a, t \mid tat^{-1} = a^2 \rangle.$$

The direction chosen for t fixes the displayed convention. This group is nonabelian: the transformations $a(x) = x + 1$ and $t(x) = 2x$ of the real line satisfy the relation and do not commute. The cellular chain calculation for a mapping torus is the cone of $1 - d_*$ on the chains of the fibre. On $H_1(S^1)$ this is multiplication by -1, and on $H_0(S^1)$ it is zero. The resulting exact sequence yields

$$H_0(T_d; \mathbf{Z}) = \mathbf{Z}, \qquad H_1(T_d; \mathbf{Z}) = \mathbf{Z}, \qquad H_q(T_d; \mathbf{Z}) = 0 \quad (q \geq 2).$$

Thus the total space has the homology of the base circle although it retains a substantial nonabelian fundamental group.

Now regard the projection $T_d \to S^1$ solely as a map of homotopy types. Its homotopy fibre is the infinite cyclic cover of the mapping torus. Cutting that cover at the integral parameter values exhibits it as the telescope of successive degree-two maps. Its fundamental group is therefore

$$\operatorname{colim}(\mathbf{Z} \xrightarrow{2} \mathbf{Z} \xrightarrow{2} \cdots) = \mathbf{Z}[1/2],$$

and its higher homotopy groups vanish: every map from a sphere has compact image in a finite portion of the telescope, which retracts onto a circle. Transport around the base now acts invertibly, by multiplication by 2 or its inverse according to orientation. The passage to locally constant relative homotopy types has changed the fibre from $K(\mathbf{Z}, 1)$ to $K(\mathbf{Z}[1/2], 1)$.

This example can be made entirely categorical. Use the one-object groupoid $B\mathbf{Z}$ and the functor induced by $m \mapsto 2m$, then form its Grothendieck construction over $B\mathbf{N}$. Its nerve has the indicated homotopy-colimit type by the homotopy-colimit theorem (Thomason, 1979, Theorem 1.2); the precise statement and natural comparison are reproduced by Rubin (2020, §2.3, Theorem 2.6). The example extends the earlier walking-arrow tests: it shows, through an explicit group calculation, the information that is lost when all transport is forced to be invertible.

Dans le cas de Cat, la classe $\mathcal{L}$ des isomorphismes locaux (disons) permet de définir, comme ci-dessus, le localiseur $W_S^{\mathcal{L}} = W_S^{\mathrm{g}}$ dans les Cat/S, comme formé des $u : X \longrightarrow Y$ sur S qui sont dans W et le restent par tout changement de base $S' \longrightarrow S$ qui est dans $\mathcal{L}$. Mais il y a lieu de *saturer* $\mathcal{L}$, en regardant la classe $\mathcal{L}^\wedge$ des flèches $f : S \longrightarrow S'$ de Cat telles que le changement de base

$$f^* : \mathrm{Cat}/S \longrightarrow \mathrm{Cat}/S'$$

envoie W_S^{g} dans $W_{S'}^{\mathrm{g}}$. Ce $\mathcal{L}^\wedge$ est tautologiquement stable par composition, et contient les
ed. 142 isomorphismes (mieux, contient $\mathcal{L}$ = ensemble des isomorphismes locaux). Il n'est pas clair, par la définition donnée ici, qu'il soit stable par changement de base - on va renforcer la définition en conséquence, en exigeant, pour que $f : S' \longrightarrow S$ soit dans $\mathcal{L}^\wedge$, que pour tout T sur S, considérons $f_T : T' = S' \times_S T \longrightarrow T$, $f_T^* : \mathrm{Cat}/T \longrightarrow \mathrm{Cat}/T'$ soit compatible avec les localiseurs W_T^{g}, $W_{T'}^{\mathrm{g}}$. Alors $\mathcal{L}^\wedge$ est (tout comme $\mathcal{L}$) stable par composition et par changement de base, et de plus il contient $\mathcal{L}$. De plus, pour tout S, on a $W_S^{\mathcal{L}} = W_S^{\mathcal{L}^\wedge}$. Ce petit sorite pourrait se faire bien sûr pour tout modéliseur $(\mathcal{M}, W)$. Mais la chose intéressante ici, c'est que $\mathcal{L}^\wedge$ contient l'ensemble Liss_W des flèches W-lisses. (J'ignore s'il est égal.) On aurait donc pu aussi bien partir de l'ensemble de flèches Liss_W, pour définir les localiseurs W_S^{g} comme ms. page 223

$$W_S^{\mathrm{g}} = W_S^{\mathrm{Liss}_W} \qquad \text{au lieu de } W_S^{\mathrm{g}} = W_S^{\mathrm{Isoloc}},$$

ce qui est équivalent.

Commentary · Development (commentators') [ms. 222]

The maximal class of harmless base changes

Grothendieck strengthens his first definition of $\mathcal{L}^\wedge$ because a useful class of changes of base must remain useful after it is pulled back. The strengthened definition does more than supply that stability. It identifies a largest class of tests which leaves the relative weak equivalences unchanged.

Proposition (universal saturation of the tests). [ours] Let $\mathcal{M}$ have pullbacks, let W be a class invariant under isomorphisms of arrows, and let $\mathcal{L}$ contain all isomorphisms and be closed under composition and pullback. Write $E_S = W_S^{\mathcal{L}}$. Define $\widehat{\mathcal{L}}$ to contain $f : S' \to S$ when, for every $T \to S$, pullback along $f_T : S' \times_S T \to T$ sends E_T into $E_{S' \times_S T}$. Then $\widehat{\mathcal{L}}$ contains $\mathcal{L}$, is closed under composition and pullback, and

$$W_S^{\widehat{\mathcal{L}}} = E_S, \qquad \widehat{\widehat{\mathcal{L}}} = \widehat{\mathcal{L}}.$$

Moreover, if $\mathcal{K}$ has the same closure properties and $W_S^{\mathcal{K}} = E_S$ for every S, then $\mathcal{K} \subseteq \widehat{\mathcal{L}}$.

Proof. First take f in $\mathcal{L}$ and u in E_T. To test $f_T^* u$ at $g : R \to S' \times_S T$ in $\mathcal{L}$, pull back u along the composite $f_T g$. Both factors belong to $\mathcal{L}$, so that composite is an admissible test and its pullback of u belongs to W. Thus $\mathcal{L} \subseteq \widehat{\mathcal{L}}$.

For the pullback of a member f of $\widehat{\mathcal{L}}$, every subsequent test is already among the base changes in its definition. This proves pullback stability. For composable members $f : S' \to S$ and $g : S'' \to S'$, each base change of fg factors as the corresponding base change of f followed by one of g. Their pullback functors preserve the respective E classes in succession. This proves composition stability; identities satisfy the same condition immediately.

Since $\mathcal{L} \subseteq \widehat{\mathcal{L}}$, testing against $\widehat{\mathcal{L}}$ can only shrink the resulting class, so $W_S^{\widehat{\mathcal{L}}} \subseteq E_S$. Conversely, for $u \in E_S$ and $f : S' \to S$ in $\widehat{\mathcal{L}}$, the defining condition with $T = S$ gives $f^* u \in E_{S'} \subseteq W_{S'}$. Hence u passes every $\widehat{\mathcal{L}}$ test. This proves equality. Repeating the construction consequently uses exactly the same family E_S, so gives exactly the same class $\widehat{\mathcal{L}}$.

Finally, take $f \in \mathcal{K}$ and any $T \to S$. If $u \in E_T = W_T^{\mathcal{K}}$, its pullback along f_T passes every $\mathcal{K}$ test because such a test followed by f_T is again in $\mathcal{K}$. The pulled-back map therefore belongs to $W^{\mathcal{K}}_{S' \times_S T} = E_{S' \times_S T}$. This is precisely $f \in \widehat{\mathcal{L}}$. □

The proof does not use a model structure, a factorization axiom, or even two-out-of-three for W. Invariance under arrow isomorphisms only ensures independence of the choices of pullbacks and their canonical associativity isomorphisms. If W is weakly saturated, each E_S is weakly saturated because it is an intersection of inverse images of W under functors. We give the maximality and idempotence explicitly as a development of the source's sorite; we did not locate this exact formulation in the checked accounts of smooth functors and derived base change. The label makes no claim of priority. The variance of the first displayed f on manuscript p. 222 is reversed in the edition; the strengthened definition, and the argument above, use $f : S' \to S$.

D'autre part, en travaillant avec les localisés $\mathrm{HOT}^{\circ}_W(S) = (\mathrm{Cat}/S)(W_S^{\mathrm{g}})^{-1}$, le rôle de $\underline{\mathrm{Fib}}_W S$ pour la théorie des $\mathrm{HOT}^{\mathrm{lc}}_W(S)$ est joué ici par $\underline{\mathrm{Prop}}_W(S)$. On voit donc que dans la théorie des W-types d'homotopie relatifs non localement constants, mode HOT°_W, les ensembles de flèches Liss_W et Prop_W jouent un rôle en quelque sorte complémentaire : les flèches $f : S' \longrightarrow S$ de Liss_W sont (pratiquement) celles qui permettent directement de définir

$$f^{*\circ}_W : \mathrm{HOT}^{\circ}_W(S) \longrightarrow \mathrm{HOT}^{\circ}_W(S')$$

comme induit par

$$f^* : (\mathrm{Cat}/S, W_S^{\mathrm{g}}) \longrightarrow (\mathrm{Cat}/S', W_{S'}^{\mathrm{g}}),$$

tandis que les flèches de Liss_W permettent de définir pour tout S dans Cat la sous-catégorie pleine

$$\underline{\mathrm{Prop}}_W S \subseteq \mathrm{Cat}/S,$$

donnant lieu à une équivalence de catégories

$$\begin{cases} (\underline{\mathrm{Prop}}_W S)(W_S^{\mathrm{u}})^{-1} \xrightarrow{\sim} \underbrace{(\mathrm{Cat}/S)(W_S^{\mathrm{g}})^{-1}}_{=\mathrm{HOT}^{0}_W(S)} \\ \text{avec} \\ W_S^{\mathrm{u}} = W_S^{\mathrm{g}} \text{ sur } \underline{\mathrm{Prop}}_W S \end{cases}$$

(ce qui visiblement est le substitut annoncé de "l'axiome de la fibre W-homotopique"). Cette équivalence, qui permet de décrire $\mathrm{Hot}^{\circ}_W(S)$ en termes de $\underline{\mathrm{Prop}}_W S \subseteq \mathrm{Cat}/S$ et d'un localiseur W_S^{u} *stable par* **tout** *changement de base,* permet d'autre part de définir la loi contravariante attendue pour $\mathrm{HOT}^{\circ}_W(S)$. ms. page 224

Commentary · Later developments [ms. 223]

The saturation question has an affirmative answer in Cat

The question in parentheses on p. 222 can be answered using the later characterization of smooth functors. With Grothendieck's localizer W_S^{g} and the universal definition of $\mathcal{L}^\wedge$, one has

$$\mathcal{L}^\wedge = \mathrm{Liss}_W.$$

This is an implication of an established theorem, not a new smoothness criterion claimed by the commentators. A functor is W-smooth exactly when all its base changes preserve W-aspherical functors (Maltsiniotis, 2005, Theorem 1.2(c)).

Here is the precise translation. A functor $v : A \to T$, regarded as a morphism from A/T to the terminal object T/T of the slice, belongs to W_T^{g} exactly when $A/t \to T/t$ belongs to W for every t. Since T/t has a terminal object, this says exactly that every A/t is W-aspherical. Thus it says that v is a W-aspherical functor. If $f : S' \to S$ belongs to $\mathcal{L}^\wedge$, apply the preservation condition after every $T \to S$ to these particular arrows $v : A \to T$. Their pullbacks are again W-aspherical. The cited characterization implies that f is W-smooth. The opposite inclusion is the smooth base-change property used in the source. This proves the equality, including its universal quantifier.

There is an editorial distinction on this page that should not obscure the argument. The sentence introducing the full subcategory $\underline{\mathrm{Prop}}_W S$ repeats "Liss" where its role requires "Prop". The underbrace subsequently prints $\mathrm{HOT}^0_W(S)$, with a zero, although the theory throughout the paragraph is $\mathrm{HOT}^\circ_W(S)$. Both readings are retained and recorded; neither denotes a third relative theory.

ed. 143 D'autre part, quand on échange le rôle de Liss_W et Prop_W, on trouve la théorie complémentaire du $\mathrm{HOT}_W(S)$,

$$\begin{cases} \mathrm{HOT}_W(S) \overset{\text{déf}}{=} (\mathrm{Cat}/S)(W_S^{\mathrm{d}})^{-1} \overset{\sim}{\leftarrow} (\underline{\mathrm{Liss}}_W S)(W_S^{\mathrm{u}})^{-1}, \\ \text{sur } \underline{\mathrm{Liss}}_W S,\ W_S^{\mathrm{d}} = W_S^{\mathrm{u}}, \end{cases}$$

la description de $\mathrm{HOT}_W(S)$ en termes de $\underline{\mathrm{Liss}}_W S$ et de W_S^{u} permet d'en définir le caractère contravariant en S, pour *toute* flèche $f : S' \longrightarrow S$ dans Cat. Tandis que si on veut pouvoir passer aux catégories de fractions sur Cat/S et Cat/S' tout entier (via W_S^{d}, $W_{S'}^{\mathrm{d}}$), il faut se limiter aux changements de base W-propres.

Du coup, me vient la perplexité si cette complémentaire, voire cette dualité, entre deux ensembles de flèches, les 'lisses' et les 'propres', ne serait pas un fait général qui se retrouvait tout au moins dans les catégories de modèles proche de la description de HOT ou d'un Hot_W.

Il se pourrait bien que dans $\mathbf{\Delta}^\wedge$ on ait une dualité parfaite entre ces deux espèces de notions (il faudra que j'examine la chose), peut-être même dans toute catégorie $\mathcal{A}^\wedge$ (mais dans $\mathbf{\Delta}^\wedge$ il y a un automorphisme involutif $K \longmapsto K^\circ$, correspondant au $X \longmapsto X^\circ$ dans Cat …). Et après tout, même dans le contexte des espaces topologiques, les notions de propreté d'une part, d'asphéricité locale d'autre part, pour une flèche $X \longrightarrow Y$, sont bien définies, et pourraient bien s'ajuster comme le font les notions correspondantes dans Cat, et (qui sait) donner lieu à deux versions complémentaires, ou 'duales' l'une de l'autre, d'une notion de type d'homotopie relatif. ms. page 225

N'en ayant pas le cœur net, je suis un peu indécis comment présenter une description axiomatique de la théorie des $\mathrm{Ho}^{\mathcal{L}}_W(S)$, pour une catégorie de modèles générale $(\mathcal{M}, W)$. Dois-je me donner d'emblée

$$\mathrm{Liss}, \mathrm{Prop} \subseteq \mathrm{Fl}(\mathcal{M}),$$

stables par composition, par changement de base, contenant les isomorphismes, et tels que (peut-être)

$$\mathrm{Liss} \cap \mathrm{Prop} \subseteq \mathrm{Fib}_W,$$

mais surtout ils permettent de définir, pour S de $\mathcal{M}$ ms. page 226

$$\begin{cases} W_S^{\mathrm{g}} \overset{\text{déf}}{=} W_S^{\mathrm{Liss}} \subseteq \mathcal{F}(\mathcal{M}/S) \\ W_S^{\mathrm{d}} \overset{\text{déf}}{=} W_S^{\mathrm{Prop}} \subseteq \mathcal{F}(\mathcal{M}/S) \end{cases}$$

Commentary · Context [ms. 225]

Smoothness and properness depend on a coefficient theory

Grothendieck's proposed pair of classes is meant to encode two ways in which a square admits base change. The geometric names come from proper and smooth base-change theorems in étale cohomology, but their categorical definitions concern the invertibility of specific comparison transformations. This is why exchanging the two classes in the text also exchanges the direction of the relative theory. The comparison with geometry is a source of the formalism; it does not identify a categorical proper functor with a proper continuous map.

Once a coherent indexed category $\mathscr{E} : S \mapsto \mathscr{E}(S)$ is given, an adjunction $f_! \dashv f^*$ produces a base-change mate for each pullback square, and an adjunction $f^* \dashv f_*$ produces its other version. Requiring the relevant mate to be invertible after all further base changes defines a stable class. Thus a meaningful duality has three pieces of data: the coefficient theory, its two adjunctions where they exist, and the chosen variance. Merely knowing which arrows of an ambient category are weak equivalences does not supply all these pieces.

A modern formulation makes precisely this dependence explicit. Anel and Weinberger (2024, Definition 9 and Proposition 10) associate smooth and proper classes to an indexed category over a base with finite limits; these are the largest classes along which the corresponding indexed sums and products exist with stable Beck–Chevalley compatibility. Their examples in Sections 3.2–3.3 include categorical and topological versions. This gives a general setting for the complementarity sought here. It is not a proof that every proposed $(\mathcal{M}, W, \mathcal{L})$ satisfies the localization equivalences of p. 226.

The involution on simplicial sets mentioned by Grothendieck is entirely concrete. Reverse the order on each finite ordinal: for $\alpha : [m] \to [n]$, set $\alpha^{\mathrm{rev}}(i) = n - \alpha(m-i)$. These maps define an involutive automorphism of Δ, hence, by precomposition, an involution $K \mapsto K^{\mathrm{op}}$ of simplicial sets. The identity $N(C^{\mathrm{op}}) = (NC)^{\mathrm{op}}$ is immediate from a string of composable arrows. The corresponding assertion for a general presheaf category requires an appropriate duality of its indexing category; none is part of the present hypotheses. Consequently the speculation about all presheaf categories should remain a programme with specified additional structure, rather than an unqualified theorem or a single well-posed open conjecture.

ⓐ Si $f : S' \longrightarrow S$ est dans Prop (resp. Liss), alors $f^* : \mathcal{M}/S \longrightarrow \mathcal{M}/S'$ transforme W_S^{d} dans $W_{S'}^{\mathrm{d}}$ (resp. W_S^{g} dans $W_{S'}^{\mathrm{g}}$),

ed. 144 ce qui est une pure tautologie, et ne concerne pas encore les relations de Prop avec Liss, mais par contre :

ⓑ
$$\begin{cases} (\underline{\mathrm{Liss}}S)(W_S^{\mathrm{u}})^{-1} \xrightarrow{\sim} (\mathcal{M}/S)(W_S^{\mathrm{d}})^{-1} \texttt{ [est]} \text{ une équivalence} \\ \text{et } W_S^{\mathrm{u}} = W_S^{\mathrm{d}} \text{ sur } \underline{\mathrm{Liss}}S, \end{cases}$$

et dualement

$$\begin{cases} (\underline{\mathrm{Prop}}S)(W_S^{\mathrm{u}})^{-1} \xrightarrow{\sim} (\mathcal{M}/S)(W_S^{\mathrm{g}})^{-1} \texttt{ [est]} \text{ une équivalence} \\ \text{et } W_S^{\mathrm{u}} = W_S^{\mathrm{g}} \text{ sur } \underline{\mathrm{Prop}}S. \end{cases}$$

De plus, il y a lieu d'énoncer ⓒ deux propriétés d'adjonction (duales l'une de l'autre), pour lesquelles je renvoie à VI, théorème-scholie 2, p. 108-113. Il se pose ici la question subsidiaire de simplifier les conditions de validité de la formule d'adjonction, un peu hétéroclites dans loc. cit.

Il se pose d'autre part la question de faire la théorie des lois covariantes $f_!$ et f_* pour $\mathrm{Ho}_W^{\mathrm{lc}}(S)$ et pour $\mathrm{Ho}_W^{\mathrm{Prop}}(S)$, $\mathrm{Ho}_W^{\mathrm{Liss}}(S)$.

ms. page 227

Commentary · Development (commentators') [ms. 226]

Postcomposition already gives a direct image

Grothendieck postpones the direct images because the hard part of his construction has been the inverse image. One part of his expectation follows from the elementary structure of the test classes alone. It is useful to isolate it before bringing in a theory of derived adjunctions.

Proposition (descent of postcomposition). [ours] Under the hypotheses of the universal-saturation proposition, every $f : S' \to S$ induces a functor

$$f_{\#} : (\mathcal{M}/S')[(W^{\mathcal{L}}_{S'})^{-1}] \longrightarrow (\mathcal{M}/S)[(W^{\mathcal{L}}_{S})^{-1}]$$

by postcomposition with f. These functors compose canonically. If f belongs to $\widehat{\mathcal{L}}$, ordinary pullback also descends, and the ordinary adjunction $f_{\#} \dashv f^*$ descends with its unit and counit.

Proof. Take $u : X \to Y$ over S' in $W^{\mathcal{L}}_{S'}$. For a test $T \to S$ in $\mathcal{L}$, its pullback $T' = S' \times_S T \to S'$ again belongs to $\mathcal{L}$. The underlying arrow obtained by pulling back $f_{\#}u$ to T is canonically the underlying arrow obtained by pulling back u to T'. It belongs to W. Thus postcomposition sends the required weak equivalences to weak equivalences and factors through localization. The equalities of ordinary postcomposition give the composition isomorphisms, with their associativity.

When $f \in \widehat{\mathcal{L}}$, its pullback functor is homotopical by definition. Both functors in the ordinary slice adjunction therefore descend. A natural transformation between relative functors descends as well: its naturality equation for an inverted arrow remains valid after that arrow is inverted. Apply this observation to the unit and counit. Their two triangle identities are equalities before localization and remain equalities afterwards, proving the adjunction. □

This argument establishes the direct-image functor for every f, without a functorial replacement. It does not by itself establish an adjunction to an inverse image obtained indirectly from proper or smooth representatives when raw f^* is not homotopical. In that case one must compare the replacement with the ordinary slice adjunction. The source's proposed axioms are designed to make this possible; equality of the three localizers on a full subcategory alone is not the comparison. The earlier Chapter VI commentary, at manuscript pp. 137–145, supplies that comparison in its categorical setting. The proposition above records the additional generality that follows directly from the present definition, without claiming a new priority for descent of adjunctions.

J'ai bon espoir que le foncteur $f_!$ peut être décrit, et son adjonction avec f^* établie, à aussi bon compte dans ce contexte général que dans Cat. Mais je n'ai pas envie de m'y arrêter à présent.

6 Cofibre W-homotopique dans Cat.

Par contre, j'ai envie de regarder ici sous quelles conditions sur le localiseur fondamental W, il existe dans (Cat, W) une théorie duale de celle de la fibre W-homotopique.

La question-clef est, bien sûr, celle d'avoir une bonne prise sur les W-cofibrations. Or je ne connais jusqu'à présent *que* les immersions ouvertes de Dwyer, les immersions fermées de Dwyer, et ce qui s'en déduit par composition etc. Le travail de Thomason peut motiver l'espoir que la connaissance de ces immersions-là, qui semblent ici jouer un rôle similaire (dual) à celui des morphismes W-parfaits, suffira pour faire une bonne théorie des 'cofibres W-homotopiques'.

||| Je suppose dans toute cette section que W satisfait W(7 bis) (axiome des carrés cocartésiens), pour avoir des bonnes propriétés des immersions ouvertes de Dwyer ([124]), et plus généralement, pour les W-cofibrations.

ed. 145 Il se pose donc la question de la factorisation duale d'une flèche $f : X \longrightarrow Y$ de Cat en ms. page 228

$$X \xrightarrow[i_f]{W\text{-cofibration}} \tilde{Y} \xrightarrow[p_f]{\in W} Y.$$

124.

a) Ce sont des W-cofibrations (résulte de b) et c)).

b) Si

Commentary · Exposition [ms. 227]

Why a longer categorical interval is needed

The passage from fibres to cofibres begins with a manageable class of maps along which strict gluing has the correct homotopical effect. For an inclusion $A \hookrightarrow B$, the Dwyer condition provides exactly such control. In its original form it says that A is a full sieve, and that its inclusion in the cosieve $Z \subseteq B$ generated by A has a right adjoint $r : Z \to A$ restricting to the identity of A. The counit $ir \to \mathrm{id}_Z$ is a categorical deformation of the neighbourhood Z onto A. This accounts for the usefulness of Dwyer maps in gluing (Thomason, 1980, Definition 4.1 and Proposition 4.3).

For $I = \Phi_n$, the endpoints 0 and $2n$ form a sieve. Their generated cosieve consists of the four vertices $0, 1, 2n-1, 2n$ when $n \geq 2$. It is the disjoint union of two arrows, $0 \to 1$ and $2n \to 2n-1$. Send the first arrow to the endpoint 0 and the second to $2n$. This is the required right adjoint. For $n = 1$, the generated cosieve is the whole cospan $0 \to 1 \leftarrow 2$. A right adjoint to the inclusion of the two endpoints would have to assign to 1 an endpoint receiving all arrows from either endpoint, which is impossible. The lower bound $n \geq 2$ therefore has an exact purpose: the two deformation neighbourhoods must not meet.

Taking a product with X preserves the sieve and cosieve conditions and the adjunction, now with right adjoint $\mathrm{id}_X \times r$. The nerve of Φ_n realizes to a subdivided interval, so $X \times I \to X$ is an ordinary weak equivalence. The stronger description as W_ω-perfect records the corresponding universal statement in the categorical theory. Thus the factorization of the codiagonal has both the disjoint endpoint inclusion needed for the mapping cylinder and the weakly contractible cylinder direction needed for its retraction.

The more general fibred base change asserted in the source has a similarly explicit proof. Pull a Dwyer inclusion $A \hookrightarrow B$ back along a Grothendieck fibration $E \to B$. Over its generated cosieve Z, lift each counit arrow $r(b) \to b$ cartesianly to an arrow $r'(e) \to e$. Choose identity lifts over A. The cartesian universal property defines r' on morphisms, with functoriality following from uniqueness. For an object a' over A, an arrow $a' \to e$ factors uniquely through that cartesian lift: its image in B first factors uniquely through the counit by the original adjunction. Hence r' is right adjoint to the pulled-back inclusion. Moreover every object over Z receives such a lifted arrow from an object over A, so the pulled-back cosieve is exactly the generated one. This proves the asserted stability and explains why an arbitrary base change, without a lifting condition, was not claimed.

The terminology must remain precise. Grothendieck's W-cofibration is a map whose cobase changes preserve the relevant W-equivalences. It is a homotopical gluing condition, not the definition by a lifting property in Thomason's model structure. Dwyer maps supply examples; one should not identify the two classes. Nor should one assert that every Thomason cofibration is a Dwyer map: Cisinski (1999, pp. 227–231) gave a counterexample to closure of the original Dwyer maps under retracts and repaired the properness argument. That correction leaves the explicit mapping-cylinder construction below intact.

Les résultats de Thomason assurent que ça existe, avec i une immersion ouverte de Dwyer, et p une W-fibration - du moins dans le cas $W = W_\infty$. Je vais essayer de le voir directement, en calquant dualement la construction de Cartan-Serre.

Commentary · Exposition [ms. 228]

An interval with room at both ends

Grothendieck wants to replace every map by an inclusion along which gluing respects the chosen weak equivalences. This will make a homotopy cofibre accessible to the same relative methods that have already produced homotopy fibres. The interval is therefore being chosen for a relative property of its two endpoints. Its contractibility supplies only the other half of the construction.

We recall precisely the relevant meaning of cofibration. A map $i : A \to B$ is a W-cofibration when the pushout functor

$$A\backslash\mathcal{M} \longrightarrow B\backslash\mathcal{M}, \qquad (A \to T) \longmapsto (B \to B \amalg_A T),$$

preserves morphisms belonging to W. This is the definition on manuscript pp. 109–110 (Grothendieck, 1990–1991d, Definition 2(c)). It includes every subsequent change of the object under A. Associativity of pushouts immediately makes this class stable under pushout and composition. A Quillen cofibration is defined by a lifting property; the relation between the two notions requires a properness or gluing theorem. In the present argument, the required gluing property is part of the definition of Cof_W.

The geometry of a Dwyer map provides a tractable supply of such inclusions. Write an open immersion as a full sieve $A \subseteq B$: an arrow of B whose target belongs to A has its source in A. It is Dwyer when the inclusion of A into its generated cosieve $Z_B A$ has a right adjoint r with $r|_A = 1_A$. The counit gives arrows $r(b) \to b$, coherently in b. Thus objects immediately outside A have canonical points of attachment in A; this is the categorical structure used when the inclusion is pushed out (Thomason, 1980, Definition 4.1).

For the fence $I = \Phi_n$, the cosieve generated by its endpoints is

$$\{0 \longrightarrow 1\} \amalg \{2n \longrightarrow 2n-1\}, \qquad n \geq 2.$$

The right adjoint sends the first component to 0 and the second to $2n$. The unit is the identity, and the two displayed arrows give its counit. Taking its product with X gives the required adjoint for $X \amalg X \subseteq X \times I$. The same argument also explains the lower bound on n. For $n = 1$, the vertex 1 receives arrows from both 0 and 2. If a right adjoint existed, its value at 1 would have to represent the functor on the discrete two-point category which takes both objects to a singleton. Neither object represents that functor. The two endpoint neighbourhoods need a vertex between them before the Dwyer condition can hold.

The notation W_ω belongs to the earlier construction of a minimal localizer from saturation, the relative Theorem A condition, and the terminal-object axiom (Grothendieck, 1990–1991f, manuscript p. 14). The elementary contraction of this finite fence already belongs to that small class. One can remove the outermost endpoint, then its newly terminal neighbour, and repeat; each removal is witnessed by an adjunction between the remaining posets. Products preserve these adjunctions. Consequently $X \times I \to X$ is a homotopy equivalence for every X, and remains one after an arbitrary change of its base X.

Il s'agit donc d'abord de factoriser

$$X \amalg X \xrightarrow{\text{codiag}_X} X,$$

et pour ceci je choisis un intervalle fixe

$$I \;=\; \Phi_n \;=\; (0 \longrightarrow 1 \longleftarrow 2 \longrightarrow \cdots \longrightarrow 2n-1 \longleftarrow 2n)$$

avec

$$n \geq 2$$

de sorte que l'inclusion

$$\varepsilon = \text{catégorie discrète } \{0,1\} \xrightarrow{\partial} I, \qquad \partial(0) = 0, \quad \partial(1) = 2n,$$

soit une immersion ouverte de Dwyer. Cette propriété est stable par changement de base Cat-fibrant, en particulier en prenant un produit

$$\underbrace{X \times \varepsilon}_{\simeq X \coprod X} \xrightarrow{i_X} X \times I,$$

ed. 146 d'autre part

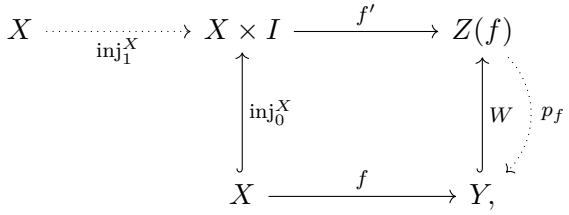
$$\begin{array}{ccc} U & \xrightarrow{\;i\;} & X \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ U' & \xrightarrow{\;i'\;} & X' \end{array}$$

ms. page 229

avec i immersion ouverte de Dwyer, alors

$$\begin{aligned} i \in W \quad &\Longleftrightarrow \quad i' \in W \\ p \in W \quad &\Longleftrightarrow \quad q \in W, \end{aligned}$$

j'ai donc besoin de W(7 bis) *et* même de W(7) pour la deuxième implication.



c) Les immersions ouvertes de Dwyer [sont] stables par cochangement de base et par composition, contiennent les isomorphismes.

$$X \times I \xrightarrow{\mathrm{pr}_1} X$$

est W_ω-parfait, d'où la factoriastion cherchée

$$X \amalg X \xrightarrow{i_X} X \times I \xrightarrow{p_X = \mathrm{pr}_1^X} X$$

- il n'y a pas plus simple! Comment l'utiliser pour construire la factorisation d'une flèche $f : X \longrightarrow Y$ quelconque, en dualisant les constructions relatives aux espaces de chemins? On définit $Z(f)$ par le carré cocartésien dans Cat

on a

$$Z(f) \xrightarrow{\alpha} Y \qquad \text{induit par } \mathrm{pr}_1 : X \times I \longrightarrow X,$$

et la factorisation cherchée de f est

$$X \xrightarrow{i_f = f' \circ \mathrm{inj}_1^X} Z(f) \xrightarrow{p_f} Y.$$

Commentary · Development (commentators') [ms. 228]

Conservative gluing is an additional hypothesis

The continued footnote 124 is stronger than the gluing theorem usually used in homotopy theory. It prints two biconditionals for a Dwyer pushout. Its stated hypotheses include the conservative axioms W(7 bis), and for the second assertion W(7), inherited from earlier pages (Grothendieck, 1990–1991d, Chapter XII, manuscript pp. 76–78). The conditional assertion should not be silently replaced by a theorem about W_∞. In fact the reverse implications fail in the ordinary homotopy theory, even for finite posets and an open cover.

Example (a conservative converse fails). [ours] There is a pushout square of finite posets

$$\begin{array}{ccc} A & \xhookrightarrow{i} & B \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ C & \xhookrightarrow[i']{} & D \end{array}$$

in which i and p are Dwyer maps, i' and q belong to W_∞, and neither i nor p belongs to W_∞.

Construction and proof. Start with a connected finite acyclic complex K with nontrivial fundamental group. For completeness, the presentation complex with two generators and two relations

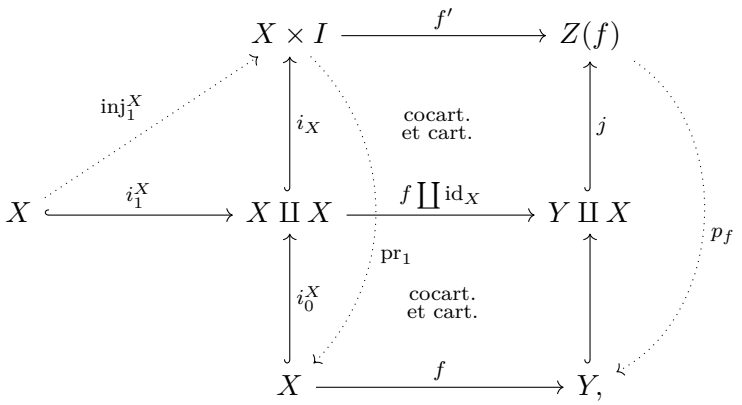
$$\langle a, b \mid a^5 b^{-3},\ b^3 (ab)^{-2} \rangle$$

has cellular boundary matrix $\left(\begin{smallmatrix} 5 & -2 \\ -3 & 1 \end{smallmatrix}\right)$, of determinant -1, so its reduced integral homology vanishes. Sending a to (12345) and b to (253) defines a nontrivial homomorphism of its fundamental group to A_5: $a^5 = b^3 = (ab)^2 = 1$, since $ab = (12)(45)$. Hence it is not contractible. This is the acyclic complex of Hatcher (2002, Example 2.38). Choose a finite simplicial model of the same homotopy type. Such a model can be obtained by replacing the two attaching maps by simplicial maps between subdivided finite graphs and using their finite triangulated mapping cylinders before adjoining the two discs.

Let $P(L)$ be the poset of nonempty simplices of a finite simplicial complex L, ordered by inclusion. Set

$$A = P(K), \quad B = P(C_+ K), \quad C = P(C_- K), \quad D = P(\Sigma K).$$

The two cones are subcomplexes of the suspension and meet in K. Their face posets are sieves, their union is D, and there are no arrows between the two complements. Their ordinary pushout is therefore D. For $A \hookrightarrow B$, the cosieve generated by A consists of all simplices except the one-vertex apex simplex. On this cosieve, deleting the apex defines a right adjoint to the inclusion of A: a simplex of K is a face of σ if and only if it is a face of σ with the apex removed. This verifies the Dwyer condition. The proof for $A \hookrightarrow C$ is identical.



The realization of $NP(L)$ is the barycentric subdivision of L. Both B and C are therefore contractible. The suspension of a connected space is simply connected, and its reduced homology is the shifted reduced homology of the space. Thus ΣK is simply connected and acyclic. If it had a first nonzero homotopy group, the Hurewicz theorem would identify that group with a nonzero homology group. It has none, and Whitehead's theorem makes ΣK contractible. Consequently i' and q are weak equivalences, whereas i and p cannot be, because $|NA|$ has nontrivial π_1. □

This application of a classical acyclic example is included to expose the strength of the assumed axiom, not as a claim of novelty. We checked the original Dwyer pushout theorem, its retract correction, and the later categorical refinement; they assert preservation, not these converse implications. The earlier W(7 bis), formulated for a union of open sieves, already fails on the displayed union. The claim in Chapter XII, manuscript p. 78, that W_∞ satisfies the stronger W(7), cannot supply it. The present proof of the mapping cylinder and Proposition 16 uses only the forward gluing implications, which are valid for W_∞. Keeping this distinction allows the construction to survive with its natural hypotheses.

Je dis que

$$\begin{cases} i_f \text{ est immersion ouverte de Dwyer, donc une } W\text{-cofibration.} \\ p_f \in W. \end{cases}$$

On voit sur le diagramme plus complet ms. page 230

ed. 147

$$i_f = f' \circ \mathrm{inj}_1^X = f' i_X i_1^X = j \underbrace{(f \amalg \mathrm{id}_X) i_1^X}_{\substack{\text{inclusion canonique} \\ \text{de } X \text{ dans} \\ Y \coprod X}} ,$$

c'est [une] immersion ouverte de Dwyer, comme composé de $Y \longrightarrow Y \amalg X$ et $j : Y \amalg X \longrightarrow Z(f)$ qui le sont (j obtenu par cochangement de base à partir de i_X, qui est immersion ouverte de Dwyer).

D'autre part, $X \xrightarrow{\mathrm{inj}_0^X} X \times I$ est [une] immersion ouverte de Dwyer et dans W, donc coüniversellement dans W, donc $Y \longrightarrow Z(f)$ est elle aussi dans W, donc aussi la rétraction p_f.

Commentary · Examples [ms. 230]

A cylinder and a circle in finite categories

The mapping cylinder puts the preceding two properties to work simultaneously. Its construction is worth following through a small example, because the example also shows what a homotopy cofibre retains that a strict categorical quotient can lose. First write its two structural maps without the changing names in the display:

$$Z(f) = (X \times I) \amalg_{X\times\{0\}} Y, \qquad s_f : Y \longrightarrow Z(f), \qquad p_f : Z(f) \longrightarrow Y.$$

The map p_f is induced by $f \operatorname{pr}_1$ on $X \times I$ and by 1_Y on Y. Hence $p_f s_f = 1_Y$, while the free endpoint defines $i_f : X \to Z(f)$ with $p_f i_f = f$. These equations also show that the construction is functorial in a commutative square of functors: the two maps on the pieces agree on the identified endpoint and therefore induce a unique map on their pushout.

To see that the free endpoint is still a Dwyer inclusion, separate both endpoints before making the attachment. The pushout of $X \amalg X \hookrightarrow X \times I$ along $f \amalg 1_X$ is

$$j : Y \amalg X \longrightarrow Z(f).$$

The desired inclusion is j composed with the X-summand inclusion. Both are Dwyer maps. The printed sentence has $Y \to Y \amalg X$ in this position; its preceding formula and its source X specify the intended summand. The other endpoint inclusion $X \to X \times I$ is a weak equivalence, and its pushout s_f is one by the forward gluing property. Two-out-of-three applied to $p_f s_f = 1_Y$ proves $p_f \in W$. No fibration property of p_f is required for this finite construction.

Now take $X = \{a, b\}$ discrete, $Y = \{y\}$, and let f be the unique functor. Choose $I = \Phi_2$. The category $Z(f)$ has the nine objects

$$y, \quad a_1, a_2, a_3, a_4, \quad b_1, b_2, b_3, b_4.$$

Its nonidentity arrows are exactly, for $x = a, b$,

$$y \longrightarrow x_1 \longleftarrow x_2 \longrightarrow x_3 \longleftarrow x_4.$$

There are no composable pairs of nonidentity arrows. Thus its nerve has precisely these vertices and eight nondegenerate edges, and no higher nondegenerate simplices. Its realization is a tree with two arms. The contraction to y verifies directly that p_f is a weak homotopy equivalence. The free endpoints a_4, b_4 form a Dwyer subcategory: their generated cosieve consists of the two separate arrows $a_4 \to a_3$ and $b_4 \to b_3$.

We may consequently form the homotopy cofibre by the strict pushout

$$C(f) = Z(f) \amalg_{\{a_4,b_4\}} \{t\}.$$

It has eight objects and eight nonidentity arrows. Its nerve is the graph obtained from the tree by identifying its two free endpoints. This graph is an eight-edge circle. In particular,

$$H_1(NC(f); \mathbb{Z}) = \mathbb{Z}, \qquad \pi_1(NC(f), t) \cong \mathbb{Z}.$$

The direct pushout $\{y\} \amalg_{\{a,b\}} \{t\}$ in Cat is instead the terminal category: both maps identify the two objects at once. The cylinder has retained the two paths by which the gluing takes place. This is the finite categorical model of the familiar homotopy pushout $* \amalg^h_{S^0} * \simeq S^1$, and it is the reason the question on p. 232 requires a proof.

Commentary · Later developments [ms. 230]

What the appeal to Thomason supplies

Grothendieck's appeal to Thomason supplies a stronger factorization in the ordinary spatial case. The cellular construction in the proof of the model-category theorem factors a functor as a Dwyer inclusion followed by a trivial fibration for the Thomason model structure (Thomason, 1980, proof of CM5 and Theorem 4.9). The cylinder just constructed gives a finite and transparent substitute for the weaker factorization needed here.

A later correction matters when using that historical reference. Cisinski (1999) exhibited a retract of a Dwyer map which is a Thomason cofibration but is not itself Dwyer, and repaired the properness argument. Thomason's assertion that all cofibrations are Dwyer therefore cannot be used to justify the first paragraph. The particular cellular factorization survives, as do the pushout and composition properties used in this passage. Grothendieck's explicit cylinder is also independent of closure under retracts. The distinction protects exactly the argument being made, without changing its conclusion.

D'autre part, la proposition duale de

$$\underline{\mathrm{Fib}}_W S \cap W_S = W_{S\,\mathrm{univ}}^{\mathrm{u}}$$

est valable pour les W-cofibrations :

des W*-cofibrations, et soit* $f : X \longrightarrow Y$ *un morphisme de* $S\backslash\mathrm{Cat}$ *tel que* $f \in W$*. Alors pour tout cochangement de base* $S \longrightarrow S'$*, la flèche correspondante*

$$f' : X' = X \amalg_S S' \longrightarrow Y' = Y \amalg_S S'$$

est dans W*.*

Commentary · Exposition [ms. 230]

The mapping cylinder, with the two endpoints distinguished

The construction now turns the endpoint geometry into a factorization of an arbitrary functor. Let $a_0, a_1 : X \to X \times I$ denote the two endpoint inclusions and form

$$Z(f) = Y \amalg_{X,a_0} (X \times I).$$

Write $k : Y \to Z(f)$ and $f' : X \times I \to Z(f)$ for the coprojections. The maps $f\,\mathrm{pr}_X$ and id_Y agree on the identified copy of X, hence induce a unique $p_f : Z(f) \to Y$. Put $i_f = f'a_1$. Then $p_f i_f = f$ and $p_f k = \mathrm{id}_Y$. The displayed α in the source is this same p_f; the projection used to define it is followed by f on the cylinder summand.

The endpoint a_0 is a Dwyer map and a weak equivalence. Its pushout k is consequently a weak equivalence by the forward gluing property. Two-out-of-three applied to $p_f k = \mathrm{id}_Y$ gives $p_f \in W$. To prove the other assertion, use both endpoints at once. The map

$$j : Y \amalg X \longrightarrow Z(f)$$

is the pushout of $a_0 \amalg a_1 : X \amalg X \to X \times I$ along $f \amalg \mathrm{id}_X$, hence is Dwyer. The inclusion of the second summand $X \hookrightarrow Y \amalg X$ is Dwyer, and its composite with j is i_f. Closure under composition proves the required assertion. The edition says $Y \to Y \amalg X$ in this sentence; the formula immediately preceding it requires the second summand X.

The construction is functorial in f. A commutative square $bf = f'a$ gives maps b on the Y summand and $a \times \mathrm{id}_I$ on the cylinder summand, compatible on the attaching copy of X. The universal property gives the induced map of mapping cylinders, and uniqueness proves compatibility with composition and identities. This supplies an actual replacement functor on the arrow category, not merely objectwise existence of a factorization. Nothing in this argument says that the displayed p_f is a Thomason fibration; the source only claims $p_f \in W$ for this explicit factorization. The stronger model-category factorization mentioned earlier is a different choice.

A small computation shows what the construction buys. Let X be the discrete two-object category and let $f : X \to e$ be the unique functor. With $I = \Phi_2$, $Z(f)$ is made of two four-edge intervals sharing their attached endpoint y. Form the further pushout $e \amalg_X Z(f)$, identifying their

125. N'a rien à voir avec Cat - une chose générale quand il y a assez de W-cofibrations.

two free endpoints to a second point z. The resulting poset has eight vertices: y, z, and three interior vertices on each arm. Every nonidentity arrow runs from an even vertex to an adjacent odd vertex, so there are no nondegenerate simplices of its nerve in dimensions above one. Its realization is the graph of two four-edge paths from y to z, hence a circle. Its cellular differential has rank seven, giving $H_1 = \mathbf{Z}$ and $H_q = 0$ for $q > 1$; a spanning tree leaves one generator of π_1. This is the homotopy cofiber of the collapse $S^0 \to *$, obtained by an ordinary categorical pushout only after the mapping-cylinder replacement.

Démonstration. On factorise $S \longrightarrow S'$ en

$$S \xrightarrow{i} S'_0 \xrightarrow{j} S',$$

avec i immersion ouverte de Dwyer (donc W-cofibration), et $j \in W$. On a donc le diagramme à carrés cocartésiens

$$\begin{array}{ccccc} S & \longrightarrow & X & \xrightarrow{f} & Y \\ {\scriptstyle i}\downarrow & & \downarrow & & \downarrow \\ S'_0 & \longrightarrow & X'_0 & \xrightarrow[W]{f'_0} & Y'_0 \\ {\scriptstyle \in W}\downarrow & & \downarrow{\scriptstyle W} & & \downarrow{\scriptstyle W} \\ S' & \longrightarrow & X' & \xrightarrow{f'} & Y'. \end{array}$$

Comme i est une W-cofibration et $f \in W$, on a $f'_0 \in W$. D'autre part, comme $S \longrightarrow X$, donc
ed. 148 $S'_0 \longrightarrow X'_0$ est une W-cofibration, $X'_0 \longrightarrow X'$ est dans W, et pour la même raison, $Y'_0 \longrightarrow Y$ ms. page 232
l'est aussi. Donc f' l'est aussi.

NB Ici, c'est un argument formel, valable (sous forme duale) dans tout $(\mathcal{M}, W)$ où on a un énoncé de factorisation pour une flèche quelconque $f : X \longrightarrow Y$ en $X \xrightarrow{i_f} \bar{X} \xrightarrow{\alpha} Y$, avec $i_f \in W$ et α une W-fibration. Alors, si X, Y sont W-fibrés sur S, toute S-flèche de X dans Y qui est dans W, est dans W^{u}_S. Et dualement, si toute flèche $X \longrightarrow Y$ se factorise en $X \longrightarrow \tilde{Y} \longrightarrow Y$, avec $X \longrightarrow \tilde{Y}$ une W-cofibration et $\tilde{Y} \longrightarrow Y$ dans W.

Commentary · Exposition [ms. 232]

Weak equivalences between objects under a fixed base

Proposition 16 provides the independence of replacement that a relative homotopy construction needs. A map under S can be a weak equivalence while its image after a badly behaved attachment is not. The proposition locates a class of objects under S for which every attachment behaves correctly: both structure maps from S must be W-cofibrations. It does not require the map between those objects to be a cofibration.

The argument can be expressed in any category with the pushouts in question. Let $a : S \to X$ and $b : S \to Y$ be W-cofibrations, and let $f : X \to Y$ satisfy $fa = b$ and $f \in W$. To change S into an arbitrary T, factor the change of base as

$$S \xrightarrow{k} T_0 \xrightarrow{q} T, \qquad k \in \mathrm{Cof}_W, \quad q \in W.$$

Set $X_0 = X \amalg_S T_0$, $Y_0 = Y \amalg_S T_0$, and set $X_T = X \amalg_S T$, $Y_T = Y \amalg_S T$. The map $f_0 : X_0 \to Y_0$ is in W because k is a W-cofibration and it pushes out the map f in $S\backslash\mathcal{M}$. On the other hand, $T_0 \to X_0$ and $T_0 \to Y_0$ are pushouts of a and b, so they are W-cofibrations. Pushing out q along them gives weak equivalences

$$u : X_0 \longrightarrow X_T, \qquad v : Y_0 \longrightarrow Y_T.$$

The equality $f_T u = v f_0$ now proves $f_T \in W$ by two-out-of-three. These are three separate applications of the cofibration condition, each with its own fixed base. They account for every marked W in the displayed proof.

There is a useful immediate consequence. If $a : S \to X$ is both a W-cofibration and a weak equivalence, apply the proposition to the two objects $1_S : S \to S$ and $a : S \to X$ of $S\backslash\mathcal{M}$. Every

pushout of a belongs to W. Thus, once these factorizations exist, a trivial W-cofibration is exactly a couniversal weak equivalence. This is the abstract version of the special Dwyer fact used to construct the cylinder. The order of proof is sound: the special Dwyer statement constructs enough cofibrations first, and Proposition 16 then gives the general statement.

The dual formulation on p. 232 is obtained by taking opposite categories throughout. A weak equivalence between two W-fibrations over S survives every pullback along $T \to S$. The symmetry is a symmetry of the relative arguments. It does not assert that every object of a slice or coslice is already suitable for calculating a derived change of base.

Il me vient ici une (petite) inquiétude : ai-je au moins prouvé que si

$$S \longrightarrow X$$

est une W-cofibration, alors pour toute flèche $S' \longrightarrow S$ dans Cat, le carré cocartésien dans Cat

$$\begin{array}{ccc} S & \longrightarrow & X \\ \downarrow & & \downarrow \\ S' & \longrightarrow & X' \end{array}$$

est aussi W-cocartésien ([126])? Autrement, à quoi ce carré-là serait-il bon?! Pour le prouver, factorisons encore $S \longrightarrow S'$ en

ms. page 233

$$\underset{\substack{\text{immersion}\\ \text{ouverte de}\\ \text{Dwyer}}}{S \hookrightarrow} \; S'_0 \underset{\in W}{\longrightarrow} S',$$

d'où le diagramme de 2 carrés cocartésiens

$$\begin{array}{ccc} S & \xrightarrow{\mathrm{Cof}_W} & X \\ {\scriptstyle D_W}\downarrow & & \downarrow{\scriptstyle D_W} \\ S'_0 & \xrightarrow{\mathrm{Cof}_W} & X'_0 \\ {\scriptstyle \in W}\downarrow & & \downarrow{\scriptstyle \in W} \\ S' & \xrightarrow{\mathrm{Cof}_W} & X', \end{array}$$

ed. 149 où $X'_0 \longrightarrow X'$ est $\in W$ d'après l'hypothèse sur X sous S. Il faut donc vérifier :

a) Un carré cocartésien construit sur une flèche qui est `[une]` immersion de Dwyer, est W-cocartésien.

b) Un carré commutatif dans lequel deux côtés opposés sont dans W, est W-cocartésien.

c) Le composé de deux carrés W-cocartésiens est W-cocartésien.

Commentary · Exposition [ms. 232]

Why Proposition 16 is a formal gluing lemma

Grothendieck needs weak equivalences between objects under S to survive an arbitrary change of the attaching object. The hypothesis that both objects are W-cofibrant under S is exactly what controls the two comparisons introduced by a factorization of that change. It cannot be replaced by a statement about the underlying objects alone.

Assume an ambient category has pushouts, a weakly saturated class W, and a class of W-cofibrations stable under pushout, with the property that pushout along such a map preserves W-equivalences. Suppose every map factors as a W-cofibration followed by a member of W. Let

126. dans le sens ancien, spécial à Cat (déf. 3, p. 131). Pour le comparer avec la théorie générale, cf. prop. 20, p. 262.

$S \to X$ and $S \to Y$ be W-cofibrations, and let $f : X \to Y$ be a W-equivalence under S. Factor the chosen $S \to S'$ as

$$S \xrightarrow{i} S'_0 \xrightarrow{j} S', \qquad i \in \mathrm{Cof}_W, \quad j \in W.$$

Put $X'_0 = X \amalg_S S'_0$ and $Y'_0 = Y \amalg_S S'_0$. The map $X \to X'_0$ is a pushout of i, hence a W-cofibration. Pushing out f along this map gives $f'_0 : X'_0 \to Y'_0$ in W; its target is $Y \amalg_X X'_0 \cong Y \amalg_S S'_0$. The maps $S'_0 \to X'_0$ and $S'_0 \to Y'_0$ are pushouts of the two original cofibrations. Pushing out j along them gives weak equivalences $v_X : X'_0 \to X'$ and $v_Y : Y'_0 \to Y'$. In the square

$$f' v_X = v_Y f'_0,$$

the right-hand composite belongs to W, and v_X belongs to W. Two-out-of-three proves $f' \in W$.

This is the whole argument. It uses neither a lifting axiom nor the conservative converses of footnote 124. It also identifies the dual hypotheses precisely: pullbacks, fibrations whose pullback functors preserve weak equivalences, stability under pullback, and a factorization as a weak equivalence followed by a fibration. Under those hypotheses a weak equivalence between fibrations over the same base is universally a weak equivalence over that base. Thus the parallel with the preceding fibre theory is mathematical, not just terminological.

The small slips in the final prose are harmless once the diagram is read: the comparison is $Y'_0 \to Y'$, not $Y'_0 \to Y$, and the subsequent cobase-change arrow is $S \to S'$, not $S' \to S$. Both are printed slips and remain in the source text. They are not gaps in Proposition 16.

Commentary · Exposition [ms. 233]

Comparing the two meanings of homotopy pushout

Grothendieck now asks whether the replacement method agrees with the earlier construction special to small categories. The earlier definition starts with a span $X_1 \leftarrow X_0 \to X_2$, integrates that diagram into a category $\mathcal{X}$, and calls a cocone to Y homotopy cocartesian when its comparison $\mathcal{X} \to Y$ belongs to W. The new method starts with an ordinary pushout and asks whether a W-cofibration makes that pushout homotopically correct. The two descriptions have different starting data; their agreement is the content of the corollary on p. 239, and later of Proposition 20.

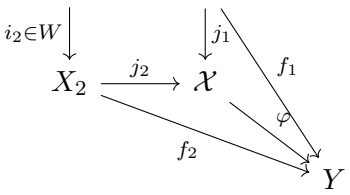
The proof has three stages, and keeping their dependence visible avoids a misleading impression of circularity. A pushout along a Dwyer inclusion is first reduced to a pushout whose two incoming maps are Dwyer inclusions, followed by a square with two opposite sides in W. In the first square, both categories embed as open subcategories of their union, so the earlier open-cover calculation applies. In the second, the definition of W-cofibration supplies the second weak equivalence. The only remaining operation is composition of homotopy-cocartesian squares.

That composition rule is then proved independently, by replacing the comparison maps with inclusions between categories of elements. Its proof uses restrictions of a single diagram over a six-object poset and a union of closed subcategories. It therefore does not presuppose that all Dwyer pushouts have already been identified as homotopy pushouts. Finally, an arbitrary W-cofibration is handled by factoring the other incoming map through a Dwyer inclusion and a weak equivalence. The two resulting squares fall under the established cases.

The assertion about two opposite weak equivalences has an especially short explanation. In the source's notation, if $i_2 : X_0 \to X_2$ is in W, the other leg $j_1 : X_1 \to \mathcal{X}$ of the integrated span is in W. The cocone satisfies $\varphi j_1 = f_1$. If f_1 also belongs to W, two-out-of-three gives $\varphi \in W$. This argument concerns the actual coherent square, including its commutativity. It will reappear in the general formalism as the rule that a homotopy pushout of an equivalence is an equivalence.

Admettons provisoirement b) et c), et prouvons a), pour un carré cocartésien

$$\begin{array}{ccc} U & \xhookrightarrow{\ i\ } & X \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ U' & \xhookrightarrow{\ i'\ } & X', \end{array}$$



où i est immersion ouverte de Dwyer. On procède encore comme tantôt, en factorisant p en $U \xhookrightarrow{j} U'_0 \xrightarrow{p'} U'$, où j est [une] immersion ouverte de Dwyer, $p' \in W$. On a donc un ms. page 234

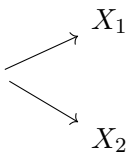


diagramme de deux carrés cocartésiens accolés

$$\begin{array}{ccc} U & \xrightarrow{i\in D_W} & X \\ {\scriptstyle D_W}\downarrow & & \downarrow \\ U'_0 & \xrightarrow{D_W} & X'_0 \\ {\scriptstyle p'\in W}\downarrow & & \downarrow{\scriptstyle q'\in W} \\ U' & \longrightarrow & X', \end{array}$$

où le premier carré est formé d'immersions ouverts. On sait alors qu'il est W-cocartésien. Dans le deuxième, on a $p' \in W$, donc $q' \in W$ puisque i est une immersion de Dwyer, donc une W-cofibration. Donc il est également W-cocartésien. On conclut alors grâce à c) ci-dessus.

Prouvons b), pour $\begin{array}{ccc} X_0 & \xrightarrow{i_1} & X_1, \\ {\scriptstyle i_2\in W}\downarrow & & \downarrow{\scriptstyle f_1\in W} \\ X_2 & \xrightarrow{f_2} & Y \end{array}$ en l'insérant dans $\begin{array}{ccc} X_0 & \xrightarrow{i_1} & X_1, \\ {\scriptstyle i_2\in W}\downarrow & & \downarrow{\scriptstyle j_1} \\ X_2 & \xrightarrow{j_2} & \mathcal{X} \end{array}$ où

$\mathcal{X} = \int X_0$  .

Comme $i_2 \in W$, on sait qu'il en résulte $j_1 \in W$, et comme $f_1 \in W$, il en résulte que $\varphi \in W$, q.e.d.

Commentary · Exposition [ms. 234]

Completing the pasting step

At the end of manuscript page 234, the proof that a pushout along a W-cofibration is W-cocartesian still invokes the composition of homotopy pushout squares. This is the deferred item c), not a defect in item b), whose proof has just been given. The composition statement is a standard consequence of coherent homotopy colimits; in derivator language it is the composition part of Groth (2013, Proposition 3.13, published version). We spell out the argument to make clear which compatibility is required.

Consider a coherent commutative diagram

$$\begin{array}{ccc} A & \longrightarrow & B \\ \downarrow & & \downarrow \\ C & \longrightarrow & D \\ \downarrow & & \downarrow \\ E & \longrightarrow & F. \end{array}$$

Suppose each small square is a homotopy pushout. Its two universal properties give

$$D \simeq B \amalg^h_A C, \qquad F \simeq D \amalg^h_C E.$$

For any test object T, write $M_U = \mathrm{Map}(U, T)$. These mapping spaces are derived mapping spaces, so that homotopy colimits become homotopy limits. Then

$$\begin{aligned} \mathrm{Map}(F, T) &\simeq (M_B \times^h_{M_A} M_C) \times^h_{M_C} M_E \\ &\simeq M_B \times^h_{M_A} M_E. \end{aligned}$$

The second equivalence is the associative law for homotopy pullbacks: both sides are limits of the same diagram after eliminating the repeated M_C. The natural equivalences identify the maps to M_B

and M_E and their common homotopy over M_A. The mapping-space universal property therefore identifies F with $B \amalg^h_A E$, including its cocone. This proves that the outside rectangle is a homotopy pushout.

For Grothendieck's W-cocartesian comparison, we give the categorical calculation explicitly. Suppose W is a fundamental localizer. First, integrating an objectwise W-equivalence $\theta : H \to H'$ of covariant diagrams on J gives a W-equivalence. Indeed, the over-category $(\int_J H)/j$ of the projection to J has an evaluation functor

$$(i, x, \alpha : i \to j) \longmapsto H(\alpha)x.$$

It is left adjoint to $y \mapsto (j, y, \mathrm{id}_j)$, with identity counit. Its nerve is therefore a homotopy equivalence. The analogous evaluation for H' commutes with θ; two-out-of-three shows that the induced maps of over-categories belong to W. The relative Theorem A gives $\int \theta \in W$. Here and below an ordinary weak equivalence belongs to W by Cisinski (2004, Theorem 2.2.11).

Write $H_1 = \int(B \leftarrow A \to C)$ and $H_2 = \int(D \leftarrow C \to E)$. The two small squares being W-cocartesian means that their canonical maps $H_1 \to D$ and $H_2 \to F$ lie in W. Objectwise invariance now shows that

$$H_{12} = \int (H_1 \leftarrow C \to E) \longrightarrow H_2 \longrightarrow F$$

belongs to W. To compare this iterated integral with the outside span, introduce the five-object poset K whose only nonidentity arrows are

$$a \to b, \quad a \to c_1, \quad c_0 \to c_1, \quad c_0 \to e.$$

Assign A, B, C, C, E to a, b, c_1, c_0, e, with the identity on the arrow between the two copies of C. Flattening the two Grothendieck constructions identifies its integral with H_{12}: the outer copy of C is c_0, and the copy inside H_1 is c_1.

Let K' have objects a, b, c, e and arrows generated by $a \to b$ and $a \to c \to e$. The functor $r : K \to K'$ identifies c_0, c_1 with c. Let $G : K' \to \mathrm{Cat}$ be the original diagram $A \to B$, $A \to C \to E$. Thus the flattened diagram is r^*G. Let $L \subset K'$ be the full subcategory on a, b, e; its integral is the outside-span integral $H_0 = \int(B \leftarrow A \to E)$.

Both r and $L \hookrightarrow K'$ are homotopy final. This can be checked without an abstract pasting theorem. For r, the comma category a/r is the tree-shaped poset K; c/r is the cospan $c_1 \leftarrow c_0 \to e$; and $b/r, e/r$ are singletons. All have contractible nerves. For the inclusion of L, the comma categories at a, b, c, e are respectively a span with initial object a, a singleton, the singleton e, and a singleton. Homotopy cofinality for homotopy colimits, together with the nerve comparison for integration (Thomason, 1979, Theorem 1.2), therefore gives ordinary weak equivalences

$$H_{12} \longrightarrow \int_{K'} G \longleftarrow H_0.$$

All these functors respect the cocone to F. Since $H_{12} \to F$ lies in W, two-out-of-three first gives $\int_{K'} G \to F$ in W and then $H_0 \to F$ in W. This proves the required pasting statement for every fundamental localizer. It supplies the comparison and its compatibility with the cocone, rather than merely an equality of unstructured homotopy types.

Item b) has an equally transparent interpretation. If $A \to C$ is a weak equivalence, then $B \to B \amalg^h_A C$ is a weak equivalence. If also $B \to D$ is a weak equivalence, the comparison from that homotopy pushout to D is one by two-out-of-three. The final integral diagram in the source is a categorical model for exactly this proof. For a general W, use the objectwise invariance of integration just proved instead of appealing to ordinary spaces.

These two facts complete the reduction. Factor the cobase-change map through a Dwyer inclusion followed by a weak equivalence. The first pushout is W-cocartesian by the Dwyer gluing theorem, and the second has the two opposite weak equivalences supplied by the W-cofibration hypothesis. Item b) handles the second square; pasting handles their composite. This proof establishes the intended statement without adding a converse detection axiom for individual edges.

The Dwyer condition ultimately controls more than the weak homotopy type of the nerve. Hackney et al. (2024, Theorems 1.5 and 1.6; arXiv version 3) prove that pushouts along Dwyer maps are preserved when ordinary categories are viewed as $(\infty, 1)$-categories. Equivalently, the comparison from the pushout of nerves to the nerve of the ordinary pushout is a categorical equivalence, a stronger assertion than Thomason's weak homotopy equivalence. Their formulation also covers suitable generalized Dwyer maps.

This later theorem concerns the fidelity of the gluing construction. It supplies no converse of the kind excluded by the acyclic example above. It is compatible with Grothendieck's strategy of finding strict representatives on which homotopy operations become ordinary operations, while explaining why the coherence of the original diagram must be retained. In the pointed derivator formulation, a cofiber is correspondingly functorial on the category of coherent arrows, rather than determined by an arrow in the ordinary homotopy category alone (Groth, 2013, Definition 3.18).

Overview · XIIc-a

These pages begin by asking what the categorical loop constructions actually detect, and end by constructing their dual, a categorical mapping cylinder (Grothendieck, 1990–1991h, manuscript pp. 171–234). Between these two constructions Grothendieck makes a decisive change of viewpoint. A path category is first a concrete device for computing homotopy groups. It then becomes one possible presentation of an intrinsically defined operation on localized categories. The problem is to retain enough of the family of relative homotopy types that changing the presentation does not change the operation or its compatibility with a further change of base.

The first section tests this programme against a classical comparison between cohomology and homotopy. For a small category X, write $BX = |NX|$. Constant coefficients detect connected components, while locally constant coefficients detect transport around the fundamental groupoid. Grothendieck's several formulations of W_0 and W_1 are therefore exact descriptions of the information that a zero-type and a one-type retain. The nonabelian degree-one condition matters: an abelian cohomology test alone can leave a perfect fundamental group undetected. Our commentary spells out the small group-theoretic argument showing why surjectivity on constant nonabelian H^1, together with the local-system H^0 test, already determines the fundamental groupoid.

The attempted extension to higher degrees is more delicate. With his notation, a_n means that every homotopy fibre is n-connected; b_n means that the map induces isomorphisms on homotopy groups through degree n, including components; and c_n means that it induces the corresponding cohomology isomorphisms through degree n for all permitted locally constant coefficients. The range of i is missing from the printed statement of c_n, but is fixed by the proof. The corrected theorem establishes

$$a_n \implies b_n \implies c_n \implies a_{n-1}.$$

The homotopy exact sequence explains the first loss of one degree. The next implication uses the cohomological spectral sequence of the homotopy fibre, with its monodromy retained. The last implication tests the first possible nonzero fibre group against itself as a coefficient module. These arguments are sound once the stated verifications concerning twisted coefficients and the degree-one fibre group are supplied.

The withdrawn equivalence $b_n \Leftrightarrow c_n$ really does fail, but the footnote's suggested degree-two failure does not occur. The inclusion $S^2 \to \mathbf{CP}^\infty = K(\mathbf{Z}, 2)$ is a cohomology isomorphism through degree three with every abelian coefficient group and has trivial fundamental-group data; it kills $\pi_3(S^2)$. In degree two, by contrast, after identifying the fundamental groups, the coinduced local system

$$\mathrm{Hom}_{\mathbf{Z}}(\mathbf{Z}[\pi], \mathbf{Q}/\mathbf{Z})$$

dually detects the second homology of the universal cover. The natural Hurewicz isomorphism then detects π_2. The commentary gives the complete argument and distinguishes it from a claim of historical priority. It also completes the universal-cover spectral-sequence approach that Grothendieck leaves aside: a finite-range truncation argument for derived invariants supplies the needed comparison without assuming an isomorphism in the next degree.

There is a second correction at the end of the section. The class a_n is not a localizer, because it fails two-out-of-three. For a nonzero abelian group A, the composite

$$* \longrightarrow K(A, n+1) \longrightarrow *$$

is the identity, and the second map has n-connected fibre, whereas the first does not. The class b_n, the equivalences detected by Postnikov n-truncation, supplies the intended weak equivalences. There is nevertheless a precise sense in which a_n suffices: its saturation generates

the same localization. The two conditions already agree for maps to a point, so this correction leaves Theorem 2 intact. That theorem recognizes weak contractibility by connectedness of all iterated loop categories. At the degree-two endpoint its reverse induction needs the abelianness of $\pi_1\Omega X$; we supply the Eckmann–Hilton verification. The modern identification of the minimal fundamental localizer with W_∞ and the later loop-based characterization are established by Cisinski (2004, Theorems 2.2.11 and 2.3.6).

The question on p. 191 is consequently no longer whether the path objects work, but in what sense their answers are canonical. Fix a base S. A replacement consists of an endofunctor C of Cat/S, a natural map $i : 1 \to C$ whose components belong to W, and the requirement that $C(X)$ be W-fibred over S. Two replacements compare through their composite. The compatibility of this comparison with the units is exactly naturality, and two-out-of-three shows that the comparison maps are weak equivalences. These elementary observations already contain the solution to the coherence problem posed a few pages later.

Indeed, fixing one replacement C_0, composition gives natural transformations from the identity functor on the category of replacements to $C \mapsto CC_0$, and from the constant functor at C_0 to the same functor. Passing to nerves contracts the identity to a constant map. Thus this category is contractible whenever it is nonempty, and its fundamental groupoid is equivalent to the terminal groupoid. The manuscript's assertion of filteredness is not justified by its common-target construction: equalizing parallel arrows is a separate requirement. Contractibility provides exactly the comparison that is needed without that assertion. The localization argument on pp. 204–207 gives a second formulation: the inclusion of suitable fibred representatives induces an equivalence of localized categories, and the unit of replacement supplies the specified comparison to its quasi-inverse.

This concern with operations independent of their computation is continuous with the programme of Grothendieck (1983, §69, printed pp. 1–3). There the derived categories of diagrams, together with their change-of-index functors and adjoints, replace the information lost on keeping only one derived category. The letter to Thomason makes the distinction between the relative category $(\mathcal{M}, W)$ and supplementary choices of fibrations and cofibrations explicit (Grothendieck, 1991a, points 1–2). The present pages examine that distinction in a concrete and demanding case. An ordinary functor $\Pi S \to \mathrm{Hot}$ records the homotopy types of fibres and their first transport, but it does not by itself retain all higher coherence of a locally constant family. The later theories of derived diagrams and homotopy Kan extensions preserve the additional structure rather than identifying these two levels of information.

The fourth section asks how much of this picture can be stated for a category with pullbacks and weak equivalences. Its intrinsic W-fibrations are maps whose pullback functors preserve weak equivalences. These are the maps later called sharp in a model-category setting; they should not be identified indiscriminately with an independently chosen class of Quillen fibrations. Grothendieck compares the localization of the entire slice at underlying weak equivalences with the localization of the subcategory of such fibrations at universally preserved weak equivalences. The fibre axiom says that these localizations agree. The adjoining axiom says that the two weak-equivalence classes already agree on fibrant representatives, before localization.

Some care with the hypotheses is essential here. The stated two-out-of-three assumption does not imply closure under retracts. Our finite-set example shows that the corresponding claimed retract closure of intrinsic fibrations also fails at precisely that level of generality; imposing retract closure on W repairs it. On the other hand, a functorial fibrant replacement with a weak-equivalence unit gives the desired localization comparison for every full intermediate subcategory containing its image. This proves the intermediate-subcategory assertion in the situations for which the manuscript actually has a replacement construction. The bare logical implication from the two fibre axioms to that assertion is not settled here; this restricted conclusion is recorded as such, not presented as a newly identified open problem.

The subsequent manuscript discussion at pp. 240–241 adds a factorization hypothesis and its own caution about fibrancy over a terminal object.

Non-locally-constant relative types require more structure than the preceding slice localization. Grothendieck introduces a pullback-stable class $\mathcal{L}$ of allowed tests and defines $W_S^{\mathcal{L}}$ by preservation under these tests. In Cat the two comma-category variances give W_S^{g} and W_S^{d}. Smooth and proper functors provide complementary ways of changing the base and choosing representatives. Our commentary proves the formal universal-saturation construction and identifies the saturation asked about on p. 222 with W-smooth functors. The key is to test a W-aspherical map as an arrow to the terminal object of its slice and use the universal pullback characterization in Maltsiniotis (2005, Theorem 1.2(c)). A calculation with a degree-two self-map of a circle then shows why a genuinely varying diagram and a locally constant family are different objects. The abstract existence of both adjoints to restriction requires further hypotheses; in the combinatorial model-category setting the resulting strong derivator is established by Groth (2013, Proposition 1.30).

Finally the interval Φ_n, with $n \geq 2$, gives a Dwyer inclusion of its two endpoints. Multiplying by X produces a cylinder, and attaching its first endpoint to Y along $f : X \to Y$ gives a factorization of f into a Dwyer inclusion and a weak equivalence. The commentary identifies the required adjoints explicitly, explains why the shorter interval fails for the two-endpoint inclusion, and verifies the induced pushout and comparison maps. Proposition 16 then follows by factoring a change of cobase and applying preservation of weak equivalences along cofibrations. The final pasting step is completed with its hypotheses stated; its later derivator formulation is Groth (2013, Proposition 3.13).

The two biconditionals in footnote 124 need a different reading. They use the manuscript's stronger conservative pushout axioms, whose converse implications are not properties of ordinary weak homotopy equivalences. A finite acyclic, noncontractible complex and the two cones in its suspension give a counterexample by face posets, even with Dwyer inclusions. This does not invalidate the mapping-cylinder construction or Proposition 16: their proofs use forward preservation, which is the part available for W_∞. Keeping that distinction visible lets the successful construction retain its force while preventing an extra axiom from silently becoming a claim about classical homotopy theory.

Reste à prouver c). Je vais le déduire d'une p. 150

Proposition 17. *Soit un carré commutatif*

$$Q \quad = \quad \begin{array}{ccc} X_0 & \xrightarrow{i_1} & X_1 \\ {\scriptstyle i_2}\downarrow & & \downarrow{\scriptstyle f_1} \\ X_2 & \xrightarrow{f_2} & Y \end{array}$$

dans Cat*, et $\mathscr{X}_Q$ la catégorie fibrée sur*

$$\tilde{\Phi} \quad (\simeq \mathbf{\Delta}^1 \times \mathbf{\Delta}^1) \quad = \quad \begin{array}{ccc} 0 & \longleftarrow & 1 \\ \uparrow & & \uparrow \\ 2 & \longleftarrow & 3 \end{array}$$

qui l'intègre. Soit $\mathscr{X}$ l'image inverse du fermé

$$\begin{array}{ccc} 0 & \longleftarrow & 1 \\ \uparrow & & \\ 2 & & \end{array}$$

dans $\mathscr{X}_Q$, qui intègre le diagramme [page 235]

$$\begin{array}{ccc} & & X_1 \\ & \nearrow & \\ X_0 & & \\ & \searrow & \\ & & X_2 \end{array}$$

. Pour que Q soit W-cocartésien, il faut et il suffit que l'inclusion

$$i : \mathscr{X} \longrightarrow \mathscr{X}_Q$$

soit dans W.

Comme $\mathscr{X}_Q$ est lisse sur $\tilde{\Phi}$, et 3 est objet initial de $\tilde{\Phi}$, il s'ensuit que l'inclusion de la fibre de $\mathscr{X}_Q$ en le sommet 3 de $\tilde{\Phi}$ est dans W,

$$Y \xrightarrow{i_Y} \mathscr{X}_Q \qquad\qquad \in W.$$

Considérons alors le diagramme

$$\begin{array}{ccc} \mathscr{X} & \xrightarrow{\varphi_Q} & Y \\ & {\scriptstyle i}\searrow \quad \swarrow{\scriptstyle i_Y \in W} & \\ & \mathscr{X}_Q. & \end{array} \qquad \alpha$$

Ce diagramme n'est pas commutatif, mais il y a une flèche de commutativité p. 151

$$\alpha : i_Y \varphi_Q \longrightarrow i.$$

Commentary · Exposition [ms. 235]

The integral criterion with its natural transformation

Proposition 17 turns the comparison with a homotopy pushout into a test on one inclusion. This is what makes the pasting proof manageable: several comparison maps can then be placed in the same category and related by literal inclusions. The natural transformation in the triangle is essential to that change of viewpoint.

Here is an explicit model, fixing the variance. Regard the square as a contravariant diagram $F : \widetilde{\Phi}^{\mathrm{op}} \to \mathrm{Cat}$, with $F(0) = X_0$, $F(1) = X_1$, $F(2) = X_2$, and $F(3) = Y$. The fibred Grothendieck construction $E = \int F$ has objects (b, x) for $x \in F(b)$. A morphism $(b, x) \to (c, y)$ consists of an arrow $u : b \to c$ in the base together with an arrow $x \to F(u)(y)$ in $F(b)$. Composition uses the contravariance of F.

The vertex 3 is initial in $\widetilde{\Phi}$. Its unique arrows $3 \to b$ therefore define a functor

$$r : E \longrightarrow Y, \qquad r(b, x) = F(3 \to b)(x).$$

For $y \in Y$ there is a natural bijection

$$\mathrm{Hom}_E\big((3, y), (b, x)\big) = \mathrm{Hom}_Y\big(y, r(b, x)\big).$$

Thus the fibre inclusion $i_Y : Y \to E$ is left adjoint to r, with $r i_Y = 1_Y$. The counit $i_Y r \Rightarrow 1_E$ is the arrow over $3 \to b$ represented by the identity of $F(3 \to b)x$. This displays the homotopy equivalence of Y with E directly.

Now restrict to $\mathcal{X} = E|_{\{0,1,2\}}$. The restricted functor $r|_{\mathcal{X}}$ is exactly the source's comparison $\varphi_Q : \mathcal{X} \to Y$. Restricting the counit gives

$$\alpha : i_Y \varphi_Q \Longrightarrow i, \qquad i : \mathcal{X} \hookrightarrow E.$$

This is an arrow between functors with source $\mathcal{X}$ and target E. In the edition it is drawn inside the triangle. The transcription had instead attached it to the vertices Y and $\mathcal{X}$; the correction register restores the interior arrow.

To finish the criterion, a natural transformation $g \Rightarrow h$ determines a functor $\mathcal{X} \times [1] \to E$. The projection $\mathcal{X} \times [1] \to \mathcal{X}$ and its two sections belong to the localizer. Consequently g belongs to W exactly when h does. Applying this to α, and then using $i_Y \in W$, gives

$$i \in W \iff i_Y \varphi_Q \in W \iff \varphi_Q \in W.$$

The triangle need not commute strictly. Its specified transformation is precisely enough because the localizer already identifies naturally homotopic functors.

On sait que ceci implique que

$$i \in W \qquad \Longleftrightarrow \qquad (i_Y \varphi_Q) \in W$$

(cf. lemme p. 2), et comme $i_Y \in W$,

$$(i_Y \varphi_Q) \in W \qquad \Longleftrightarrow \qquad \varphi_Q \in W,$$

d'où

$$i \in W \qquad \Longleftrightarrow \qquad \varphi_Q \in W,$$

q.e.d.

Nous pouvons maintenant prouver

Proposition 18 ([127]). (Moyennant W(7 bis).) *Considérons un diagramme commutatif* [page 236]

$$(*) \qquad \begin{array}{ccccc} X_0 & \longrightarrow & X_1 & \longrightarrow & X_2 \\ \downarrow & 1 & \downarrow & 2 & \downarrow \\ X'_0 & \longrightarrow & X'_1 & \longrightarrow & X'_2 \end{array}$$

127. devrait être vrai dans toute catégorie de modèles ayant assez de cofibrations.

d'où un carré composé

$$\begin{array}{ccc} X_0 & \longrightarrow & X_2 \\ \downarrow & 3 & \downarrow \\ X'_0 & \longrightarrow & X'_2. \end{array}$$

Supposons que le carré 1 *soit W-cocartésien. Alors le carré* 2 *est W-cocartésien si et seulement si le carré* 3 *l'est.*

Démonstration.

`[Maintenant,` X_i `et` X'_i `échangent leurs rôles.]`

Soit p. 152

$$I \quad = \quad \begin{pmatrix} 0 & \longleftarrow & 1 & \longleftarrow & 2 \\ \downarrow & & \downarrow & & \downarrow \\ 0' & \longleftarrow & 1' & \longleftarrow & 2' \end{pmatrix}$$

et soit $\mathscr{X}$ l'intégrale du diagramme $(*)$, catégorie fibrée sur $\mathscr{X}$. On désigne par $\mathscr{X}_{010'}$ la sous-catégorie pleine de $\mathscr{X}$ image inverse de la sous-catégorie pleine

$$\underbrace{I_{010'}}_{=\{0,1,0'\}} \quad \subseteq I,$$

et de même pour toute autre partie A de $\operatorname{Ob} I = \{0, 1, 2, 0', 1', 2'\}$, donnant une sous-catégorie pleine $\mathscr{X}_A$ de $\mathscr{X}$. On pose

$$U \quad = \quad \begin{array}{ccccc} 0 & \longleftarrow & 1 & \longleftarrow & 2 \\ \downarrow & & & & \\ 0' & & & & \end{array} \quad , \qquad V \quad = \quad \begin{array}{ccccc} 0 & \longleftarrow & 1 & \longleftarrow & 2 \\ \downarrow & & \downarrow & & \\ 0' & \longleftarrow & 1' & & \end{array} \quad ,$$

d'où

$$\mathscr{X}_U = \mathscr{X}_{0120'}, \qquad \mathscr{X}_V = \mathscr{X}_{0120'1'}.$$

Les flèches entre les $\mathscr{X}_A$ sont les inclusions

déduites d'inclusions $A \hookrightarrow A'$ dans $\mathfrak{P}(\operatorname{Ob} I)$. Ainsi, le caractère W-cocartésien des carrés 1, 2, 3 s'exprime respectivement par la condition que les inclusions [page 237]

$$\begin{array}{ccc} \mathscr{X}_{010'} & \xrightarrow{\varphi_1} & \mathscr{X}_{010'1'} \\ \mathscr{X}_{121'} & \xrightarrow{\varphi_2} & \mathscr{X}_{121'2'} \\ \mathscr{X}_{020'} & \xrightarrow{\varphi_1} & \mathscr{X}_{020'2'} \end{array}$$

soient dans W. Considérons alors le diagramme de flèches d'inclusion p. 153

$$\begin{array}{ccc} \mathscr{X}_{020'} & \xrightarrow{\varphi_3} & \mathscr{X}_{020'2'} \\ {\scriptstyle\alpha}\downarrow & & \downarrow{\scriptstyle\beta} \\ \mathscr{X}_U & \xrightarrow{\psi_3} & \mathscr{X} \\ {\scriptstyle\psi_1}\downarrow & & \downarrow{\scriptstyle\mathrm{id}} \\ \mathscr{X}_V & \xrightarrow{\psi_2} & \mathscr{X} \\ {\scriptstyle\alpha'}\uparrow & & \uparrow{\scriptstyle\beta'} \\ \mathscr{X}_{121'} & \xrightarrow{\varphi_2} & \mathscr{X}_{121'2'}. \end{array}$$

Je dis que dans ce diagramme on a

$$(*) \qquad \alpha, \beta, \alpha', \beta' \in W$$

et

$$(**) \qquad \varphi_1 \in W \ \text{ (i.e. carré 1 } W\text{-cocartésien)} \qquad \Longleftrightarrow \qquad \psi_1 \in W.$$

Les relations $(*)$ impliquent déja que

$$\begin{aligned} \varphi_2 \in W \quad &\Longleftrightarrow \quad \psi_2 \in W \\ \varphi_3 \in W \quad &\Longleftrightarrow \quad \psi_3 \in W, \end{aligned}$$

et sous l'hypothèse W-cocartésienne $(**)$, impliquant $\psi_1 \in W$,
on trouve [page 238]

$$\psi_2 \in W \qquad \Longleftrightarrow \qquad \psi_3 \in W,$$

d'où

$$\varphi_2 \in W \qquad \Longleftrightarrow \qquad \varphi_3 \in W,$$

ce qu'il fallait prouver.

Il reste à établir $(*)$ et $(**)$. Les relations $(*)$ proviennent de la remarque que si $i : A \longrightarrow A'$ est une inclusion de sous-catégories pleines de I, telle que i soit W-*asphérique* (i.e. A/j W-asphérique pour $j \in \mathrm{Ob}\, A' \backslash \mathrm{Ob}\, A$), alors $\mathscr{X}_A \longrightarrow \mathscr{X}_{A'}$ l'est aussi (changement de base lisse), donc est `[dans]` W. On doit vérifier la W-asphéricité pour les quatre inclusions

$$\begin{aligned} \{0,2,0'\} &\longrightarrow U = \{0,1,2,0'\} && \mathbf{\Delta}^0 \\ \{0,2,0',2'\} &\longrightarrow I && \mathbf{\Delta}^0/\mathbf{\Delta}^1 \\ \{1,2,1'\} &\longrightarrow V = \{0,1,2,0',1'\} && \mathbf{\Delta}^1,\ \Phi \\ \{1,2,1',2'\} &\longrightarrow I && \mathbf{\Delta}^1,\ \mathbf{\Delta}^1 \times \mathbf{\Delta}^1. \end{aligned}$$

Commentary · Examples [ms. 238]

The seven slices behind the pasting theorem

The six-object poset is the bookkeeping device that puts the left square, right square and outer rectangle in one ambient diagram. Grothendieck reduces the substantial part of pasting to seven very small slice categories. Computing them explicitly both explains the proof and corrects one harmless shape label in its margin.

Use the arrows of I exactly as printed: the top row is $2 \to 1 \to 0$, the bottom row is $2' \to 1' \to 0'$, and the vertical arrows are $k \to k'$. A slice A/j has as objects the elements of A admitting an arrow to j. Since I is a poset, its morphisms are just the induced order. For the inclusions underlying $\alpha, \beta, \alpha', \beta'$ we obtain

inclusion	j	A/j
α	1	$\{2\}$
β	1	$\{2\}$
β	$1'$	$(2 \longrightarrow 2')$
α'	0	$(2 \longrightarrow 1)$
α'	$0'$	$(2 \longrightarrow 1 \longrightarrow 1')$
β'	0	$(2 \longrightarrow 1)$
β'	$0'$	$\{1,2,1',2'\} \cong [1] \times [1]$.

Each displayed category has initial object 2. For an object j already in A, the slice A/j has terminal object 1_j, so no separate check is necessary. In the fifth line the composite $2 \to 1'$ exists: the inclusion is full, and the defining rectangle is commutative. The slice is consequently $[2] = \Delta^2$. The edition prints Φ in this place. The asphericity argument uses the initial object and is unaffected by this label.

We can also make the passage from base slices to total-category slices explicit. Let $F : I^{\mathrm{op}} \to \mathrm{Cat}$ be the integrated diagram and let $e = (j, y)$ be an object of its total category. There is a projection

$$(\mathcal{X}_A)/e \longrightarrow A/j.$$

An object above $u : a \to j$ is an arrow $x \to F(u)y$ in $F(a)$. The choice $x = F(u)y$, with the identity arrow, defines a section. For an object z of the total slice, every arrow from its image in A/j to u has a unique lift from z to this chosen object over u. Hence the projection is left adjoint to the section. The two categories are homotopy equivalent. Asphericity of A/j therefore proves asphericity of $(\mathcal{X}_A)/e$; the localizer's Theorem A condition gives $\mathcal{X}_A \to \mathcal{X}_{A'} \in W$. This is the "smooth change of base" step in concrete form.

The last ingredient is gluing. The two subsets

$$U = \{0, 1, 2, 0'\}, \qquad U' = \{0, 1, 0', 1'\}$$

are cosieves in $V = \{0, 1, 2, 0', 1'\}$: following an arrow from either subset never leaves that subset. Their total categories are therefore closed subcategories covering $\mathcal{X}_V$, with intersection $\mathcal{X}_{010'}$. The forward part of the closed-cover axiom sends $\varphi_1 \in W$ to $\psi_1 \in W$. As $\psi_3 = \psi_2\psi_1$, two-out-of-three then says that $\psi_2 \in W$ exactly when $\psi_3 \in W$. The four slice equivalences transport this assertion back to φ_2 and φ_3.

The proof thus needs only the forward part of W(7 bis). The source writes the stronger equivalence $\varphi_1 \in W \iff \psi_1 \in W$, which its full hypothesis permits, but its reverse direction is not used. Cancellation of the right square against the outer rectangle is produced by a known weak equivalence ψ_1 and two-out-of-three. It should be kept separate from the stronger conservative gluing condition examined in the appendix.

p. 154

(NB J'ai marqué en marge les catégories qu'on obtient comme A/j, à isomorphisme près, dans les quatre cas envisagés - elles ont toutes un objet initial, donc sont W-asphériques.)

Reste à prouver (∗∗). Soit

$$U' = \{0, 1, 0', 1'\}, \qquad \text{donc } V = U \cup U', \quad U \cap U' = \{0, 1, 0'\},$$

où U, U' sont des *fermés* de V qui recouvrent V. Donc on aura de même

$$\mathscr{X}_V = \mathscr{X}_U \cup \mathscr{X}_{U'}, \qquad \mathscr{X}_U \cap \mathscr{X}_{U'} = \mathscr{X}_{010'},$$

[page 239]

$$\begin{array}{ccc} \mathscr{X}_{U\cap U'} & \longrightarrow & \mathscr{X}_U \\ \downarrow{\scriptstyle \varphi_1} & & \downarrow{\scriptstyle \psi_1} \\ \mathscr{X}_{U'} & \longrightarrow & \mathscr{X}_V. \end{array}$$

Donc par W(7 bis) (cas dual des immersions fermées), on a

$$\varphi_1 \in W \qquad \Longleftrightarrow \qquad \psi_1 \in W,$$

q.e.d.

Notons pour mémoire le corollaire qui nous avait motivé.

Corollaire. *Supposons* W(7 bis) (comme dans toute cette section). *Soit un carré cocartésien dans* Cat

$$\begin{array}{ccc} X_0 & \xrightarrow{i_1} & X_1 \\ {\scriptstyle i_2}\downarrow & & \downarrow \\ X_2 & \longrightarrow & X_3, \end{array}$$

avec i_1 (ou i_2) une W-cofibration (p.ex. une immersion de Dwyer). Alors ce carré est W-cocartésien.

Commentary · Later developments [ms. 239]

From categorical gluing to coherent cocartesian squares

The corollary finishes the comparison that motivated this detour. Factor the second leg of a strict pushout as a Dwyer map followed by a weak equivalence. The first resulting square is homotopy

cocartesian by the Dwyer case; the second is so because its opposite sides are weak equivalences, using the first leg's W-cofibration property. Proposition 18 identifies their composite as homotopy cocartesian. The categorical integral and the replacement construction therefore give the same answer on these pushouts.

In the modern derivator language, put $\square = [1] \times [1]$ and let $\ulcorner \subset \square$ omit $(1,1)$. A coherent square $Q \in \mathbb{D}(\square)$ is cocartesian when the counit

$$\iota_! \iota^* Q \longrightarrow Q, \qquad \iota : \ulcorner \hookrightarrow \square,$$

is an isomorphism. The composition and cancellation rule for such squares is Groth (2013, Proposition 3.13). It requires neither stability nor a zero object. This identifies the modern form of the assertion in footnote 127: the coherence belongs to an object of $\mathbb{D}([2] \times [1])$, and the left square controls equivalence of the two remaining cocartesianness tests.

For Dwyer maps the later result is stronger still. Hackney et al. (2024, Theorems 1.5–1.6, arXiv version 3) show that if $D = B \amalg_A C$ and $A \to B$ is Dwyer, then

$$NB \amalg_{NA} NC \longrightarrow ND$$

is a weak categorical equivalence in the Joyal model structure. Thus the ordinary pushout represents the pushout of the corresponding $(\infty, 1)$-categories, retaining categorical information before passage to the homotopy types of their classifying spaces. The hypotheses concern the attaching map, so the result applies directly to the finite cylinders above.

The source's final sentence on cofibres should be read at this finite level. It has exhibited functorial replacements, proved the relative invariance needed to compare them, and established the basic gluing calculus. Those constructions supply the material for the abstract homotopy-square theory in the next section. A claim that all homotopy Kan extensions exist for an arbitrary relative category would require further hypotheses; no such claim is established by this closing factorization alone.

Cette digression (p. 232 ff.) n'est pas nécessaire d'ailleurs pour formuler dès maintenant la conclusion de nos cogitations sur les cofibres W-homotopiques : *Il y a une telle théorie dans* Cat, pourvu seulement que W satisfasse à W(7 bis). En effet, tout résulte du fait que toute flèche $f : X \longrightarrow Y$ dans Cat se factorise en

$$X \xrightarrow{i_f} \tilde{Y} \xrightarrow{p_f} Y,$$

avec i_f une W-cofibration (et même une immersion ouverte de Dwyer), et $p_f \in W$.

p. 155
[page 240]

7 Retour sur l'axiomatique de la fibre W-homotopique.

Je reviens sur la réflexion du n° 4. Finalement, pour

$$(\mathcal{M}, W \subseteq \mathrm{Fl}(\mathcal{M}))$$

donnés avec W faiblement saturé, il apparaît qu'une excellente théorie des fibres W-homotopiques, satisfaisant aux conditions ⓐⓑⓒ du n° 4 (pages 215-218), existe dès que l'axiome d'apparence anodine suivant est satisfait (en plus de l'existence de l'objet final et des produits fibrés ([128])).

Factorisation gauche : ([129], [130]). Toute flèche $f : X \longrightarrow Y$ de $\mathcal{M}$ se factorise en

$$X \xrightarrow{i_f} \bar{X} \xrightarrow{p_f} Y,$$

128. et encore! il me semble qu'il suffit de supposer que les $X \longrightarrow Y$ qui sont W-fibrants sont 'quarrables'.

129. Sous ces conditions, $\mathcal{M}$ muni de (W, F_W) est une catégorie à cofibrations de K.S. Brown-Anderson, et 'tout est O.K.', mais il faudrait vérifier a) b) c) ci-dessus (p. 215, 218), je ne suis pas sûr de l'avoir fait.

130. **NB** L'axiome de factorisation gauche n'est suffisant pour l'existence d'une bonne théorie des fibres homotopiques (semble-t-il) que dans le cas où tout X dans $\mathcal{M}$ est W-fibrant, i.e. est dans $\underline{\mathrm{Fib}}_W e$.

avec

$$i_f \in W, \qquad p_f \in \mathrm{Fib}_W.$$

L'axiome dual donne lieu à une bonne théorie des cofibres W-homotopiques.

Factorisation droite : Toute flèche $f : X \longrightarrow Y$ dans $\mathcal{M}$ se factorise en

$$X \xrightarrow{j_f} \tilde{Y} \xrightarrow{q_f} Y,$$

avec

$$q_f \in W, \qquad j_f \in \mathrm{Cofib}_W.$$

Je voudrais à présent développer quelque peu le formalisme des fibres W-homotopiques, sous l'hypothèse (disons) que W satisfait l'axiome de factorisation gauche. [page 241]

Commentary · Context [ms. 240]

The factorization axiom and Brown's hypothesis

Grothendieck now wants to detach the theory of homotopy fibres from the particular geometry of categories. The interval and mapping-cylinder arguments of the preceding pages have supplied a mechanism; he asks which part of that mechanism belongs to an arbitrary category with weak equivalences. His phrase "catégorie de modèles" here means a category equipped with a class W and the properties under discussion. It does not silently import all the axioms of a Quillen model category.

The relevant meaning of W-fibration is likewise intrinsic to W. Precisely, for $p : X \to Y$, the pullback functor $p^* : \mathcal{M}/Y \to \mathcal{M}/X$ must preserve the arrows whose underlying maps belong to W. This also implies the same assertion after another base change. This is the property used below, together with the stability of these maps under composition and pullback. In particular, one must not replace Fib_W by the fibrations of an arbitrary model structure without checking the corresponding properness statement. Here "weakly saturated" means that W contains the isomorphisms and satisfies two-out-of-three; it does not mean that every arrow inverted by localization already belongs to W. A factorization $f = pi$ with $i \in W$ and $p \in \mathrm{Fib}_W$ is sufficient for the replacement operations that are actually written down; it is not, by its form alone, a pair of lifting axioms.

The two footnotes beneath the axiom record a real issue in its scope. Brown's category of fibrant objects requires every map to the terminal object to be a fibration. Brown also requires pullbacks of fibrations and of trivial fibrations to exist and to remain of the same kind, and a path-object factorization of every diagonal. His factorization lemma produces a factorization of every map into a weak equivalence followed by a fibration; conversely, applying such a factorization to the diagonal supplies the path-object axiom (Brown, 1973, Part I, §1, pp. 420–422). Thus the all-object-fibrancy qualification in footnote 130 gives the clean connection with Brown. The word "cofibrations" in footnote 129 is a slip for the fibration version of this theory.

Here is why a weakened existence condition on pullbacks is reasonable. If S is fixed and $A \to S$, $B \to S$ are W-fibrations, their product over S is formed by pulling back one of those fibrations. The projection to the other factor is again a fibration, and the composite to S is a fibration. The same observation constructs a product with any finite number of factors; the empty product is $S \to S$. A factorization of a diagonal then provides the path objects required in this relative category. Arbitrary pullbacks in $\mathcal{M}$ are consequently stronger than what these constructions use. Footnote 128 is a proposed economy of axioms, rather than an obstruction to the argument.

The distinction between Brown's category and a category merely admitting fibrant replacement matters for the footnote's present status. In the language of left derivable categories, the written factorization and pullback hypotheses already suffice for the finite diagram theorem. We verify this below, including the required stability of trivial fibrations; no global-fibrancy hypothesis has to be added. Functorial factorization gives a shorter separate proof of the two replacement lemmas, but is also unnecessary in the derivable-category argument. Thus the source's cautious necessity suggestion is not part of the modern theorem.

Considérons un diagramme cartésien

$$\begin{array}{ccc} X_1 & \xleftarrow{q_2} & Y \\ {\scriptstyle p_1}\downarrow & & \downarrow{\scriptstyle q_1} \\ S & \xleftarrow[p_2]{} & X_2 \end{array}$$

dans $\mathcal{M}$. Si p_1 est dans Fib_W, alors Y sur X_2 peut s'interpréter comme la fibre W-homotopique de X_1/S en X_2/S. Plus précisément, il en est ainsi de la classe $\mathrm{ho}^{\mathrm{lc}}_{W,X_2}(Y)$, p. 156

$$(*) \qquad \mathrm{ho}^{\mathrm{lc}}_{W,X_2}(Y) \simeq p_2^*(\mathrm{ho}^{\mathrm{lc}}_{W,S}(X_1/S)).$$

Mais en tant qu'objet sur X_1, Y peut s'interpréter également comme fibre W-homotopique de X_2/S en X_1/S :

$$(**) \qquad \mathrm{ho}^{\mathrm{lc}}_{W,X_1}(Y/X_1) \simeq p_1^*(\mathrm{ho}^{\mathrm{lc}}_{W,S}(X_2/S)).$$

À dire vrai, il faudrait le prouver. Pour ceci, considérons une factorisation

$$X_2 \xrightarrow{i_2} \bar{X}_2 \xrightarrow{\bar{p}_2} S \qquad i_2 \in W \; p_2 \in \mathrm{Fib}_W,$$

de sorte qu'on trouve un diagramme de carrés cartésiens

$$\begin{array}{ccccc} X_1 & \xleftarrow{\bar{q}_2} & \bar{Y} & \xleftarrow[W]{j_2} & Y \\ \downarrow & & \downarrow & & \downarrow \\ S & \xleftarrow{\bar{q}_2} & \bar{X}_2 & \xleftarrow[W]{i_2} & X_2. \end{array}$$

Par définition de p_1^*, on a [page 242]

$$p_1^*(\mathrm{ho}^{\mathrm{lc}}_{W,S}(X_2/S)) \simeq \mathrm{ho}^{\mathrm{lc}}_{W,X_1}(\bar{Y}/X_1),$$

d'autre part, comme $X_1 \longrightarrow S$ est dans Fib_W, et $i_2 \in W$, on a $j_2 \in W$, donc

$$\mathrm{ho}^{\mathrm{lc}}_{W,X_1}(Y/X_1) \xrightarrow{\sim} \mathrm{ho}^{\mathrm{lc}}_{W,X_1}(\bar{Y}/X_1),$$

d'où la formule $(**)$.

Ainsi, l'objet Y a deux interprétations homotopiques différentes, suivant qu'on le regarde comme étant sur X_1, ou sur X_2. On aimerait alors une interprétation qui englobe les deux à la fois. On va considérer le diagramme

$$\begin{array}{ccc} X_1 & & \\ \downarrow & & \\ S & \longleftarrow & X_2 \end{array}$$

de type Ψ°, ou

$$\Psi \quad = \quad \begin{array}{ccc} 1 & & \\ \uparrow & & \\ 0 & \longrightarrow & 2 \end{array} \qquad \text{ou} \qquad \begin{array}{ccc} & & 1 \\ & \nearrow & \\ 0 & & \\ & \searrow & \\ & & 2 \end{array} \quad ,$$

dont Y se déduit par produit fibré, en complétant ce diagramme en un diagramme de type p. 157 [page 243]

$\tilde{\Psi}^\circ$, où

$$\tilde{\Psi} = \begin{array}{ccccc} & & 1 & & \\ & \nearrow & & \searrow & \\ 0 & & & & 3 \\ & \searrow & & \nearrow & \\ & & 2 & & \end{array} \qquad (\simeq \mathbf{\Delta}^1 \times \mathbf{\Delta}^1).$$

Pour toute catégorie I, soit

$$\mathrm{Ho}_{\mathcal{M},W}(I) \;\text{ ou }\; \mathrm{Ho}_W(I) \overset{\text{déf}}{=} \mathcal{M}(I)W(I)^{-1},$$

où

$$\begin{cases} \mathcal{M}(I) & = & \underline{\mathrm{Hom}}(I^\circ, \mathcal{M}) \\ W(I) & \subseteq & \mathrm{Fl}(\mathcal{M}(I)) \text{ est formé des } u : F \longrightarrow G \text{ telles que} \\ & & u_i : F(i) \longrightarrow G(i) \text{ dans } W \text{ pour tout } i \text{ dans } \mathrm{Ob}\, I. \end{cases}$$

Commentary · Exposition [ms. 242]

One pullback with two relative meanings

The symmetry that Grothendieck is seeking concerns the whole square. A pullback $P = A \times_S B$ has a map to A and a map to B; a construction that remembers only its isomorphism class in a homotopy category has forgotten part of the answer. Suppose $A \to S$ is a W-fibration and factor $B \to S$ as $B \xrightarrow{w} \bar{B} \to S$, with $w \in W$ and $\bar{B} \to S$ a W-fibration. Then

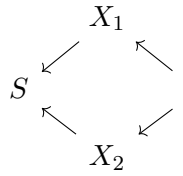
$$A \times_S B \longrightarrow A \times_S \bar{B}$$

is the pullback of w along the base change of $A \to S$. It belongs to W. It is also a morphism over A, so it identifies the class of the original pullback over A with the result of deriving the base-change operation on B. This proves the second interpretation in the text, while the first interpretation is already computed by the good representative $A \to S$. No second fibration hypothesis on $B \to S$ has been introduced.

The natural domain of this simultaneous construction is therefore the category of cospans before localization. With the manuscript's contravariant convention,

$$\Psi = (1 \leftarrow 0 \rightarrow 2), \qquad \mathcal{M}(\Psi) = \mathrm{Fun}(\Psi^{\mathrm{op}}, \mathcal{M}),$$

so an object of $\mathcal{M}(\Psi)$ is $A \to S \leftarrow B$. The additional vertex 3 of $\tilde{\Psi}$ points, after taking the opposite, to both 1 and 2. A right Kan extension along $\Psi^{\mathrm{op}} \hookrightarrow \tilde{\Psi}^{\mathrm{op}}$ consequently puts a limit at vertex 3. This orientation explains the star in i_*: it is a right adjoint to restriction.



One should retain the distinction already emphasized in the commentary on Chapter VI, manuscript p. 87. The category

$$\mathrm{Fun}(\Psi^{\mathrm{op}}, \mathcal{M})[W(\Psi)^{-1}]$$

retains how the maps and their weak-equivalence comparisons occur together. It is not being replaced by $\mathrm{Fun}(\Psi^{\mathrm{op}}, \mathcal{M}[W^{-1}])$. In the latter, a commutativity equation is only an equality of homotopy classes. The former is the diagram category on which a canonical homotopy completion can be defined. This is precisely the reason that the later derivator formalism forms diagram categories first and localizes afterwards (Groth, 2013, pp. 313–315).

The coming proof accordingly has two tasks. It must show that the chosen good cospans present the localization, and then show that taking their strict pullbacks respects weak equivalences. The first task concerns all morphisms and relations in a localized category; replacing one object at a time does not settle it.

Ainsi, le diagramme $\begin{array}{ccc} & & X_1 \\ & \swarrow & \\ S & & \\ & \nwarrow & \\ & & X_2 \end{array}$ définit un objet ξ de $\mathcal{M}(\Psi)$, donc de $\mathrm{Ho}_W(\Psi)$, et le

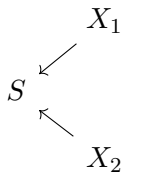


diagramme  peut de même s'interpréter comme un objet $\tilde{\xi}$ de $\mathrm{Ho}_W(\tilde{\Psi})$, dont la restriction à Ψ est ξ.

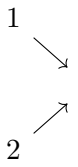
Ceci posé, j'aimerais définir un foncteur

$$i_* : \mathrm{Ho}_W(\Psi) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi})$$

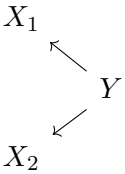
(où

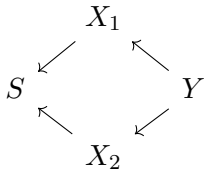
$$i : \Psi \longrightarrow \tilde{\Psi}$$



est l'inclusion, qui est une immersion ouverte), lequel doit correspondre, dans le cas d'un objet  de $\mathrm{Ho}_W(\Psi)$ avec $p_1 \in \mathrm{Fib}_W$ [: $X_1 \longrightarrow S$], à l'opération de produit fibré ([131]).

La construction de ce foncteur i_* devrait être essentiellement sorital, avec ce dont nous disposons. Nous allons définir d'abord, pour S *fixé,* un foncteur canonique p. 158 [page 244]





$$(*) \qquad \mathrm{Ho}^{\mathrm{lc}}_W(S) \times \mathrm{Ho}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{Ho}_{W,S}(\Psi),$$

où le deuxième membre est défini, par analogie avec les $\mathrm{Ho}_W(I)$, par

$$\mathrm{Ho}_{W,S}(I) \overset{\text{déf}}{=} ((\mathcal{M}/S)(I))(W_S(I))^{-1}$$

- i.e. c'est la même définition, sauf que $(\mathcal{M}, W)$ est remplacé par $(\mathcal{M}/S, W_S)$. Quant à $\Phi =$  , on le considère comme une sous-catégorie fermée de $\tilde{\Psi}$, qui s'en déduit en lui rajoutant un objet initial 0 (tout comme $\tilde{\Psi}$ se déduit de Ψ en lui rajoutant un objet final 3). D'autre part, on a un foncteur tautologique

$$(*') \qquad \mathrm{Ho}_{W,S}(\Phi) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi}),$$

qui sur les objet consiste à compléter un diagramme  de $\mathcal{M}/S$ en le diagramme carré  de $\mathcal{M}$.

[page 245]

131. **NB** Cette construction, qui se fait ici assez lourdement, devient immédiate, et aussi ses principales propriétés, si on admet que la catégorie à fibrations $(\mathcal{M}, W, \mathrm{Fib}_W)$ définit un *dérivateur* sur le domaine des ensembles ordonnés finis, ce qui se prouve en effet assez simplement (avec pas plus de mal que je ne me donne ici).

Le composé de $(*)$ et de $(*')$ donnera donc un foncteur

$$(**) \qquad \mathrm{Ho}^{\mathrm{lc}}_W(S) \times \mathrm{Ho}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi}),$$

très proche déjà du foncteur i_* à construire. Pour construire $(*)$, on interprète (à équivalence de catégories près) le premier membre comme

$$(\underline{\mathrm{Fib}}_W S \times \underline{\mathrm{Fib}}_W S)(W_S \times W_S)^{-1},$$

donc il faut construire un foncteur

$$\underline{\mathrm{Fib}}_W S \times \underline{\mathrm{Fib}}_W S \longrightarrow \mathrm{Ho}_{W,S}(\Phi),$$

qui transforme flèches dans $W_S \times W_S$ en isomorphismes. On prendra le foncteur

$$(X_1, X_2) \longmapsto \begin{pmatrix} X_1 & \longleftarrow & X_1 \times_S X_2 \\ & & \downarrow \\ & & X_2 \end{pmatrix},$$

et il faut seulement vérifier que si

p. 159

$$X_1 \xrightarrow{\alpha_1} X_1', \qquad X_2 \xrightarrow{\alpha_2} X_2'$$

sont deux flèches dans $\underline{\mathrm{Fib}}_W S$, d'où

$$X_1 \times_S X_2 \xrightarrow{\alpha = \alpha_1 \times_S \alpha_2} X_1' \times_S X_2',$$

alors

$$\alpha_1 \in W,\ \alpha_2 \in W \qquad \Longrightarrow \qquad \alpha \in W,$$

ce qui est immédiat sur la factorisation

$$X_1 \times_S X_2 \underbrace{\longrightarrow}_{\substack{\in W \\ \text{car } X_2 \in \underline{\mathrm{Fib}}_W S}} X_1' \times_S X_2 \underbrace{\longrightarrow}_{\substack{\in W \\ \text{car } X_1' \in \underline{\mathrm{Fib}}_W S}} X_1' \times_S X_2'.$$

On a prouvé la

Proposition 18. *Soit S dans $\mathcal{M}$. Il existe, à isomorphisme unique près, un foncteur et un seul* [page 246]

$$\mathrm{Ho}^{\mathrm{lc}}_W(S) \times \mathrm{Ho}^{\mathrm{lc}}_W(S) \xrightarrow{\pi} \mathrm{Ho}_{W,S}(\Phi)$$

donnant lieu à un carré commutatif à isomorphisme près

$$\begin{array}{ccc} & X_1 & \\ & \nwarrow & \\ (X_1, X_2) \longmapsto & X_1 \times_S X_2 & \\ & \swarrow & \\ & X_2 & \end{array}$$

$$\begin{array}{ccc} \underline{\mathrm{Fib}}_W S \times \underline{\mathrm{Fib}}_W S & \longrightarrow & (\mathcal{M}/S)(\Phi) \\ \downarrow & & \downarrow \\ \mathrm{Ho}^{\mathrm{lc}}_W(S) \times \mathrm{Ho}^{\mathrm{lc}}_W(S) & \longrightarrow & \mathrm{Ho}_{W,S}(\Phi) \\ (= (\mathcal{M}/S)(W_S)^{-1} \times (\mathcal{M}/S)(W_S)^{-1}) & & (= \mathcal{M}/S(\Phi)(W_S(\Phi))^{-1}). \end{array}$$

Pour X_1, X_2 dans $\mathcal{M}/S$, le diagramme

$$\pi(X_1, X_2) \overset{\text{déf}}{=} \pi(\mathrm{ho}^{\mathrm{lc}}_{W,S}(X_1), \mathrm{ho}^{\mathrm{lc}}_{W,S}(X_2))$$

se 'calcule' ainsi, à isomorphisme canonique près : on choisit

$$X_1 \xrightarrow{\alpha_1} \bar{X}_1, \qquad X_2 \xrightarrow{\alpha_2} \bar{X}_2 \qquad \textit{flèches dans } \mathcal{M}/S$$

avec

$$\alpha_1, \alpha_2 \in W_S, \qquad \bar{X}_1, \bar{X}_2 \in \operatorname{Ob} \underline{\operatorname{Fib}}_W S,$$

ce qui définit

$$\pi(\alpha_1, \alpha_2) : \pi(X_1, X_2) \xrightarrow{\sim} \pi(\bar{X}_1, \bar{X}_2) = \operatorname{ho}_{S,W,\Phi} \begin{pmatrix} \bar{X}_1 & \longleftarrow & \bar{X}_1 \times_S \bar{X}_2 \\ & & \downarrow \\ & & \bar{X}_2 \end{pmatrix}.$$

Commentary · Exposition [ms. 246] p. 160 [page 247]

A product together with its projections

The intermediate construction over a fixed base is more than a calculation of the object $A \times_S B$. Grothendieck keeps both projections in the value of π. Thus π lands in the localized category of Φ^{op}-diagrams in $\mathcal{M}/S$, where $\Phi = (1 \to 3 \leftarrow 2)$. The occurrence of Ψ in the first display of ms. 244 is an edition slip: the next functor, and Proposition 18 itself, require Φ.

Write $\mathcal{C}_S$ for the full subcategory of $\mathcal{M}/S$ on the W-fibrations. If $a : A \to A'$ and $b : B \to B'$ are weak equivalences in this category, the comparison of products has the factorization

$$A \times_S B \xrightarrow{a \times_S 1} A' \times_S B \xrightarrow{1 \times_S b} A' \times_S B'.$$

The first arrow is a pullback of a along a base change of $B \to S$; the second is a pullback of b along a base change of $A' \to S$. Both belong to W. The same morphism of spans has a and b at its other vertices, so it is an objectwise weak equivalence. This proves exactly the compatibility needed to descend the entire span functor.

There is also a small categorical point behind the source's product of localizations. For relative categories $(\mathcal{C}, U)$ and $(\mathcal{D}, V)$, with identities in U, V, there is a canonical equivalence

$$(\mathcal{C} \times \mathcal{D})[(U \times V)^{-1}] \simeq \mathcal{C}[U^{-1}] \times \mathcal{D}[V^{-1}].$$

Indeed a functor out of $\mathcal{C} \times \mathcal{D}$ inverts $U \times V$ precisely when it inverts $(u, 1)$ and $(1, v)$ separately. Localizing successively in the two variables gives the displayed universal property, including natural transformations. Applied to $\mathcal{C}_S$ twice, this justifies the domain used in Proposition 18. The localization equivalence between $\mathcal{C}_S$ and the relative homotopy category is an earlier input to this paragraph, not a consequence of the displayed product calculation.

The phrase "unique up to unique isomorphism" is understood relative to the specified comparison with the functor on good representatives. Without that comparison, a functor can have automorphisms and the uniqueness assertion would be too strong. With it, full faithfulness of restriction along a localization supplies the required uniqueness. A pair of replacement arrows $A \to \bar{A}$, $B \to \bar{B}$ therefore gives the canonical comparison written by Grothendieck; it does not require a preferred strict map between every two independently chosen replacements.

This proposition is numbered 18 a second time in the edition. We distinguish it from the pasting proposition on ms. 236 by its page and by the name "fixed-base product proposition". Its content will also be used when the base itself varies, where a further argument is needed.

Corollaire. *Description du foncteur*

$$(\xi_1, \xi_2) \longmapsto \xi_1 \times_S \xi_2 : \mathrm{Ho}^{\mathrm{lc}}_W(S) \times \mathrm{Ho}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{Ho}^{\mathrm{lc}}_W(S).$$

Ce foncteur est bel et bien un produit cartésien dans $\mathrm{Ho}^{\mathrm{lc}}_W(S)$ ([132]), *où les produits finis existent* ([133]).

132. mais c'est un cas particulier des cas de Ho_W (si $\mathcal{M}$ a des produits binaires), en remplaçant $\mathcal{M}$ par $\mathcal{M}/S$.
133. Dire aussi que les foncteurs $f^* : \mathrm{Ho}^{\mathrm{lc}}_W(S) \longrightarrow \mathrm{Ho}^{\mathrm{lc}}_W(S')$ (pour $f : S' \longrightarrow S$) commutent aux produits finis.

Pour prouver ce dernier point, posant

$$\mathcal{H} = \mathrm{Ho}_W^{\mathrm{lc}}(S),$$

il faut montrer que les foncteurs

$$\mathcal{H} \underset{\pi}{\overset{\delta}{\rightleftarrows}} \mathcal{H} \times \mathcal{H}$$

sont adjoints, avec

$$\begin{array}{rcccccc} \delta & = & \mathrm{diag}_{\mathcal{H}} & : & \xi & \longmapsto & (\xi, \xi) \\ \pi & = & \text{'produit'} & : & (\xi_1, \xi_2) & \longmapsto & \xi_1 \times_S \xi_2. \end{array}$$

On va définir les homomorphismes d'adjonction

$$\begin{array}{rcccccc} \mathrm{id}_{\mathcal{H}} & \overset{\alpha}{\to} & \pi\delta & \text{i.e.} & \xi & \overset{\alpha_\xi}{\longrightarrow} & \xi \times_S \xi \\ \mathrm{id}_{\mathcal{H}\times\mathcal{H}} & \overset{\beta}{\leftarrow} & \delta\pi & \text{i.e.} & (\xi_1, \xi_2) & \overset{\beta_{\xi_1,\xi_2}}{\longleftarrow} & (\xi_1 \times_S \xi_2, \xi_1 \times_S \xi_2). \end{array}$$

Pour ceci, on décrit $\mathcal{H}$ comme

$$\mathcal{H} = (\underline{\mathrm{Fib}}_W S)(W_S)^{-1}$$

et on note que δ, π proviennent de foncteurs adjoints au niveau de $\mathcal{H}_0 = \underline{\mathrm{Fib}}_W S$

$$\mathcal{H}_0 \underset{\pi_0}{\overset{\delta_0}{\rightleftarrows}} \mathcal{H}_0 \times \mathcal{H}_0 \ ,$$

lesquels donnent lieu à α_0, β_0

$$\begin{array}{rcl} \mathrm{id}_{\mathcal{H}_0} & \overset{\alpha_0}{\longrightarrow} & \pi_0\delta_0 \\ \mathrm{id}_{\mathcal{H}_0\times\mathcal{H}_0} & \overset{\beta_0}{\longleftarrow} & \delta_0\pi_0. \end{array}$$

On définit α, β par passage aux catégories de fractions pour α_0, β_0. Les 2 compatibilités, étant vérifiées pour α_0, β_0, le sont aussi pour α, β. Q.e.d. p. 161 [page 248]

Je dégage ici le

Lemme. *Soit* $\mathcal{X} \underset{g}{\overset{f}{\rightleftarrows}} \mathcal{Y}$ *un couple de foncteurs adjoint, et soient* Σ, Σ' *des localiseurs dans* $\mathcal{X}$, $\mathcal{Y}$ *tels que* $f(\Sigma) \subseteq \Sigma'$, $g(\Sigma') \subseteq \Sigma$, *de sorte qu'on a un couple de foncteurs*

$$\mathcal{X}\Sigma^{-1} \underset{\bar{g}}{\overset{\bar{f}}{\rightleftarrows}} \mathcal{Y}\Sigma'^{-1} \ .$$

Alors $\bar{f}$, $\bar{g}$ *sont adjoints, les flèches d'adjonction étant déduites de celles pour* f, g.

Corollaire. *Soit* $(\mathcal{M}, W)$ *une catégorie de modèles, supposons que dans* $\mathcal{M}$ *les produits binaires (resp. les produits finis) existent, et que pour* $u_1 : X_1 \longrightarrow X_1'$ *et* $u_2 : X_2 \longrightarrow X_2'$, *si* $u_1, u_2 \in W$, *alors* $u_1 \times u_2 : X_1 \times X_2 \longrightarrow X_1' \times X_2'$ *est dans* W. *Alors dans* $\mathcal{M}W^{-1}$ *les produits binaires (resp. produits finis) existent, et le foncteur localisation* $\mathcal{M} \longrightarrow \mathcal{M}W^{-1}$ *y commute.*

On applique le lemme à

$$\mathcal{M} \underset{\pi}{\overset{\delta}{\rightleftarrows}} \mathcal{M} \times \mathcal{M} \qquad \text{et } W,\ W \times W,$$

et pour l'objet final,

$$\mathcal{M} \underset{\bullet}{\overset{e}{\rightleftarrows}} e \qquad \text{et } W,\ W_0 = \{\mathrm{id}_e\}.$$

[page 249]

Commentary · Exposition [ms. 248]

Why the product remains a categorical product

The assertion about products in $\mathrm{Ho}^{\mathrm{lc}}_W(S)$ is stronger than the existence of a homotopically well-defined binary operation. Grothendieck proves the universal property by descending an adjunction. This is an efficient place to make the small localization argument completely explicit.

Suppose $F : \mathcal{C} \rightleftarrows \mathcal{D} : G$ is an adjunction, with F left adjoint to G, and both functors preserve the chosen weak equivalences. Its unit $\eta : 1 \to GF$ and counit $\epsilon : FG \to 1$ have images in the localizations. Their naturality for an inverted weak equivalence follows from their naturality for that weak equivalence: multiply the naturality square by the inverse image of the equivalence. Naturality then holds for any composite of ordinary arrows and formal inverses, which are the morphisms of the localization. The identities

$$\epsilon_{FX} F(\eta_X) = 1_{FX}, \qquad G(\epsilon_Y)\eta_{GY} = 1_{GY}$$

are equations already true before localization, hence remain true afterwards. The descended unit and counit establish $\bar{F} \dashv \bar{G}$. No lifting property and no fullness assertion about the localization functor are needed.

Apply this argument to the diagonal functor on $\mathcal{C}_S$ and its right adjoint, the ordinary product over S. The preceding block proves that this right adjoint preserves weak equivalences. The unit is the diagonal $A \to A \times_S A$; the counit consists of the two projections. Consequently the operation constructed from good representatives is the categorical product in the localized relative category. Applying the same argument to the unique functor $\mathcal{C}_S \to e$ and the functor selecting $S \to S$ proves that this object remains terminal. This supplies all finite products.

The statement in footnote 133 has an equally concrete proof. Pullback along $f : S' \to S$ sends good objects to good objects and, by the preceding relative invariance theorem, sends weak equivalences between them to weak equivalences. The canonical strict isomorphism

$$f^*(A \times_S B) \cong f^*A \times_{S'} f^*B$$

is compatible with both projections; also $f^*(S \to S) = (S' \to S')$. Their images after localization are therefore the comparison isomorphisms for a functor preserving finite products. This proof concerns the product in the relative homotopy category. It does not assert that an arbitrary strict pullback in $\mathcal{M}$ is already a homotopy pullback.

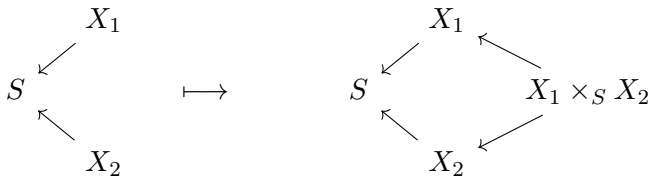
Je vais maintenant construire le foncteur

$$i_* : \mathrm{Ho}_W(\Psi) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi}).$$

Il me faut d'abord prouver le

Lemme 1. *Soit $\mathcal{F}$ la sous-catégorie pleine de $\mathcal{M}(\Psi)$, catégorie des diagrammes*

$$\begin{array}{ccc} & & X_1 \\ & {\scriptstyle p_1}\swarrow & \\ S & & \\ & {\scriptstyle p_2}\nwarrow & \\ & & X_2 \end{array}$$



dans S [plutôt dans $\mathcal{M}$, sur S], formée de ceux pour lesquels p_1, p_2 sont dans Fib_W. Soit $W_{\mathcal{F}}$ le localiseur induit sur $\mathcal{F}$ par $W(\Psi)$ (W-équivalences terme à terme). Alors

$$\mathcal{F}W_{\mathcal{F}}^{-1} \xrightarrow{\sim} \mathcal{M}(\Psi)W(\Psi)^{-1} \ (\overset{déf}{=} \mathrm{Ho}_W(\Psi)).$$

Nous allons prouver ce lemme plus bas. En l'admettant, pour construire i_*, il suffit de construire p. 162

$$\mathcal{F} \longrightarrow \mathrm{Ho}_W(\tilde{\Psi})$$

qui applique $W_{\mathcal{F}}$ en des isomorphismes. Je prendrai, bien sûr,

$$\mathcal{F} \quad \longrightarrow \quad \mathrm{Ho}_W(\Psi).$$

Vérifions qu'il transforme flèches de $W_{\mathcal{F}}$ en isomorphismes.

[page 250]

Commentary · Exposition [ms. 249]

The deferred lemmas with functorial factorization

Grothendieck has deliberately separated the existence of useful representatives from the assertion that they compute the whole localization. Lemmas 1 and 2 assert the latter. Their proofs are deferred, and the promise on ms. 257 does not complete them in the pages supplied here. There is a particularly short completion when the factorization axiom is available functorially. We state that extra hypothesis explicitly, since the axiom on ms. 240 does not include it.

Let $D = \mathcal{M}(\Psi)$, and suppose that the assignment

$$(A \xrightarrow{p} S) \longmapsto (A \xrightarrow{j_p} R(p) \xrightarrow{r_p} S)$$

is a functor on the arrow category, with $j_p \in W$, $r_p \in \mathrm{Fib}_W$, and $r_p j_p = p$. For $d = (A \xrightarrow{p} S \xleftarrow{q} B)$, set

$$R_D d = (R(p) \xrightarrow{r_p} S \xleftarrow{r_q} R(q)).$$

This gives a functor $R_D : D \to \mathcal{F}$ and a natural transformation $j : 1_D \to JR_D$, where $J : \mathcal{F} \hookrightarrow D$ is inclusion. Every component of j is an objectwise weak equivalence. If $a : d \to d'$ is in $W(\Psi)$, naturality gives

$$(JR_D a) j_d = j_{d'} a.$$

At each vertex the two maps $j_d, j_{d'}$ and the map a belong to W; two-out-of-three therefore implies that $R_D a$ is in $W_{\mathcal{F}}$. The functor R_D consequently descends to localization. Restricted to $\mathcal{F}$, the same natural transformation has both source and target in $\mathcal{F}$. After localization it supplies an isomorphism $1 \cong \bar{R}_D \bar{J}$, while its unrestricted version supplies $1 \cong \bar{J}\bar{R}_D$. These are precisely the two isomorphisms that show $\bar{J}$ is an equivalence. This proves Lemma 1 with the additional hypothesis. Over a fixed base S, the same argument applies to every full intermediate category between $\mathrm{Fib}_W(S)$ and $\mathcal{M}/S$: the replacement always lands in $\mathrm{Fib}_W(S)$ and the natural comparison stays in the intermediate category. It therefore proves the strengthened replacement assertion (c) recalled on ms. 240 in this functorial setting.

For Lemma 2 use the identical construction on the three vertices of a square belonging to Ψ. Keep its fourth vertex T unchanged, and replace its maps to A and B by their composites with j_p and j_q. Their composites to S still agree, so this is a strictly commutative square. It defines a functor $R_E : \mathcal{M}(\tilde{\Psi}) \to \mathcal{G}$ with a natural objectwise weak equivalence $1 \to KR_E$, whose component at T is the identity. The same two-out-of-three argument makes R_E homotopical, and its restriction to $\mathcal{G}$ gives the other inverse comparison. Hence $\mathcal{G}[W_{\mathcal{G}}^{-1}] \to \mathrm{Ho}_W(\tilde{\Psi})$ is an equivalence.

This argument also specifies what the arbitrary choice of a factorization would fail to provide: not the value on an object, but the functor and the natural transformation used in the proof. It uses neither an assumption that every object is fibrant nor a saturation theorem identifying W with all maps inverted by localization. The required input is a functorial factorization, which is a separate sufficient hypothesis.

Commentary · Later developments [ms. 249]

A nonfunctorial repair by derivability

The passage to diagrams can be made without functorial choices, and the later theory also removes the need to add global fibrancy to the written hypotheses. The appropriate structure is a

left derivable category in the sense of Cisinski (2010, Definition 1.1). We check its one potentially hidden axiom. Let $p : X \to Y$ belong to $W \cap \mathrm{Fib}_W$, and let $u : Y' \to Y$ be arbitrary. Factor u as $Y' \xrightarrow{j} Z \xrightarrow{r} Y$, where $j \in W$ and $r \in \mathrm{Fib}_W$. Since r^* preserves W, the map $X \times_Y Z \to Z$ is in W. The map $X \times_Y Y' \to X \times_Y Z$ is the pullback of j along a base change of p, hence is also in W. The commutative square with bottom map j and two-out-of-three now give $X \times_Y Y' \to Y' \in W$. Thus trivial fibrations remain trivial under arbitrary pullback.

The other derivability axioms are immediate from the standing assumptions: a terminal object exists, weak equivalences contain isomorphisms and satisfy two-out-of-three, fibrations compose and are stable under the available pullbacks, and the required factorization is the axiom of ms. 240. These properties are stronger than the restricted pullback and factorization requirements of Definition 1.1. The precise later results are the finite-diagram structures and localization comparison of Theorem 1.30 and Corollaries 1.31–1.32, followed by the right-Kan-extension theorem, Proposition 2.6; Theorem 2.21 packages the construction as a one-sided derivator on finite direct categories.

This also settles the strengthened fixed-base condition (c) recalled from ms. 218. The slice $\mathcal{M}/S$, with the inherited fibrations and weak equivalences, is left derivable and has $\mathrm{Fib}_W(S)$ as its full subcategory of fibrant objects. Every full intermediate category $\mathcal{E}$ containing these objects is left derivable with the same fibrant objects: the pullbacks demanded by the axioms take place among fibrant objects, and the middle object in a factorization with fibrant target is again fibrant. Proposition 1.8 identifies the localization of each such category with that of its fibrant objects. It follows that both inclusions in condition (c) are localization equivalences. Condition (b), the equality of ordinary and universal weak equivalences between good objects, is the relative invariance argument dual to Proposition 16; together they give (a).

For clarity, the particular inclusions $\mathcal{F} \subset D$ and $\mathcal{G} \subset E$ can be checked by that paper's approximation theorem, Theorem 3.12. We give the verification, since $\mathcal{G}$ imposes no fibration condition on its fourth vertex. On $\mathcal{F}$ take a morphism (a_0, a_1, a_2) to be a fibration when the three maps

$$S \to S', \qquad A \to S \times_{S'} A', \qquad B \to S \times_{S'} B'$$

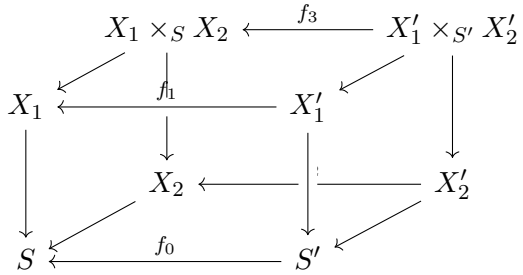
are fibrations. On $\mathcal{G}$ use these same conditions and additionally require the map $T \to T'$ between fourth vertices to be a fibration. Take weak equivalences objectwise in both cases. An object of $\mathcal{F}$ is fibrant precisely when its base S is fibrant in $\mathcal{M}$. An object of $\mathcal{G}$ is fibrant precisely when both S and its fourth vertex T are fibrant. Its remaining vertices are then fibrant because their maps to S are fibrations.

Here is the factorization needed both for these structures and for approximation. Given a map from an arbitrary cospan to a fibrant good cospan $(A' \to S' \leftarrow B')$, first factor its base map as

$$S \xrightarrow{\sim} S_1 \twoheadrightarrow S'.$$

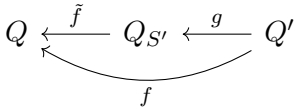
Factor the resulting maps $A \to S_1 \times_{S'} A'$ and $B \to S_1 \times_{S'} B'$ as weak equivalences followed by fibrations. Call the middle objects A_1, B_1. Their maps to S_1 are fibrations, and the resulting cospan maps to the target by a fibration of the displayed kind. This constructs an objectwise weak equivalence from the original cospan to an object of $\mathcal{F}$, compatibly with the given map to the target.

For a map of squares with fibrant target in $\mathcal{G}$, make those three factorizations and put



$$P_1 = A_1 \times_{S_1} B_1, \qquad P' = A' \times_{S'} B'.$$

The map $P_1 \to P'$ is a fibration. Indeed it factors through $S_1 \times_{S'} P'$; the first map is a composite of pullbacks of the two relative leg fibrations, and the second is a pullback of $S_1 \to S'$. The source corner T maps canonically to $P_1 \times_{P'} T'$. Factor this map into $T \xrightarrow{\sim} T_1$ followed by a fibration. Since $P_1 \times_{P'} T' \to T'$ is itself a fibration, so is $T_1 \to T'$. The middle square lies in $\mathcal{G}$ and is fibrant: its base maps fibrantly to the fibrant target base, and T_1 maps fibrantly to the fibrant object T'. Thus the factorization has all the required properties.



The remaining derivability axioms can be checked on these same relative maps. Composition is a composite of a relative map and a pullback of the next one. A pullback of a fibration is computed vertex by vertex; at either leg its relative map is the corresponding pullback of the original relative map, so the resulting object remains good. For a trivial fibration, the relative leg maps are also weak equivalences, by two-out-of-three applied to the weak base map and the good target leg. Their pullbacks remain weak equivalences, as do the fourth-vertex maps. This verifies the trivial-fibration axiom. Factoring a diagonal of a fibrant object by the construction above supplies its path object. The ambient categories of cospans and squares carry the objectwise fibration structures

of Cisinski's Corollary 1.31; the nontrivial factorization axiom there is supplied by the finite inverse diagram construction. The inclusions preserve fibrations, trivial fibrations, terminal objects and their pullbacks; they are exact and reflect weak equivalences.

Finally, Cisinski's approximation condition AP2 asks, for a map from an ambient fibrant object to an included fibrant object, for a weak-equivalence comparison with an object of the smaller category over the same target. The explicit factorizations just constructed supply it, with the preliminary weak equivalence of the ambient source taken to be its identity. AP1 is reflection of weak equivalences. Theorem 3.12 now proves both localization equivalences. This proves the two deferred lemmas under the written factorization and pullback hypotheses. The derivable-category argument controls the morphisms without either global fibrancy or functorial choices of replacements.

Il faut prouver que si $f_0, f_1, f_2 \in W$, alors $f_3 \in W$. Mais considérons l'image inverse du carré cartésien Q par $f_0 : S' \longrightarrow S$, d'où un carré cartésien $Q_{S'}$ et une factorisation

de $Q' \longrightarrow Q$. Comme $f_0 \in W$, et que X_1, X_2, $X_1 \times_S X_2$ sont dans $\underline{\mathrm{Fib}}_W S$, les flèches horizontales réalisant $Q_{S'} \longrightarrow Q$ sont toutes dans W. Ceci, plus le fait que $f_1, f_2 \in W$, impliquent que dans le morphisme g, les flèches g_1, g_2 sont dans W. Il en résulte que la flèche

$$g_3 : X_1' \times_{S'} X_2' \longrightarrow (X_1 \times_S X_2) \times_S S'$$

l'est aussi (théorie du produit dans $\underline{\mathrm{Fib}}_W S'$ et $\mathrm{Ho}^{\mathrm{lc}}_W(S)$), donc $f_3 = \tilde{f}_3 g_3 \in W$, q.e.d.

[page 251]

Commentary · Exposition [ms. 250]

The base is allowed to move

Having obtained good representatives, Grothendieck must show that their pullbacks vary homotopically in the base as well as in the two inputs. This is the extra content of the argument on ms. 250. The fixed-base product proposition cannot by itself be applied to a morphism of cospans whose middle objects differ.

Suppose a morphism of good cospans has components

$$a : A' \to A, \qquad b : B' \to B, \qquad s : S' \to S$$

in W. Pull the target cospan back along s, obtaining

$$\tilde{A} = S' \times_S A, \quad \tilde{B} = S' \times_S B, \quad \tilde{P} = S' \times_S (A \times_S B).$$

The projections $\tilde{A} \to A$ and $\tilde{B} \to B$ are weak equivalences because $A \to S$ and $B \to S$ are W-fibrations. The map $A \times_S B \to S$ is a composite of W-fibrations, so $\tilde{P} \to A \times_S B$ is also in W. The given maps factor through $\tilde{A}$ and $\tilde{B}$; two-out-of-three shows that $A' \to \tilde{A}$ and $B' \to \tilde{B}$ lie in W. These are now maps over the same base S'. The product calculation gives

$$A' \times_{S'} B' \longrightarrow \tilde{A} \times_{S'} \tilde{B} \cong \tilde{P} \quad \text{in } W.$$

Composition proves that the original map of pullbacks is a weak equivalence. All four components of the completed square have therefore been checked. The final parenthesis of the source should refer to $\mathrm{Ho}^{\mathrm{lc}}_W(S')$, since this intermediate product is taken over S'; the printed S is retained as an edition slip.

The calculation explains why one can descend the strict completion functor on $\mathcal{F}$. It also shows that its homotopicality is a theorem about a whole diagram, not an assertion that the pullback functor preserves arbitrary weak equivalences in each uncontrolled variable. The good-map assumptions are used at the three projections above and at the two fixed-base product maps. In Brown's setting the corresponding pullback invariance is already the content of Brown (1973, Part I, §4, Lemmas 1–2, pp. 428–429).

Notons qu'on a un isomorphisme canonique

$$(*) \qquad \alpha : i^* i_* \xrightarrow{\sim} \mathrm{id}_{\mathrm{Ho}_W(\Phi)}.$$

J'ai envie de prouver que les foncteurs

$$\mathrm{Ho}_W(\Phi) \underset{i_*}{\overset{i^*}{\leftrightarrows}} \mathrm{Ho}_W(\tilde{\Phi})$$

sont adjoints, et que $(*)$ est une des flèches d'adjonction. Il faut définir l'autre flèche d'adjonction p. 163

$$(**) \qquad \beta : i_* i^* \longleftarrow \mathrm{id}_{\mathrm{Ho}_W(\tilde{\Phi})}.$$

Mais pour ceci, je dois utiliser le

Lemme 2. Soit $\mathcal{G}$ la sous-catégorie pleine de $\mathcal{M}(\tilde{\Phi})$, formée des $\begin{array}{ccc} X_1 & \xleftarrow{q_2} & X_3 \\ {\scriptstyle p_1}\downarrow & & \downarrow{\scriptstyle q_1} \\ S & \xleftarrow[p_2]{} & X_2 \end{array}$ tels que $p_1, p_2 \in \mathrm{Fib}_W$ et soit $W_{\mathcal{G}}$ le localiseur induit par $W(\tilde{\Phi})$ (W-équivalences terme à terme). Alors l'inclusion $\mathcal{G} \longrightarrow \mathcal{M}(\tilde{\Phi})$ induit une équivalence

$$\mathcal{G}W_{\mathcal{G}}^{-1} \xrightarrow{\sim} \mathcal{M}(\tilde{\Phi})W(\tilde{\Phi})^{-1} \overset{\text{déf}}{=} \mathrm{Ho}_W(\tilde{\Phi}).$$

Je vais pour le moment admettre ce

lemme, tout comme le lemme 1 (p. 249). Je vais considérer i^*, i_* comme des flèches entre les categories $\mathcal{F}W_{\mathcal{F}}^{-1}$, $\mathcal{G}W_{\mathcal{G}}^{-1}$. Elles sont induites par les flèches [page 252]

$$\mathcal{F} \underset{i_{0*}}{\overset{i_0^*}{\leftrightarrows}} \mathcal{G}$$

entre $\mathcal{F}$ et $\mathcal{G}$ eux mêmes,

$$i_0^* : \quad \mathcal{G} \quad \longrightarrow \quad \mathcal{F} : \qquad \begin{array}{ccc} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ S & \longleftarrow & X_2 \end{array} \qquad \longmapsto \qquad \begin{array}{c} X_1 \\ \downarrow \\ S \end{array} \begin{array}{c} \\ \longleftarrow \\ \\ \end{array} \begin{array}{c} X_2 \\ \downarrow \\ X_2 \end{array}$$

$$i_{0*} : \quad \mathcal{F} \quad \longrightarrow \quad \mathcal{G} : \qquad \begin{array}{c} X_1 \\ \downarrow \\ S \end{array} \begin{array}{c} \\ \longleftarrow \\ \\ \end{array} \begin{array}{c} X_2 \\ \\ X_2 \end{array} \qquad \longmapsto \qquad \begin{array}{ccc} X_1 & \longleftarrow & X_1 \times_S X_2 \\ \downarrow & & \downarrow \\ S & \longleftarrow & X_2. \end{array}$$

Ces deux foncteurs sont adjoints l'un de l'autre, et compatibles aux localiseurs $W_{\mathcal{F}}$, $W_{\mathcal{G}}$. Donc les foncteurs déduits de i_0^*, i_{0*} par passage aux catégories de fractions sont également adjoints (cf. lemme p. 248).

Ainsi, modulo la démonstration des lemmes 1 et 2, on a prouvé ceci :

Théorème. *Soit $(\mathcal{M}, W)$ une catégorie de modèles ($W \subseteq Fl\,\mathcal{M}$) satisfaisant l'axiome de factorisation gauche (p. 240), donnant donc lieu à une bonne théorie des fibres W-homotopiques. Soient* p. 164 [page 253]

$$\begin{array}{ccc} & & 1 \\ \Psi = 0 & & \\ & & 2 \end{array} \qquad \xrightarrow{i} \qquad \begin{array}{ccccc} & & 1 & & \\ \tilde{\Psi} = 0 & & & & 3 \\ & & 2 & & \end{array}$$

(immersions ouvertes dans Cat*), et considérons le foncteur restriction*

$$i^* : \mathrm{Ho}_W(\tilde{\Psi}) \longrightarrow \mathrm{Ho}_W(\Psi).$$

Ce foncteur admet un adjoint à droite

$$i_* : \mathrm{Ho}_W(\Psi) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi}).$$

Ce foncteur i_* se 'calcule' ainsi : sa valeur en $\begin{array}{ccc} & & X_1 \\ & & \downarrow{\scriptstyle p_1} \\ S & \xleftarrow[p_2]{} & X_2 \end{array}$ *est canoniquement isomorphe (dans* $\mathrm{Ho}_W(\tilde{\Psi})$*) à* $\begin{array}{ccc} X_1 & \longleftarrow & X_1 \times_S X_2 \\ \downarrow & & \downarrow \\ S & \longleftarrow & X_2 \end{array}$ *, si on suppose que p_1 ou p_2 est une W-fibration.*

Dans le cas général il se calcule en factorisant p_1 en

$$X_1 \xrightarrow{i_1} \bar{X}_1 \xrightarrow{p_1'} S, \qquad i_1 \in W,\ p_1' \in Fib_W,$$

et en prenant $\begin{array}{ccc} \bar{X}_1 & \longleftarrow & \bar{X}_1 \times_S X_2 \\ \downarrow & & \downarrow \\ S & \longleftarrow & X_2 \end{array}$ *, ou en*

procédant de façon symétrique, ou en factorisant simultanement p_1 et p_2, et prenant [page 254]

$$\begin{array}{ccc} \bar{X}_1 & \longleftarrow & \bar{X}_1 \times_S \bar{X}_2 \\ \downarrow & & \downarrow \\ S & \longleftarrow & \bar{X}_2. \end{array}$$

Commentary · Examples [ms. 254]

The missing corner can be an entire group

A groupoid calculation makes the difference between a strict pullback and its homotopy replacement visible without any topological machinery. Work in groupoids with equivalences as W, and let G be a group. Write BG for the one-object groupoid with automorphism group G. Consider the cospan

$$* \longrightarrow BG \longleftarrow *.$$

Its strict pullback is the terminal groupoid: there is one pair of objects, and the only pair of morphisms is the pair of identities. The homotopy pullback will instead be the discrete groupoid on the set G.

To compute it, let EG be the groupoid whose objects are the elements of G and with exactly one morphism from each object to every other object. Define $p : EG \to BG$ by sending the unique morphism $g \to h$ to hg^{-1}. The composition formula

$$(kh^{-1})(hg^{-1}) = kg^{-1}$$

shows that this is a functor. The inclusion $* \to EG$ selecting the identity element is fully faithful and essentially surjective, hence is an equivalence; its composite with p is the specified map $* \to BG$.

The functor p is an isofibration. Given an object g and an arrow a in BG, the arrow $g \to ag$ lies above a. Isofibrations of groupoids have the required W-fibration property. For completeness, pull back an equivalence $u : C \to D$ over a base along an isofibration $E \to S$. The induced functor on pullbacks is fully faithful because u is. Given an object (d, e) of the target pullback, choose an isomorphism $u(c) \cong d$; its image in S lifts through the isofibration, and the lift changes e to an object lying strictly over the image of c. This produces an object in the source pullback isomorphic to (d, e), proving essential surjectivity. The same reasoning applies after any base change.

We can therefore replace the left leg by $* \xrightarrow{\sim} EG \xrightarrow{p} BG$. In the strict pullback $EG \times_{BG} *$, an object is an element $g \in G$. A morphism from g to h exists precisely when its image hg^{-1} in BG is the identity, which is equivalent to $g = h$. Thus

$$EG \times_{BG} * \cong G_{\mathrm{disc}}.$$

For $G = \mathbb{Z}/2$, the strict pullback has one connected component while the homotopy pullback has two. For a general group, its elements record the possible isomorphisms between the two images of the chosen object of $*$. The derived completion preserves those comparisons.

This is the cospan version of the groupoid computations already used in the commentary on Chapter VI, manuscript p. 107. Its purpose here is narrower: it exhibits the actual fourth vertex produced by the theorem and explains why the maps $* \to BG$ must be replaced. The whole completed square, including its two projections and its map to the original cospan after localization, is the value of i_*.

p. 165

La loi fonctorielle s'obtient à l'aide du lemme 1 p. 249, qui permet de se borner aux arguments $\begin{array}{ccc} X_1 & & \\ {\scriptstyle p_1}\downarrow & & \\ S & \xleftarrow[p_2]{} & X_2 \end{array}$ *tels que* $p_1, p_2 \in Fib_W$*, de sorte que l'on trouve un foncteur*

$$\begin{array}{ccc} X_1 & & \\ \downarrow & & \\ S & \longleftarrow & X_2 \end{array} \quad \longmapsto \quad \begin{array}{ccc} X_1 & \longleftarrow & X_1 \times_S X_2 \\ \downarrow & & \downarrow \\ S & \longleftarrow & X_2, \end{array}$$

compatible aux localiseurs, et passant aux catégories de fractions $\mathrm{Ho}_W(\Psi)$ *et* $\mathrm{Ho}_W(\tilde{\Psi})$ *respectivement.*

NB En procédant de façon similaire, plus simple (sans besoin d'un recours au lemme 1), on trouve l'existence d'un *adjoint à gauche* $i_!$ de $i^* : \mathrm{Ho}_W(\Psi) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi})$, sous réserve de l'existence d'un objet initial φ dans $\mathcal{M}$. Cet foncteur $i_!$ est donné par

[page 255]

$$i_! \left(\begin{array}{ccc} X_1 & & \\ \downarrow & & \\ S & \longleftarrow & X_2 \end{array} \right) \quad = \quad \left(\begin{array}{ccc} X_1 & \longleftarrow & \varphi \\ \downarrow & & \downarrow \\ S & \longleftarrow & X_2 \end{array} \right),$$

la loi fonctorielle étant évidente.

Commentary · Exposition [ms. 254]

The adjunction determines the completion

The adjunction is what makes Grothendieck's construction a canonical completion of a cospan. On the good-diagram categories, restriction $r : \mathcal{G} \to \mathcal{F}$ has right adjoint c, where c supplies the strict pullback. A morphism from a square Q to $c(d)$ is uniquely determined by its three components on the cospan $r(Q)$: the fourth component exists uniquely by the pullback universal property. This gives the adjunction bijection before localization.

The counit $rc \to 1_{\mathcal{F}}$ is the identity on the original three vertices. The unit at a square with fourth vertex T is the map to its completion, whose fourth component is

$$T \longrightarrow A \times_S B.$$

At a completed square this map is the identity, and restricting the unit to its three original vertices also gives the identity. These observations verify both triangle identities directly. Restriction preserves objectwise weak equivalences; the preceding base-change calculation proves that completion does too. The localization lemma on ms. 248 therefore descends the adjunction. Once Lemmas 1 and 2 identify the localized good-diagram categories with the required diagram categories, it is exactly $i^* \dashv i_*$, with invertible counit $i^* i_* \to 1$.

The formula using only one fibrant leg follows by an explicit comparison, not by a symmetry convention. If $A \to S$ is already a W-fibration, replace only B by $\bar{B}$. The map

$$A \times_S B \longrightarrow A \times_S \bar{B}$$

is in W, as in the block at ms. 242, and forms an objectwise weak equivalence between the completed square and one with two good legs. The latter computes i_*. For an arbitrary cospan, first replace A; the same argument compares the one-leg and two-leg formulas. Interchanging A and B gives the other formula. These comparisons concern objects of $\mathrm{Ho}_W(\tilde{\Psi})$ and retain all the projection maps.

There is also the left adjoint mentioned in the concluding NB. If $\mathcal{M}$ has an initial object φ, extending a cospan by putting φ at vertex 3 is left adjoint to restriction already on ordinary diagram categories. The fourth component of any extension of a map of cospans is the unique map $\varphi \to T$. This extension preserves objectwise weak equivalences, since its fourth component on every morphism is 1_φ, so the adjunction descends by the same lemma. It needs no fibrant replacement. The displayed type of i^* in that NB is reversed in the edition; its correct type remains $\mathrm{Ho}_W(\tilde{\Psi}) \to \mathrm{Ho}_W(\Psi)$. Likewise the $\Phi, \tilde{\Phi}$ used on ms. 251–252 denote the $\Psi, \tilde{\Psi}$ of the theorem, not a second pair of diagram shapes.

Commentary · Exposition [ms. 255]

Two extensions of the same cospan

Grothendieck has now reached the point at which a homotopy fibre can be characterized by its relation to all diagrams, rather than by a particular construction of paths. The two extensions of the three-vertex diagram make this distinction visible. Restriction has the direction

$$i^* : \mathrm{Ho}_W(\tilde{\Psi}) \longrightarrow \mathrm{Ho}_W(\Psi).$$

The reversed direction in the preceding NB is an edition slip. Its left adjoint, discussed in the preceding block, fills the fourth vertex with an initial object; its right adjoint fills that vertex with a homotopy pullback. These operations answer different universal problems on the same cospan.

For the right adjoint, the fourth vertex must instead receive a compatible pair of maps. Once the two legs to S are W-fibrations, that universal object is $X_1 \times_S X_2$. The extra work in Lemmas 1 and 2 is what allows this calculation on suitably replaced diagrams to determine a functor and an adjunction on the original localization. The homotopy limit of the cospan is then obtained by evaluating this completed square at vertex 3.

The indexing convention explains the apparently reversed endpoint in the following lemma. An object of $\mathcal{M}(I)$ is a functor $I^{\mathrm{op}} \to \mathcal{M}$. If t is terminal in I, each arrow $i \to t$ induces $F(t) \to F(i)$. A natural transformation from the constant diagram on A to F is consequently determined by its component $A \to F(t)$, and every such component gives a natural transformation. Thus

$$\mathrm{Hom}_{\mathcal{M}(I)}(p^* A, F) \cong \mathrm{Hom}_{\mathcal{M}}(A, F(t)).$$

Evaluation at t is a right adjoint. The displayed formula survives localization because both functors preserve the designated weak equivalences. In particular, the object constructed here is universal for maps of coherent cospans. There is no assertion that taking an ordinary pullback in $\mathcal{M}[W^{-1}]$ would recover it.

Ce n'est pas encore la fin du sorite! Il faut encore interpréter le foncteur composé

$$\mathrm{Ho}_W(\Psi) \xrightarrow{i_*} \mathrm{Ho}_W(\tilde{\Psi}) \xrightarrow{\varepsilon_3^*} \mathrm{Ho}_W(e) = \mathrm{Ho}_W,$$

où

$$\varepsilon_3 : e \xrightarrow{\sim} \{3\} \qquad \longrightarrow \qquad \begin{array}{ccccc} & & 1 & & \\ & \swarrow & & \nwarrow & \\ 3 & & & & 0 \\ & \nwarrow & & \swarrow & \\ & & 2 & & \end{array}$$

est l'inclusion du sommet 3 dans $\tilde{\Psi}$. Si $\mathrm{Ho}_W(\Psi)$ est interprété, conformément au lemme 1, comme $\mathcal{F}W_{\mathcal{F}}^{-1}$, ce foncteur composé n'est autre que

$$\begin{array}{ccc} X_1 & & \\ \downarrow & \longmapsto & X_1 \times_S X_2 \\ S \longleftarrow & X_2 & \end{array}$$

$$\text{(pour } \begin{array}{ccc} X_1 & & \\ {\scriptstyle p_1}\downarrow & & \\ S & \xleftarrow[p_2]{} & X_2 \end{array} \in \mathrm{Ob}\,\mathcal{F}\text{, i.e. } p_1, p_2 \in \mathrm{Fib}_W.)$$

On veut interpréter ce foncteur comme un $\varprojlim$ W-homotopique, i.e. vu comme un 'produit fibré W-homotopique'. De façon précise, on a ceci : p. 166

Corollaire 1. *Considérons $p_\Psi : \Psi \longrightarrow e$, et le foncteur* [page 256]

$$p_\Psi^* : \mathrm{Ho}_W(e) = \mathrm{Ho}_W \longrightarrow \mathrm{Ho}_W(\Psi),$$

déduit par passage aux catégories de fractions du foncteur

$$\begin{array}{ccc} \mathcal{M} & \longrightarrow & \mathcal{M}(\Psi) \\ X & \longrightarrow & \begin{array}{ccc} X & & \\ \downarrow & & \\ X & \longleftarrow & X \end{array} \end{array}.$$

Ce foncteur admet le foncteur $\varepsilon_3^* i_*$ précédent comme adjoint à droite, i.e.

$$p_{\Psi *} = \varepsilon_3^* i_* : \mathrm{Ho}_W(\Psi) \longrightarrow \mathrm{Ho}_W.$$

Démonstration. On peut regarder p_ψ comme le composé

$$\Psi \xrightarrow{i} \tilde{\Psi} \xrightarrow{p_{\tilde{\Psi}}} e,$$

et on a donc

$$p_\Psi^* \simeq i^*(p_{\tilde{\Psi}})^*.$$

Donc l'existence et la détermination d'un adjoint à droite pour p_Ψ^* résultera de l'existence et de la détermination d'adjoints à droite i_*, $(p_{\tilde{\Psi}})_*$ de i^*, $(p_{\tilde{\Psi}})^*$, via [page 257]

$$(p_\Psi)_* \simeq (p_{\tilde{\Psi}})_* i_*. \qquad \text{p. 167}$$

Donc le corollaire 1 résulte de la formule

$$p_{\tilde{\Psi}\,*} = \varepsilon_3^*,$$

qui elle-même est un cas particulier du

Lemme. *Soit I dans* Cat*, avec objet final e, considérons l'inclusion*

$$\varepsilon : e \longrightarrow I, \qquad \text{et } p : I \longrightarrow e.$$

Soit $(\mathcal{M}, W)$ une catégorie de modèles, et considérons

$$\mathrm{Ho}_W(I) \xleftarrow{p^*} \mathrm{Ho}_W.$$

Ce foncteur admet un adjoint à gauche `[plutôt à droite]` *p_*, lequel est isomorphe à ε^*.*

Démonstration. Considérons le couple de foncteurs adjoints

$$\mathcal{M}(I) \underset{p_*=\varprojlim_I}{\overset{p^*}{\leftleftarrows}} \mathcal{M} \quad ;$$

comme I admet l'objet final e, le foncteur p_* est isomorphe à ε^*. Ces foncteurs p^*, ε^* sont compatibles aux localiseurs $W(I)$, W, donc on conclut par le lemme page 248.

Il ne reste plus qu'à prouver les lemmes 1 et 2. Je le ferai demain.

Aujourd'hui, j'ai envie encore de donner les sorites des carrés W-cartésiens dans une [page 258]

Proposition 19 : *Soit* $\begin{array}{ccc} X_1 & \xleftarrow{f_1} & X_3 \\ {\scriptstyle p_1}\downarrow & & \downarrow{\scriptstyle f_2} \\ S & \xleftarrow[p_2]{} & X_2 \end{array}$ *un carré commutatif dans $\mathcal{M}$. Considérons des factorisations de p_1, p_2 en*

$$X_1 \xrightarrow{i_1} \bar{X}_1 \xrightarrow{\bar{p}_1} S, \qquad X_2 \xrightarrow{i_2} \bar{X}_2 \xrightarrow{\bar{p}_2} S,$$

$i_1, i_2 \in W$, $\bar{p}_1, \bar{p}_2 \in F_W$ `[= Fib`$_W$`]`, et considérons les flèches induites par $X_3 \longrightarrow X_1 \times_S X_2$ ($\bar{X}_1 \times_S X_2$ déduite de Q) via $X_1 \times_S X_2 \longrightarrow \begin{array}{c} \nearrow \bar{X}_1 \times_S X_2 \\ \longrightarrow\ \bar{X}_1 \times_S \bar{X}_2 \\ \searrow X_1 \times_S \bar{X}_2 \end{array}$ *, de sorte qu'on trouve un diagramme commutatif*

$$\begin{array}{ccc} & & \bar{X}_1 \times_S X_2 \\ & \overset{\pi_1}{\nearrow} & {\scriptstyle j_2}\downarrow \\ X_3 & \underset{\pi_2}{\overset{\pi_0}{\longrightarrow}} & \bar{X}_1 \times_S \bar{X}_2 \\ & \underset{\pi_2}{\searrow} & {\scriptstyle j_1}\uparrow \\ & & X_1 \times_S \bar{X}_2, \end{array}$$

où $j_1 = i_1 \times_S \mathrm{id}_{\bar{X}_2}$ et $j_2 = \mathrm{id}_{\bar{X}_1} \times i_2$ sont dans W (car i_1 et i_2 le sont, et $\bar{X}_1$ et $\bar{X}_2$ sont dans $\underline{\mathrm{Fib}}_W S$). On a donc

$$(\pi_1 \in W) \qquad \Longleftrightarrow \qquad (\pi_2 \in W) \qquad\qquad (\Longleftrightarrow \ \pi_0 \in W),$$

ce qui prouve que la condition $\pi_1 \in W$, qui semble dépendre du choix de la factorisation par i_1, n'en dépend pas, et idem pour $\pi_2 \in W$, et pour $\pi_0 \in W$ (qui semble dépendre à la fois de i_1, et de i_2).

Commentary · Exposition [ms. 258]

Independence of replacements and invariance of the test

Grothendieck wants the property of a square to be independent of the auxiliary factorization used to recognize it. Proposition 19 achieves this with a particularly economical comparison: one changes the first leg while holding the second fixed, then exchanges their roles. We spell out the argument because it also supplies the invariance used in the next pasting proof.

Write a square as $D \to A$, $D \to B$ over the cospan $A \to S \leftarrow B$. Choose $A \xrightarrow{a} \bar{A} \to S$ and $B \xrightarrow{b} \bar{B} \to S$ as in the proposition. The two arrows

$$\bar{A} \times_S B \longrightarrow \bar{A} \times_S \bar{B}, \qquad A \times_S \bar{B} \longrightarrow \bar{A} \times_S \bar{B}$$

are in W, since each pulls back a member of W along a W-fibration. Thus the three comparison maps from D are simultaneously in W. Now choose a second factorization of $A \to S$, retaining the chosen factorization of $B \to S$. Both first-leg tests are equivalent to the very same test $D \to A \times_S \bar{B}$. They therefore agree. The argument with A and B interchanged proves independence of the other choice. No map between the two factorizations of A has been assumed.

For the pasting argument we also need the following verification. Suppose a map of squares $Q \to Q'$ is in W at all four vertices. Denote the cospans by $A \to S \leftarrow B$ and $A' \to S' \leftarrow B'$, and choose a factorization

$$A' \xrightarrow{a'} \widehat{A}' \xrightarrow{q'} S', \qquad a' \in W, \quad q' \in \mathrm{Fib}_W.$$

Set $T = S \times_{S'} \widehat{A}'$. The projection $T \to \widehat{A}'$ is in W, being the pullback of $S \to S'$ along q'. The induced $A \to T$ is in W by two-out-of-three, since its composite to $\widehat{A}'$ is $A \to A' \xrightarrow{a'} \widehat{A}'$. Moreover $T \to S$ is a W-fibration. This is an admissible replacement of the first leg of Q.

With these choices the comparison of the two pullback objects is

$$T \times_S B \cong \widehat{A}' \times_{S'} B \longrightarrow \widehat{A}' \times_{S'} B'.$$

It is in W, since it is obtained by pulling back $B \to B'$ along the pullback of q'. The square relating these objects to $D \to D'$ commutes. Its vertical arrows are in W, so two-out-of-three shows that the comparison for Q is in W if and only if that for Q' is. This proves invariance under objectwise weak equivalences, and hence under zigzags of them, using only the factorization hypothesis and the intrinsic definition of Fib_W. Strong saturation, functorial choices of factorization, and the deferred adjunction lemmas are unnecessary for this particular assertion.

Définition. *Quand ces conditions sont satisfaites, on dit que le carré Q est W-cartésien.* p. 168

Corollaire 1. *Si Q est W-cartésien, alors l'image de Q dans $\mathrm{Ho}_W(\tilde{\Psi})$ est dans l'image essentielle de* [page 259]

$$i_* : \mathrm{Ho}_W(\Psi) \longrightarrow \mathrm{Ho}_W(\tilde{\Psi}),$$

i.e. la flèche canonique dans $\mathrm{Ho}_W(\tilde{\Psi})$

$$Q \longrightarrow i_* i^* Q$$

est [un] *isomorphisme. La réciproque est vraie si W est fortement saturé.*

Commentary · Exposition [ms. 259]

The unit and the role of strong saturation

Grothendieck now compares his concrete test with the intrinsic language of homotopy Kan extension. This comparison separates two tasks which coincide in the familiar examples: constructing an isomorphism after localization, and recognizing that a specified original arrow belongs to W.

Let Q^r be obtained by replacing $X_1 \to S$ and $X_2 \to S$ by $\bar{X}_1 \to S$ and $\bar{X}_2 \to S$, while keeping X_3 and S. There is an objectwise weak equivalence $Q \to Q^r$. The unit on Q^r is represented by the map to the completed pullback square which is the identity on $\bar{X}_1$, $\bar{X}_2$, and S, and is

$$\pi_0 : X_3 \longrightarrow \bar{X}_1 \times_S \bar{X}_2$$

at the fourth vertex. If $\pi_0 \in W$, this map of squares becomes an isomorphism. Naturality of the unit then gives the assertion for Q.

Conversely, if the unit on Q is invertible, the unit on Q^r is invertible. Evaluation at vertex 3 shows that π_0 is inverted by $\mathcal{M} \to \mathcal{M}[W^{-1}]$. Strong saturation says exactly that this forces $\pi_0 \in W$. Two-out-of-three by itself makes no such assertion about every map inverted by localization. This is the reason for the qualification in Corollary 1, rather than an incidental technical precaution.

Since $i^* i_* \cong \mathrm{id}$, the right adjoint is fully faithful, and the usual adjunction argument identifies its essential image with the squares whose unit is invertible. In modern derivator terminology this essential-image condition defines cartesian squares; the concrete W test agrees with it under the saturation hypothesis just explained. See Groth (2013, Proposition 1.20 and Lemma 1.21) for the fully faithful Kan-extension formulation. That formulation presupposes the construction of the adjunction, so it does not by itself discharge the two deferred localization lemmas in this manuscript.

Corollaire 2. *Considérons un diagramme commutatif dans* $\mathcal{M}$

$$\text{(D)} \qquad \begin{array}{ccccc} X'_0 & \longleftarrow & X'_1 & \longleftarrow & X'_2 \\ \downarrow & 1 & \downarrow & 2 & \downarrow \\ X_0 & \longleftarrow & X_1 & \longleftarrow & X_2, \end{array}$$

d'où deux carrés commutatifs 1, 2, et un carré composé

$$\begin{array}{ccc} X'_0 & \longleftarrow & X'_2 \\ \downarrow & 3 & \downarrow \\ X_0 & \longleftarrow & X_2. \end{array}$$

Supposons le carré 1 W-cartésien. Alors le carré 2 est W-cartésien si et seulement si le carré 3 l'est.

Démonstration. Considérons une factorisation de $\begin{array}{c} X'_0 \\ \downarrow \\ X_0 \end{array}$ en

$$\begin{array}{ccc} \bar{X}'_0 & \longleftarrow & X'_0 \\ & \searrow & \downarrow \\ & & X_0 \end{array}$$

avec $(X'_0 \longrightarrow \bar{X}'_0) \in W$, et $(\bar{X}'_0 \longrightarrow X_0) \in \mathrm{Fib}_W$. On peut alors remplacer dans (D) X'_0 par $\bar{X}'_0$, obtenant un diagramme $(\bar{D})$, et on voit aussitôt que chacun des carrés 1(D), 2(D), 3(D) est W-cartésien si et seulement si le carré correspondant $1(\bar{D})$, $2(\bar{D})$ ou $3(\bar{D})$ l'est. Cela montre qu'on peut supposer $X_0 \longrightarrow S$ dans $\mathrm{Fib}_W S$. Considérons alors le diagramme commutatif déduit de (D) p. 169 [page 260]

$$\begin{array}{ccccccc} X'_0 & \longleftarrow & \tilde{X}'_1 \overset{\text{déf}}{=} X'_0 \times_{X_0} X_1 & \overset{\alpha}{\longleftarrow} & X'_1 & \longleftarrow & X'_2 \\ \downarrow & & \downarrow & & & & \downarrow \\ X_0 & \longleftarrow & X_1 & \longleftarrow & & & X_2, \end{array}$$

où $\alpha \in W$ en vertu de l'hypothèse W-cartésienne sur le carré 1. On voit encore que le carré 2 est W-cartésien si et seulement si le carré correspondant avec X'_1 remplacé par $\tilde{X}'_1$ l'est, quant aux carrés 1, 3, ils ne changent pas par cette modification. Cela montre qu'on peut supposer le carré 1 *cartésien*. Considérons alors le diagramme

$$\begin{array}{ccccccc} X'_0 & \longleftarrow & X'_1 & \longleftarrow & \tilde{X}'_2 \overset{\text{déf}}{=} X'_1 \times_{X_1} X_2 & \overset{\beta}{\longleftarrow} & X'_2 \\ {\scriptstyle \mathrm{Fib}_W}\downarrow & \text{cart.} & \downarrow{\scriptstyle \mathrm{Fib}_W} & \text{cart.} & \downarrow{\scriptstyle \mathrm{Fib}_W} & & \\ X_0 & \longleftarrow & X_1 & \longleftarrow & X_2. & & \end{array}$$

Alors la proposition 19 et la définition montrent que le carré 2 est W-cartésien si et seulenment si $\beta \in W$, et de même pour le carré 3. Ce qui achève la démonstration.

Commentary · Exposition [ms. 260]

Pasting reduces two questions to the same arrow

Grothendieck's proof makes pasting effective by arranging that the first square is an actual pullback along a W-fibration. The apparently immediate replacements in the proof are justified by the objectwise invariance established in our preceding block. The printed phrase $X_0 \to S \in \mathrm{Fib}_W S$ should be read as $X_0' \to X_0 \in \mathrm{Fib}_W$; it is the latter arrow that has just been factored.

Write $E \to X_0$ for a fibrant replacement of $X_0' \to X_0$. Replacing X_0' by E changes neither relevant cartesianness test. Because the first square is W-cartesian, its comparison

$$X_1' \longrightarrow E \times_{X_0} X_1$$

is in W. We may therefore replace X_1' by $E_1 = E \times_{X_0} X_1$, preserving the test for the second square. The first square is now strictly cartesian, and $E_1 \to X_1$ is a W-fibration.

Both remaining conditions are consequently tested by the one arrow

$$X_2' \longrightarrow E_1 \times_{X_1} X_2 \cong E \times_{X_0} X_2.$$

Using the expression on the left tests the second square; using the expression on the right tests the outer rectangle. The two conditions are identical. This proves both the composition implication and its indicated cancellation, without assuming that arbitrary base change preserves W.

The result became a basic part of the calculus of derivators (Groth, 2013, Proposition 3.13). Its orientation matters: in the manuscript the horizontal arrows point towards the left, so its left-hand square is the square adjacent to the common target. One cannot replace the hypothesis by either small square indiscriminately in an unstable theory.

Corollaire 2. *Soit*
$$\begin{array}{ccc} X_1 & \xleftarrow{f_2} & X_3 \\ {\scriptstyle p_1}\downarrow & & \downarrow{\scriptstyle f_1} \\ S & \xleftarrow[p_2]{} & X_2 \end{array}$$
un carré W-cartésien. Alors

$$\begin{aligned} p_1 \in W \quad &\Longrightarrow \quad f_1 \in W \\ p_2 \in W \quad &\Longrightarrow \quad f_2 \in W, \end{aligned}$$

plus précisément, si $p_i \in W$, alors Q est W-cartésien si et seulement si $f_i \in W$.

Supposons $p_1 \in W$. Alors dans la factorisation de p_1 en $X_1 \longrightarrow \bar{X}_1 \longrightarrow S$, on peut prendre $\bar{X}_1 = S$. Donc le carré est W-cartésien si et seulement si [page 261]

$$(X_3 \longrightarrow \bar{X}_1 \times_S X_2 = X_2) \in W,$$

i.e. $f_1 \in W$, q.e.d.

Bien sûr, on ne peut en général affirmer les implications inverses : $f_i \in W$ n'implique nullement $p_i \in W$.

Commentary · Examples [ms. 261]

A nonempty counterexample to the converse

Grothendieck's final caution about cartesian squares concerns a loss of information under restriction to part of the base. A finite example already shows the issue, without empty objects or any higher homotopy calculation.

Take $\mathcal{M} = \mathrm{Set}$ and let W be the bijections. Every map is an intrinsic W-fibration, and the identity followed by the given map provides the required factorization. Put

$$S = \{0,1\}, \quad X_1 = \{a,b,c\}, \quad X_2 = \{0\}, \qquad p_1(a) = 0, \quad p_1(b) = p_1(c) = 1,$$

and let p_2 be the inclusion of $\{0\}$ in S. The pullback is $X_3 = \{a\}$. Its projection $f_1 : X_3 \to X_2$ is a bijection, whereas $p_1 : X_1 \to S$ is not. The square is strictly cartesian and hence W-cartesian.

Only the fibre over 0 has been tested. Nothing in the upper projection records the two elements over 1. The forward assertion in the source has no such problem: if $p_1 \in W$, use the factorization $X_1 \xrightarrow{p_1} S \xrightarrow{\mathrm{id}} S$, and the cartesianness comparison is precisely f_1. The later appendix will ask for a converse to the analogous pushout statement. That converse is an additional conservativity condition, rather than a formal consequence of the existence of homotopy pushouts.

p. 170

Tous ces résultats, et la notion de carré W-cartésien, se dualisent (moyennant l'axiome idoine de factorisation à droite, cf. page 240) en une théorie des sommes amalgamées W-homotopiques, et des carrés W-cocartésiens. Cette fois on travaille avec la catégorie

$$\Phi = \begin{pmatrix} & & 1 \\ & \swarrow & \\ 0 & & \\ & \nwarrow & \\ & & 2 \end{pmatrix} \qquad \overset{j}{\hookrightarrow} \qquad \tilde{\Phi} = \begin{pmatrix} & & 1 & & \\ & \swarrow & & \nwarrow & \\ 0 & & & & 3 \\ & \nwarrow & & \swarrow & \\ & & 2 & & \end{pmatrix},$$

j étant une immersion fermée. On a un foncteur restriction

$$j^* : \mathrm{Ho}_W(\tilde{\Phi}) \longrightarrow \mathrm{Ho}_W(\Phi),$$

dont on construit un adjoint à gauche

$$j_! : \mathrm{Ho}_W(\Phi) \longrightarrow \mathrm{Ho}_W(\tilde{\Phi}).$$

Et on trouve une notion naturelle de carré W-cocartésien, qui paraît irréprochable à tout points de vue, et d'une simplicité parfaite. [page 262]

Cela amène à revoir la notion en question dans Cat, où elle avait l'air très astucieuse, profonde et un peu obscure, avec des intégrales et tout ça. C'est le moment de se rendre compte que 'ce n'est que ça'. Donc de prouver la

Proposition 20. *Supposons $\mathcal{M} = \mathrm{Cat}$, W un localiseur fondamental satisfaisant W(7 bis). Considérons un carré commutatif dans* Cat

$$Q = \begin{pmatrix} S & \longrightarrow & X_1 \\ \downarrow & & \downarrow \\ X_2 & \longrightarrow & X_3 \end{pmatrix}.$$

Pour qu'il soit W-cartésien [plutôt W-cocartésien] *au sens de la théorie développée ici (pour des catégories de modèles générales), il faut et il suffit que*

$$\varphi_Q : \quad \mathcal{X}_Q = \begin{pmatrix} & & X_1 \\ & \swarrow & \\ \int S & & \\ & \nwarrow & \\ & & X_2 \end{pmatrix} \qquad \longrightarrow \qquad X_3$$

[plutôt

$$\varphi_Q : \quad \mathcal{X}_Q = \begin{pmatrix} & & X_1 \\ & \nearrow & \\ \int S & & \\ & \searrow & \\ & & X_2 \end{pmatrix} \qquad \longrightarrow \qquad X_3]$$

p. 171

soit dans W. (NB L'intérêt de ce critère est qu'il est 'intrinsèque' à Q, ne faisant pas appel à une factorisation de β_1 ou de β_2 [où $\beta_i : S \longrightarrow X_i$] en $S \xrightarrow{\in \mathrm{Cof}_W} \tilde{X}_i \xrightarrow{\in W} X_i$. Cf. application intéressante dans section V 3.4., p. 146 ff., th. 4 et corollaires.)

Commentary · Later developments [ms. 262]

The integral as a categorical homotopy pushout

Grothendieck wants to identify the abstract operation just constructed with the categorical integral used earlier in the chapter. Proposition 20 says that the older construction was already providing a model for the same homotopy pushout. Its advantage is that the comparison can be read directly from the original square.

Here Φ has arrows $1 \to 0 \leftarrow 2$, and the diagram of categories is contravariant: its data are $X_1 \leftarrow S \to X_2$. The associated fibred Grothendieck construction has objects (i, x), with x an object of the fibre at i. For $\alpha : i \to j$, a morphism over α is a map $x \to F(\alpha)(y)$ in the fibre at i. A compatible cocone to X_3 gives the displayed functor φ_Q.

For ordinary weak homotopy equivalences, this interpretation is the content of Thomason's homotopy-colimit theorem: the classifying space of the integral models the homotopy colimit of the classifying spaces of the diagram (Thomason, 1979, Theorem 1.2). We checked its statement and a later proof in Chachólski and Scherer (2001, Theorem 26.8 and Corollary 26.9); the verification note distinguishes this from inspection of the original 1979 proof. In the present shape it gives

$$|N\mathcal{X}_Q| \simeq |NX_1| \amalg^h_{|NS|} |NX_2|.$$

The fibred version follows from the usual covariant theorem by applying it to the opposite fibre categories on Φ^{op} and then taking the opposite total category. Taking opposites leaves classifying spaces canonically homeomorphic. The equivalence explains the notation, but the manuscript's argument addresses a general W under its stated axioms, rather than only W_∞.

Its proof has one directional slip worth resolving before following the reduction. The transformation $\alpha : \tilde{Q} \to Q$ induces

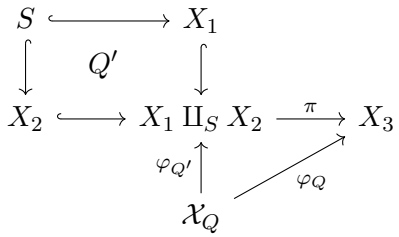
$$\lambda : \mathcal{X}_{\tilde{Q}} \longrightarrow \mathcal{X}_Q, \qquad \varphi_{\tilde{Q}} = \varphi_Q \lambda.$$

The edition reverses the horizontal arrow in this triangle. With the correct direction, the fibrewise weak-equivalence assertion gives $\lambda \in W$, and two-out-of-three gives the required equivalence of tests. Footnote 134 expressly identifies the strong localization axiom used for this step; it should not be silently dropped when W is left arbitrary.

After both legs have been replaced by Dwyer immersions, put $P = X_1 \amalg_S X_2$. The earlier result on pushouts of these immersions supplies $\mathcal{X}_Q \to P$ in W. The map to X_3 factors as $\mathcal{X}_Q \to P \xrightarrow{\pi} X_3$, so $\varphi_Q \in W$ if and only if $\pi \in W$. The integral and the abstract replacement criterion therefore agree. None of this requires the reverse assertion that a homotopy pushout reflects weak equivalences in an attached leg; that separate condition enters the appendix.

Démonstration. Considérons une factorisation de $S \longrightarrow X_1$ en [page 263]

$$S \xrightarrow{i_1} \tilde{X}_1 \xrightarrow{p_1} X,$$



avec i_1 immersion ouverte de Dwyer, $p_1 \in W$. Donc on a un carré commutatif

$$\tilde{Q} = \begin{pmatrix} S & \xhookrightarrow{\mathrm{Dw}} & \tilde{X}_1 \\ \downarrow & & \downarrow \\ X_2 & \longrightarrow & X_3 \end{pmatrix}$$

et un homomorphisme $\tilde{Q} \xrightarrow{\alpha} Q$ qui est l'identité sur les trois sommets distincts de $\tilde{X}_1$, et qui est p_1 en $\tilde{X}_1$. On en déduit un diagramme commutatif

$$\begin{array}{ccc} \mathcal{X}_Q & \xrightarrow{\mathcal{X}_\alpha = \lambda} & \mathcal{X}_{\tilde{Q}} \\ & {\scriptstyle \varphi_Q} \searrow \quad \swarrow {\scriptstyle \varphi_{\tilde{Q}}} & \\ & X_3, & \end{array}$$

et on a $\lambda \in W$ (car c'est une Φ-flèche de catégories fibrées sur Φ, qui induit une W-équivalence sur chacune de trois fibres.) Donc $\varphi_Q \in W \iff \varphi_{\tilde{Q}} \in W$, d'autre part il est clair que Q est W-cocartésien si et seulement si $\tilde{Q}$ l'est. Donc on peut supposer que $S \hookrightarrow X_1$ est [une] immersion ouverte (de Dwyer) ([134]). Appliquant ceci en changeant les rôles de X_1 et X_2, on [page 264] voit qu'on peut supposer de plus que $S \longrightarrow X_2$ est également [une] immersion ouverte de Dwyer. Considérons alors

On a $\varphi_Q = \pi\varphi_{Q'}$, d'autre part on sait que $\varphi_{Q'} \in W$ (cor. 3, p. 149). Donc p. 172

$$\pi \in W \qquad \Longleftrightarrow \qquad \varphi_Q \in W,$$

où $\pi \in W$ signifie que Q est W-cocartésien, q.e.d.

[page 265]

Commentary · Examples [ms. 264]

A four-object circle behind a strict pushout

Return to the two-point span whose cylinder cofiber was calculated at ms. 230. The integral gives a smaller categorical model of the same circle, and explains why the word "homotopy" cannot be omitted from Proposition 20. Let S be the discrete category on two objects a, b, and take $X_1 = X_2 = e$, both maps $S \to e$ being the unique functor. The ordinary pushout in Cat is e.

The fibred integral of this span has four objects, which we denote u, v, a, b. Its only nonidentity arrows are

$$u \longrightarrow a, \qquad u \longrightarrow b, \qquad v \longrightarrow a, \qquad v \longrightarrow b.$$

There are no composable pairs of nonidentity arrows. Thus its nerve has four vertices, four nondegenerate edges, and no nondegenerate simplices of dimension at least two. Its realization is the four-edge cycle, homeomorphic to a circle. Equivalently, the cellular boundary map has rank three, so its first homology is $\mathbb{Z}$.

The comparison $\mathcal{X}_Q \to e$ therefore fails to be in W_∞. The strict pushout square is not a homotopy pushout, and its actual homotopy pushout has the homotopy type of S^1. This four-edge circle and the earlier eight-edge cylinder cofiber both model the suspension of the two-point space. Neither original leg $S \to e$ is a Dwyer immersion: both identify the two objects. Replacing these legs before taking the ordinary pushout is precisely what preserves the missing circle. The example also fixes the variance of the integral without relying on a pictorial convention for its arrows.

8 Appendice : Retour sur les axiomes W(7), W(7 bis) (pages 75, 76).

([135]). On a vu (prop. 6, p. 78) que W(7 bis) implique W(7). Montrons une réciproque partielle.

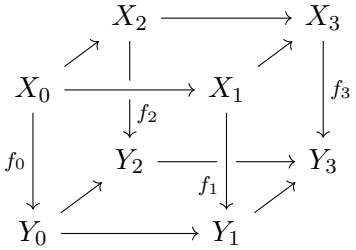
135. Reflexion provisoire, supplanté par XVI.

Commentary · Exposition [ms. 265]

What the two converse gluing assertions require

Grothendieck wants to recognize a weak equivalence from the pieces of a decomposition. The familiar direction starts with equivalences on the common part and the two pieces and concludes that their homotopy pushouts are equivalent. His appendix asks for two converses: can the common part be recovered from the pieces and their union, and can the pieces be recovered from the common part and their union? These are substantive additions to homotopy-colimit invariance.



Write a square as $A \to B$, $A \to C$, with fourth vertex P, and write

$$C_e(u) = e \amalg^{\mathrm{h}}_{\mathrm{dom}(u)} \mathrm{cod}(u)$$

for the homotopy cofiber formed using the terminal object e. Whenever the square is a homotopy pushout, an equivalence $A \to B$ gives an equivalence $C \to P$. Grothendieck's conservative axiom asks for the converse as well. Applying that converse to the defining square of $C_e(u)$ says that a terminal homotopy cofiber detects an equivalence. This detection property is the extra ingredient in the proposition, through the full hypothesis W(7 bis).

It is useful to keep the three levels separate as the proof unfolds. Invariance of a homotopy pushout is formal once a coherent homotopy-colimit theory exists. The fact that an equivalence has terminal homotopy cofiber is equally formal. The converse, that terminal cofiber forces equivalence, is generally false for spaces; a complete example appears below. Thus the proposition under W(7 bis) and the later theorem for a general category of models must be read with different hypotheses. The last theorem drops an assumption that its third assertion still needs.

Proposition. *Supposons* W(7 bis) (axiome du carré cocartésien) *satisfait, et plaçons nous sous les conditions de l'énoncé de* W(7), *et plus généralement, dans le cas d'un diagramme cubique*

où les deux carrés X et Y (face supérieure et inférieure du cube) sont W-cocartésiens. Considérons les conditions suivantes sur ce diagramme

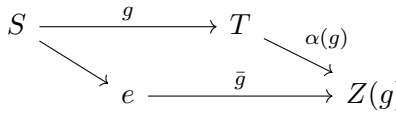
a) $f_0 \in W$.

b) f_1 *et* $f_2 \in W$.

c) $f_3 \in W$.

Alors on a les implications

$$a \ \& \ b \Longrightarrow c, \qquad b \ \& \ c \Longrightarrow a.$$

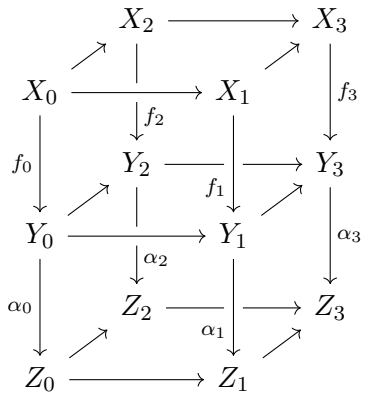


De plus, si W est stable par facteurs directs (p. ex. W fortement saturé), alors on a aussi

$$a \ \& \ c \Longrightarrow b,$$

donc la conjonction [de] *deux quelconques parmi les conditions a) b) c) implique la troisième.*

Démonstration. Utilisant la factorisation fonctorielle d'une flèche quelconque (ici les f_i) en pi, avec i immersion ouverte de Dwyer et $p \in W$ (p. 229), on est remené au cas où les f_i sont des immersions ouvertes de Dwyer. Mais pour toute flèche $g : S \longrightarrow T$ qui est dans Cof_W, soient $Z(g)$ son mapping-cone



p. 173
[page 266]

et

$$\alpha(g) : T = \mathrm{but}(g) \longrightarrow Z(g)$$

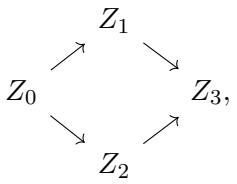
la flèche canonique ([136]). Celle-ci est fonctorielle en g, de sorte que le diagramme cubique donné se prolonge en un double cube

avec

$$Z_i = Z(f_i),\ \alpha_i = \alpha(f_i) \qquad \text{pour } i \in \{0,1,2,3\}.$$

Notons que W(7 bis) implique que si $g \in \mathrm{Cof}_W$, on a

[page 267]



$$g \in W \qquad \Longleftrightarrow \qquad \bar{g} \in W, \qquad \text{i.e. } Z(g) \text{ } W\text{-asphérique},$$

en particulier

$$f_i \in W \qquad \Longleftrightarrow \qquad Z_i \text{ } W\text{-asphérique}.$$

Ainsi, l'énoncé à prouver sur le cube initial se ramène à un énoncé sur le carré

p. 174

savoir que les trois conditions

a′) Z_0 W-asphérique.

b′) Z_1 et Z_2 W-asphériques.

c′) Z_3 W-asphérique.

donnant lieu aux implications

$$\mathrm{a}' \ \&\ \mathrm{b}' \Longrightarrow \mathrm{c}', \qquad \mathrm{b}' \ \&\ \mathrm{c}' \Longrightarrow \mathrm{a}',$$

et que si W est stable par facteurs directs, alors

$$\mathrm{a}' \ \&\ \mathrm{c}' \Longrightarrow \mathrm{b}'.$$

C'est à peu de choses près le corollaire de la page 76, complété à la page 77 (corollaire), à cela près qu'on y suppose les flèches des immersions ouvertes, et le carré cartésien (donc aussi cocartésien) dans Cat, i.e. $Z_3 = Z_1 \cup Z_2$, $Z_0 = Z_1 \cap Z_2$. Mais ce qui importe pour la validité de cet énoncé, c'est (on s'en doute) que Z_* soit W-cocartésien. Donc il faut d'abord prouver ceci.

[page 268]

136. C'est un peu vif, car il n'est pas clair que $X_1' \amalg_{X_0} X_2' \longrightarrow X_1 \amalg_{X_0} X_2$ soit `[dans]` W, sans utiliser déjà un des trois ingrédients de W(7) (savoir $f_0, f_1, f_2 \in W \implies f_3 \in W$). Il semble donc que notre argument ne marche que moyennant une hypothèse supplémentaire de cet ordre …Mais il y a le *lemme de Brown,* cf. XVI §3, notamment p. 20.

Commentary · Context [ms. 267]

The gluing step that Brown supplies

The factorization into a Dwyer immersion and a weak equivalence gives Grothendieck an explicit replacement of every vertical edge. To use the replacement on an entire cube, however, one must know that the induced replacement of a pushout is again a weak equivalence. Footnote 136 identifies this dependence. It is a gap in the chosen proof, not a counterexample to the conditional proposition.

The later discussion is unusually precise about the dependency. In Chapter XVI, Commentaire 3.2, Grothendieck observes that the appendix had used the fact that Dwyer immersions are W-cofibrations at a point where his earlier proof of that fact already used a gluing assertion. Lemma 3.2.1 and Corollary 3.2.2 isolate the required Brown lemma; Proposition 3.3 then records the intended equivalence of the strong axioms. The chapter identifies the repair but also says explicitly that its author does not have a proof of that lemma there (Grothendieck, 1991c, §3, ms. pp. 18–23).

Here is the precise external result that closes this dependency. Suppose a class C contains the isomorphisms and all maps from an initial object, is stable under composition and pushout, and every map factors as a member of C followed by a weak equivalence. Suppose also that pushout preserves $C \cap W$. These are the relevant axioms of a category of cofibrant objects. Brown's gluing lemma implies that pushing any weak equivalence out along a member of C preserves weak equivalences. In Brown's original formulation this is the dual of Part I, §4, Lemma 2; the proof uses his factorization lemma and the invariance result in Lemma 1 (Brown, 1973, pp. 428–429). With C the Dwyer immersions, this yields $C \subseteq \mathrm{Cof}_W$ and legitimizes the replacement of the cube. No converse detection property is supplied by Brown's lemma; that remains the role of W(7 bis).

Lemme. *Si le diagramme cubique p. 265 est tel que les faces X, Y soient W-cocartésiennes, et les f_i ($i \in \{0,1,2,3\}$) des W-cofibrations, alors le carré Z des cofibres des f_i est lui aussi W-cocartésien.*

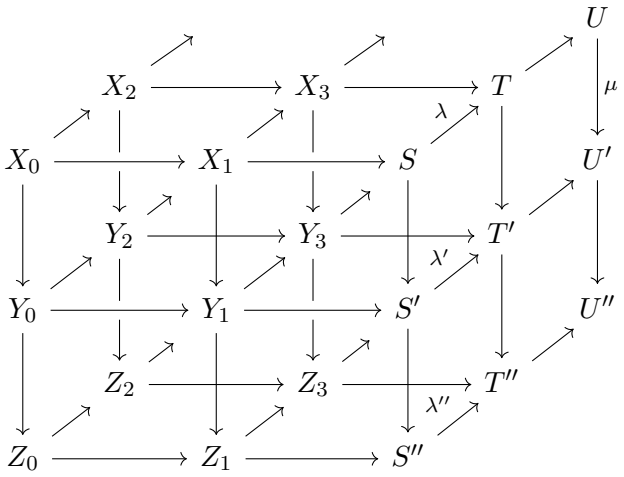
Ce lemme résulte de la théorie du 'déploiement des diagrammes cubiques', relatif à une catégorie de modèles $(\mathcal{M}, W)$ admettant une théorie des cofibres W-homotopiques, qu'il me faudra bien écrire! (Mais l'existence pour (Cat, W) d'une telle théorie des cofibres W-homotopiques, et par suite de celle des déploiements des diagrammes dans $\mathcal{M}$ de type $(\mathbf{\Delta}^1)^I$, I ensemble d'indices fini, ne dépend que de W(7 bis) - on n'a pas à faire appel à W(7).)

Commentary · Exposition [ms. 268]

Taking cofibers commutes with the pushout

The useful part of Grothendieck's large diagram is the compatibility of two successive homotopy pushouts. We can prove the lemma on p. 268 directly from this compatibility, without using the claim that a terminal cofiber detects an equivalence.

Let $J = (1 \leftarrow 0 \rightarrow 2)$, and let $X \to Y$ be a coherent morphism of homotopy-pushout squares in a homotopy theory with a terminal object and finite homotopy colimits. Put $Z_j = C_e(X_j \to Y_j)$. Computing the colimit in the two orders gives



$$\begin{aligned} \operatorname*{hocolim}_{j\in J} Z_j &\simeq \left(\operatorname*{hocolim}_{j\in J} Y_j\right) \amalg^{\mathrm{h}}_{\operatorname{hocolim}_{j\in J} X_j} \left(\operatorname*{hocolim}_{j\in J} e\right) \\ &\simeq Y_3 \amalg^{\mathrm{h}}_{X_3} e = Z_3. \end{aligned}$$

The first equivalence is the interchange of colimits of the single diagram indexed by J and the cofiber span. The constant span $e \leftarrow e \rightarrow e$ has homotopy pushout e, which proves the second equivalence. Under these identifications the comparison map is the one in the given square Z, so this proves the lemma, including its compatibility with the prescribed edges. In derivator language the same calculation is the composition of left Kan extensions, with the parameter retained; the pointwise criterion is Groth (2013, Corollary 3.14).

This proof also locates the excessive assertion on p. 269. From $u \in W$ one may conclude $C_e(u) \simeq e$ in any such theory. Going back from $C_e(u) \simeq e$ to $u \in W$ uses conservativity. The full W(7 bis) hypothesis permits that return, but the statement that the whole reduction used only its forward half is false. The pointwise-cofiber lemma survives without the reverse half; the reduction of all three cube implications does not.

Ce 'deploiement' est un diagramme infini dont toutes les suites infinies, dans les trois directions des axes de coordonnées, sont des 'suites de suspension'. Je reproduis la partie utile du déploiement.

p. 175

La condition que X soit W-cocartésien s'exprime par $\lambda \in W$, ou encore par $U \in \mathrm{Asph}_W$ (car U s'identifie à la cofibre homotopique $Z(\lambda)$ de λ …), de même Y W-cocartésien s'exprime par $U' \in \mathrm{Asph}_W$, et Z W-cocartésien par $U'' \in \mathrm{Asph}_W$. Or $U'' \sim Z(\mu)$, où $\mu : U \longrightarrow U'$ est dans W si U, U' sont W-asphériques, donc $U'' = Z(\mu)$ est alors W-asphérique. Cela prouve le lemme.

Cela montre que, moyennant W(7 bis) (en fait, on a utilisé seulement la partie 'universelle' de W(7 bis)), savoir que dans $\begin{array}{ccc} T_0 & \longrightarrow & T_2 \\ {\scriptstyle i}\searrow & & \searrow{\scriptstyle i'} \\ & T_1 & \longrightarrow & T_3 \end{array}$ diagramme cocartésien d'immersions ouvertes, $i \in W \Longrightarrow i' \in W$ (au lieu de $\Longleftrightarrow$),

[page 270]

la validité de W(7) se ramène au cas où le carré Y est le carré trivial $\begin{array}{ccc} & e & \\ e & & e \\ & e & \end{array}$, e

l'objet final de Cat.

On peut maintenant conclure : On a (moyennant la partie directe de W(7 bis))

$$\mathrm{a}' \;\&\; \mathrm{b}' \Longrightarrow \mathrm{c}',$$

car si Z_0, Z_1 sont $\in \mathrm{Asph}_W$, alors $i_1 \in W$, donc $j_1 \in W$, et si de plus $Z_2 \in \mathrm{Asph}_W$, on a donc $Z_3 \in \mathrm{Asph}_W$.

$$\begin{array}{ccccc} & & Z_1 & & \\ & {\scriptstyle i_1}\nearrow & & \searrow{\scriptstyle j_2} & \\ Z_0 & & & & Z_3 \\ & {\scriptstyle i_2}\searrow & & \nearrow{\scriptstyle j_1} & \\ & & Z_2 & & \end{array}$$

Si on a aussi la partie inverse ('inhabituelle') de W(7 bis), alors

$$\mathrm{b}' \;\&\; \mathrm{c}' \Longrightarrow \mathrm{a}',$$

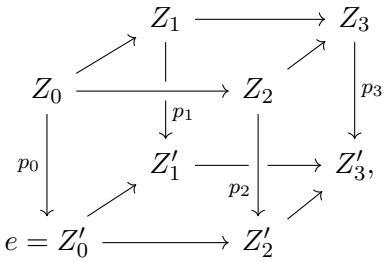
car si Z_1 et Z_3 sont W-asphériques, alors $j_2 \in W$, donc $i_2 \in W$, et si de plus Z_2 est W-asphérique, on conclut Z_0 W-asphérique.

Enfin, supposons que W soit *stable par facteurs directs,* et W(7 bis) satisfait sous forme directe. Je dis qu'alors

p. 176

$$\mathrm{c}' \;\&\; \mathrm{a}' \Longrightarrow \mathrm{b}',$$

i.e.



$$Z_0 \text{ et } Z_3 \ \in \mathrm{Asph}_W \qquad \Longrightarrow \qquad Z_1 \text{ et } Z_2 \ \in \mathrm{Asph}_W.$$

Factorisant i_1 et i_2 en

$$Z_0 \xrightarrow{i'_1} Z'_1 \xrightarrow{\alpha_1} Z_1,$$
$$Z_0 \xrightarrow{i'_2} Z'_2 \xrightarrow{\alpha_2} Z_2,$$

avec i'_1, i'_2 des immersions ouvertes de Dwyer, et $\alpha_1, \alpha_2 \in W$, on est ramené au cas où

i_1, i_2 sont des *immersions ouvertes de Dwyer,* et où le carré est cocartésien (ce qui implique [page 271]
qu'il est W-cocartésien). Faisant alors le cochangement de base par $Z_0 \xrightarrow{p_0} Z'_0 = e$, on trouve un homomorphisme de carrés cocartésiens

où toutes les faces du cube sont W-cocartésiennes, et comme $p_0 \in W$ (Z_0 étant W-asphérique), les autres flèches verticales p_1, p_2, p_3 sont `[dans]` W, donc le carré Z'_* satisfait aussi Z'_0 et Z'_3 `[`W`-]`asphériques (et de plus $Z'_0 = e$), et il faut prouver Z'_1, Z'_2 W-asphériques (d'où itou pour Z_1, Z_2). Donc, on est ramené au cas particulier où $Z_0 = e$.

Mais dans ce cas il existe une rétraction (triviale!) de Z_1 sur Z_0, donc aussi de Z_3 sur Z_2. Ainsi, Z_2 est un facteur

direct d'un objet W-asphérique, ce qui implique, par l'hypothèse sur W, que Z_2 est [page 272]
W-asphérique. Par symétrie, Z_1 l'est aussi. On a gagné!

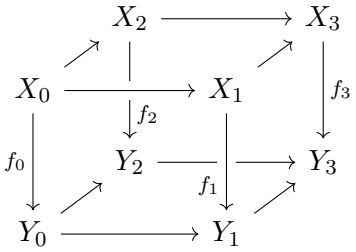
Commentary · Exposition [ms. 272]

The retract argument is valid at the level of objects

Grothendieck's reduction to a common part equal to e is sound and deserves to be retained. If

$$Z_3 \simeq Z_1 \amalg^{\mathrm{h}}_{Z_0} Z_2, \qquad Z_0 \simeq e,$$

then homotopy-colimit invariance identifies Z_3 with the homotopy coproduct of two objects under e. Each summand is a retract of that coproduct: the retraction onto Z_1 is induced by the identity of Z_1 and the composite $Z_2 \to e \to Z_1$. Both agree on e, so the universal property supplies the retraction; its composite with the summand inclusion is the identity. The same construction applies to Z_2. Consequently, if Z_3 is W-aspherical and W-aspherical objects are closed under retracts, both summands are W-aspherical. This proves the object statement without any conservative axiom.



For the source's weaker hypothesis of closure under strict retracts, realize this argument using cofibration representatives $e \to Z_i^c$ in the category under e and their ordinary pushout $P^c = Z_1^c \amalg_e Z_2^c$. These representatives compute the displayed homotopy pushout. The identity of Z_1^c and the composite $Z_2^c \to e \to Z_1^c$ agree strictly on e, so the pushout retraction and its splitting are literal maps, with composite the identity. The comparison with Z_3 makes P^c aspherical; strict retract closure applies to Z_i^c, and the replacement weak equivalences give the assertion for Z_i.

The phrase *facteur direct* here means a retract, as the explicit construction shows. Strong saturation of W also suffices because localization carries a retract diagram to a retract diagram, and a retract of an isomorphism is an isomorphism.

What this argument does not supply is the return from the objects $Z_i = C_e(f_i)$ to the maps f_i. Terminal cofibers need not detect equivalences. The object statement just proved therefore cannot by itself justify assertion 3° of the following general theorem, or the equivalence asserted in Corollary 1. Under the full conservative hypothesis that return is valid, and the final Corollary 2 survives.

NB En fait, ces arguments sont généraux, et donnent ceci :

Théorème. *Soit $(\mathcal{M}, W)$ une catégorie des modèles, admettant une théorie de la cofibre W-homotopique ([137]) (i.e. on a une factorisation de toute flèche $f : X \longrightarrow Y$ en pi, avec $i \in \mathrm{Cof}_W$, $p \in W$.) On a donc une notion de carré W-cocartésien dans $\mathcal{M}$ ([138]). Soit alors $f : X \longrightarrow Y$* p. 177 *un homomorphisme d'un carré W-cocartésien X dans un autre Y, $f = (f_0, f_1, f_2, f_3)$.*

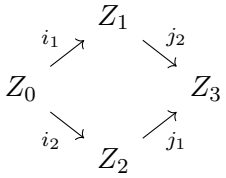
Considérons les conditions sur f

a) $f_0 \in W$.

b) f_1 et $f_2 \in W$.

c) $f_3 \in W$.

Alors



1°) a & b $\Longrightarrow$ c.

2°) Supposons que $\mathcal{M}$ ait un objet final e. Alors l'implication [page 273]

$$b \ \& \ c \Longrightarrow a$$

pour tout *homomorphisme $f : X \longrightarrow Y$ de carrés W-cocartésiens équivaut à l'axiome suivant sur W :*

Axiome des carrés W-cocartésiens conservatifs ([139]) : *Si*

est W-cocartésien, alors $j_1 \in W \Longrightarrow i_1 \in W$ (donc en fait $i_1 \in W \Longleftrightarrow j_1 \in W$ et $i_2 \in W \Longleftrightarrow j_2 \in W$).

Cet axiome est équivalent à la conjonction des deux axiomes suivants.

Commentary · Exposition [ms. 273]

A direct test for conservative homotopy pushouts

Grothendieck now isolates the property needed by the preceding reduction. Once homotopy pushouts are available coherently, there is a short proof of the test that also clarifies Cons 1 and Cons 2. We work in a homotopy theory with a terminal object and finite homotopy colimits, and use "equivalence" for a morphism detected as an isomorphism by its localization.

137. Mais on ne sait vérifier l'existence d'une telle théorie dans (Cat, W) que si on admet la forme faible de W(7), i.e. $f_0, f_1, f_2 \in W \implies f_3 \in W$, ou quelque cas particulier de celle-ci. Mais le *lemme de Brown* sauve la situation, cf. XV §3.

138. à vérifier que la factorisation suffit, même si tous les objets ne sont pas fibrants sur e. Mais on peut alors remplacer $\mathcal{M}$ par $\mathcal{M}_f$, et développer ce formalisme des fibres homotopiques en conséquence …

139. cf. argument page 78 qui montre que l'implication b & c $\Longrightarrow$ a entraine l'axiome conservatif.

For every homotopy-pushout square

$$\begin{array}{ccc} A & \xrightarrow{u} & B \\ \downarrow & & \downarrow \\ C & \xrightarrow[v]{} & P \end{array}$$

associativity gives a canonical equivalence

$$C_e(v) = e \amalg^{\mathrm{h}}_C P \simeq e \amalg^{\mathrm{h}}_C (C \amalg^{\mathrm{h}}_A B) \simeq e \amalg^{\mathrm{h}}_A B = C_e(u).$$

Thus, if terminal homotopy cofiber detects equivalences, v being an equivalence forces u to be one. Conversely, apply the conservative-pushout axiom to the defining cofiber square: if $C_e(u) \simeq e$, its lower edge $e \to C_e(u)$ is an equivalence, and the axiom forces u to be an equivalence. This proves the equivalence of conservativity and Cons 1, with the latter interpreted for a cofibration replacement of every map. The intended cocartesian Cons 2 follows: if B, C, P are terminal up to equivalence, the edge $B \to P$ is an equivalence, hence so is $A \to C$; consequently $A \simeq e$. It is therefore redundant under this coherent formulation.

These observations complete the proof of the two converse cube implications under the appropriate hypothesis. Given a morphism $f : X \to Y$ of homotopy-pushout squares, its pointwise cofibers $Z_i = C_e(f_i)$ form a homotopy-pushout square by the preceding lemma. If f_1, f_2, f_3 are equivalences, then $Z_1, Z_2, Z_3 \simeq e$; conservativity gives $Z_0 \simeq e$, and Cons 1 gives $f_0 \in W$. Conversely, the implication $b \,\&\, c \Rightarrow a$ applied to the map from a square (A, B, C, P) to (B, B, P, P) with components $(u, 1_B, v, 1_P)$ proves conservativity immediately.

If instead f_0, f_3 are equivalences and aspherical objects are closed under retracts, the object argument on pp. 271–272 gives $Z_1, Z_2 \simeq e$; Cons 1 then gives $f_1, f_2 \in W$. Together with ordinary pushout invariance this proves the final Corollary 2. It also identifies exactly what must be added to the printed assertion 3 °: a cofiber-detection hypothesis, equivalently conservative homotopy pushouts, in addition to the retract condition.

Cons 1. *Si on a un carré cocartésien* p. 178

$$\begin{array}{ccc} S & \longrightarrow & T \\ & \searrow \quad \searrow & \\ & e \longrightarrow & U, \end{array}$$

avec $f \in \mathrm{Cof}_W$*, alors* $U \in \mathrm{Asph}_W \Longrightarrow f \in W$ *(donc* $U \in \mathrm{Asph}_W \Longleftrightarrow f \in W$*).*

Cons 2. *Si on a un carré cartésien,*

$$\begin{array}{ccccc} & & Z_1 & & \\ & \overset{i_1}{\nearrow} & & \searrow & \\ Z_0 & & & & Z_3, \\ & \underset{i_2}{\searrow} & & \nearrow & \\ & & Z_2 & & \end{array}$$

avec $i_1, i_2 \in \mathrm{Cof}_W$*, alors : Si* Z_1*,* Z_2*,* Z_3 *sont* W*-asphériques,* Z_0 *l'est aussi.*

Commentary · Examples [ms. 273]

Why Cons 2 must concern pushouts

The edition prints *cartésien* in Cons 2. Taken literally, this gives a different and false consequence of conservativity. The issue can be seen inside a stable homotopy theory, where conservative homotopy pushouts do hold.

Let k be a field and use homologically graded chain complexes. Put $A = ka$ in degree zero, and let

$$B = (kb \xrightarrow{d} ka), \qquad C = (kc \xrightarrow{d} ka), \qquad d(b) = d(c) = a.$$

Embed both in the complex

$$D = (kd \longrightarrow kb \oplus kc \longrightarrow ka), \qquad \partial d = b - c, \quad \partial b = \partial c = a.$$

Here d as a basis symbol lies in degree two. Both B and C are acyclic. In D the first differential is injective, its image is the kernel of the second, and the second is surjective, so D is acyclic too. Their ordinary pullback over D is the intersection A, whose zeroth homology is k. All four inclusions are degreewise monomorphisms. Such a map is a W-cofibration for quasi-isomorphisms: pushout leaves its cokernel unchanged, and the long exact homology sequences show that a weak equivalence of sources induces one of the pushouts. Over a field these maps are also cofibrations in the usual model structure.

Thus a strict cartesian square with the printed cofibration hypotheses need not satisfy Cons 2, even when the surrounding derived theory is stable. Replacing *cartésien* by *cocartésien* restores the statement used in the argument. The source wording is retained in the text and recorded as an edition slip.

[page 274]

3°) Supposons que tout facteur direct d'un objet W-asphérique soit W-asphérique, ce qui est le cas notamment si W est lui-même stable par facteurs directs, a fortiori si W est fortement saturé. Supposons de plus que $\mathcal{M}$ ait `[un]` *objet final. Alors on a (sous les conditions générales du début)*

$$c \ \& \ a \Longrightarrow b,$$

i.e. si f_0, f_3 sont `[dans]` *W, de même f_1, f_2.*

Cette dernière partie peut se déployer ainsi :

Commentary · Development (commentators') [ms. 274]

An explicit cube testing the generalization

Grothendieck's retraction proof invites a test of the stronger assertion about arbitrary maps of squares. We give the test in full, since it distinguishes a missing hypothesis from a missing step in a proof. The acyclic complex used below is classical; the assembly into the two diagnostic cubes is our application to this passage. We checked the source's later Chapter XVI discussion, Brown's gluing lemmas, and the cofiber and Mayer–Vietoris treatments cited here; we did not find this particular counterexample to the printed generalization in those sources. No priority is claimed.

A cube with a and c, but not b. [ours] In simplicial sets with weak homotopy equivalences, there is a map between homotopy-pushout squares whose zeroth, second and third components are equivalences and whose first component is not.

Proof. Begin with the finite CW complex A having one vertex, two edges a, b, and two two-cells attached by a^5b^{-3} and $b^3(ab)^{-2}$ (Hatcher, 2002, Example 2.38). Its cellular boundary in positive dimensions is

$$0 \longrightarrow \mathbb{Z}^2 \xrightarrow{\left(\begin{smallmatrix} 5 & -2 \\ -3 & 1 \end{smallmatrix}\right)} \mathbb{Z}^2 \longrightarrow 0.$$

The determinant is -1, so A is acyclic. Its fundamental group is nontrivial: sending a to (12345) and b to (153) respects the relations, since their product is (23)(45), and gives a nontrivial permutation representation. The suspension ΣA is simply connected by van Kampen and acyclic by the suspension isomorphism in reduced homology. Hurewicz and Whitehead therefore make it contractible (Hatcher, 2002, Theorem 4.32 and Corollary 4.33).

Choose a simplicial set K of the homotopy type of A, let $CK = K \star \Delta^0$, and write $e = \Delta^0$. The inclusion $K \hookrightarrow CK$ is a cofibration, CK is contractible, and $CK \amalg_K e$ has the homotopy type of ΣA, hence is weakly contractible. Consider

$$X = \begin{pmatrix} K & = & K \\ \downarrow & & \downarrow \\ CK & = & CK \end{pmatrix}, \qquad Y = \begin{pmatrix} K & \longrightarrow & e \\ \downarrow & & \downarrow \\ CK & \longrightarrow & CK \amalg_K e \end{pmatrix}.$$

Both strict pushouts compute homotopy pushouts, since the common vertical leg is a cofibration. There is a strict map $X \to Y$ with components

$$(f_0, f_1, f_2, f_3) = (1_K,\ K \to e,\ 1_{CK},\ CK \to CK \amalg_K e).$$

Its zeroth and second components are identities; its third connects weakly contractible objects; its first is not a weak equivalence because $\pi_1(K) \neq 1$. This proves the assertion. All simplicial sets

are cofibrant, factorizations exist, and weak equivalences are strongly saturated and closed under retracts. Thus the failure is present under the printed hypotheses of assertion 3°, not a failure of replacement machinery.

The same K tests the other converse. Map the homotopy-pushout square with vertices $(K, CK, CK, CK \amalg_K CK)$ to the constant square at e. Its two cone vertices and its suspension vertex are weakly contractible, while K is not. Hence $b \,\&\, c \Rightarrow a$ fails for spaces, as the conservative axiom predicts. Finally, the object statement in Corollary 1 remains valid for spaces by the retract proof above. Its proposed equivalence with $a \,\&\, c \Rightarrow b$ therefore fails as printed. Adding cofiber detection repairs both assertions.

Corollaire 1. *Sous l'hypothèse supplémentaire* 3°) *sur W, la validité de c & $a \Longrightarrow b$ (pour toute flèche f entre carrés W-cocartésiens) équivaut à chacun des deux autres axiomes suivants sur W (qui sont donc équivalents) :*

1) Si on a un carré W-cocartésien

$$\begin{array}{ccc} & Z_1 & \\ \nearrow & & \searrow \\ Z_0 & & Z_3, \\ \searrow & & \nearrow \\ & Z_2 & \end{array}$$

alors Z_0 et Z_3 W-asphériques $\Longrightarrow$ Z_1 et Z_2 W-asphériques.

1′) Comme 1), avec $Z_0 = e$ (dans le cas où on suppose que $\mathcal{M}$ admet `[un]` *objet final e).*

Corollaire 2. *Supposons que W satisfasse l'axiome des carrés W-cocartésiens conservatifs, que tout facteur direct d'un objet W-asphérique soit W-asphérique (p. ex. W stable par facteurs directs), enfin que $\mathcal{M}$ admette un objet final. Alors pout tout homomorphisme $f : X \longrightarrow Y$ de carrés W-cocartésiens, la conjonction de deux parmi les conditions a) b) c) de p. 272 entraîne la troisième.* [page 275]

Commentary · Later developments [ms. 275]

The stable form of the cube calculus

The last corollary has a particularly transparent home in a stable derivator. Coherent cocartesian squares then are also cartesian, and their geometry gives a Mayer–Vietoris triangle

$$X_0 \xrightarrow{(i_1,-i_2)} X_1 \oplus X_2 \xrightarrow{(j_2,j_1)} X_3 \longrightarrow \Sigma X_0.$$

The existence of this triangle is Groth et al. (2014a, Theorem 6.1, arXiv v2); their Theorem 7.1 compares stability with the invertibility of suspension and of the cofiber/fiber adjunction. This gives an established realization of the suspension calculus suggested by the large diagram on p. 269.

For a morphism of two such squares, the induced map of triangles makes the three implications immediate but still instructive. Equivalences on the first and middle terms give one on the third; equivalences on the middle and third give one on the first. Equivalences on the first and third give an equivalence $f_1 \oplus f_2$. Each f_i is a retract of that direct-sum map in the arrow category, so each is an equivalence. This is the additive form of the retraction argument, with cofiber detection now supplied by stability.

Conservativity should nevertheless not be identified with stability. The former is the particular detection property isolated on p. 273; stability also requires a pointed theory and the agreement of cartesian and cocartesian squares. The source's general constructions of coherent squares and iterated cofibers remain useful in unstable theories, while the converse arguments require their stated additional hypotheses.

Overview · XIIc-b

From replacements to a calculus of coherent squares. The pages gathered here form a single mathematical movement. Grothendieck first constructs categorical cylinders and uses them to establish the gluing rules for homotopy pushouts. He then asks which part of this geometry can be recovered from a category $\mathcal{M}$ and a class W of weak equivalences alone. The answer takes the form of a homotopy completion of a cospan, characterized by an adjunction. Finally he returns to pushouts and investigates how far weak equivalences can be recovered from the pieces of a decomposition. The first two movements build the calculus; the appendix tests a considerably stronger conservativity property.

These pages are manuscript pages 228–275, printed pages 145–178 of the edition (Grothendieck, 1990–1991h): the second part of section VI of Chapter XII, that is, the end of its section 6 followed by sections 7 and 8. The audit covers that entire range, including the fragment of a footnote continued at the beginning. Page labels in the margins reproduce the two numbering systems of the transcription; citations in the commentary use manuscript pages unless another system is specified.

Why the diagrams must precede localization. The motivation is older than the technical apparatus of these pages. In section 69 of *Pursuing Stacks*, Grothendieck traces the need for derivators to the trace formalism of SGA 5: a single derived category did not retain the diagrammatic information needed for the desired compatibilities (Grothendieck, 1983, §69, pp. 1–2). His letter to Thomason of 2 April 1991 returns to this history and to the system of localized diagram categories (Grothendieck, 1991a, §2, pp. 5–6). These are historical statements checked in those texts; we do not infer that every later definition was already present there in its final form.

Here this motivation becomes a concrete distinction. With the manuscript's contravariant convention, the relevant category is

$$\mathbb{D}(I) = \mathrm{Fun}(I^{\mathrm{op}}, \mathcal{M})[W(I)^{-1}],$$

where $W(I)$ consists of the objectwise weak equivalences. It is not obtained by first passing to $\mathcal{M}[W^{-1}]$ and then forming its ordinary diagram category. A cospan remembers two maps to a common base together; its homotopy completion must preserve that relationship and its naturality in all three vertices. This explains both the attention given to the whole completed square and the two localization lemmas whose proofs the manuscript postpones. The modern introduction in Groth (2013, pp. 313–315) makes the same structural distinction.

The constructive part and its later justification. The fence interval Φ_n, with $n \geq 2$, lets both endpoints enter by a Dwyer immersion. The associated mapping cylinder gives a functorial factorization into a W-cofibration followed by a weak equivalence. The commentary proves the endpoint condition and follows the construction on the map from two discrete objects to a point. Taking its categorical cofiber produces an eight-edge circle. Later, the Grothendieck integral of the same span gives a four-edge circle. These are two explicit models of the homotopy pushout; the ordinary categorical pushout is only a point.

The appeal to Thomason is valid in the needed cellular form. It must not be strengthened to the assertion that every Thomason cofibration is a Dwyer map: the retract assertion used to obtain that conclusion is false, and Cisinski (1999) gives the counterexample and repair. The recent comparison of Dwyer pushouts with $(\infty, 1)$-categorical pushouts is stronger in a different direction, identifying what the nerve preserves rather than adding the appendix's conservative axiom (Hackney et al., 2024, Theorems 1.5–1.6, arXiv v3).

In section 7, a W-fibration means a map whose pullback functor preserves the designated weak equivalences. The factorization assumption says that every arrow is a weak equivalence followed by such a fibration. It is essential to retain this intrinsic meaning: the manuscript has not assumed a Quillen model structure with arbitrary lifting classes. Under its stated

terminal-object and pullback hypotheses, these data form a left derivable category. The commentary verifies the nontrivial axiom, stability of trivial fibrations under arbitrary base change, by a two-step factorization and two-out-of-three argument.

This observation gives a complete modern repair of the deferred Lemmas 1 and 2. We construct the appropriate fibration structures on the good cospans and good squares, check the factorization and pullback conditions, and verify approximation for their inclusions in the ambient diagram categories. Cisinski's Proposition 1.8 also supplies the strengthened replacement assertion for every full intermediate subcategory of a slice containing its fibrant objects; his Theorem 3.12 establishes the two diagram-localization equivalences (Cisinski, 2010). No functorial factorization or global assumption that all objects are fibrant is required. A separate, shorter deformation argument explains what functorial factorization would give. The audit still labels the source proofs as deferred or sketched: the later completion does not change what is written on these pages.

With those equivalences available, restriction from squares to cospans has a fully faithful right adjoint. On a cospan $A \to S \leftarrow B$ with one good leg, its missing corner is represented by $A \times_S B$. The groupoid example $* \to BG \leftarrow *$ gives the discrete groupoid G at that corner, whereas the strict pullback without replacement is a point. The adjunction retains the two projections and their compatibility, as well as the corner's homotopy type. Proposition 19 then gives an intrinsic test for cartesianness, and we prove its independence of choices, invariance under objectwise weak equivalences, and pasting directly from the factorization axiom. Strong saturation enters precisely when an isomorphism after localization must be recognized as an original member of W.

What the appendix adds, and where its generalization fails. The ordinary gluing implication says that equivalences on the common part and the two pieces induce an equivalence on their homotopy pushouts. The appendix asks for converses. Its full W(7 bis) hypothesis is substantially stronger: a homotopy pushout must also reflect weak equivalences in an attached leg. In a coherent homotopy-pushout theory this is equivalent to detection by the terminal homotopy cofiber

$$C_e(u) = e \amalg^{\mathrm{h}}_{\mathrm{dom}(u)} \mathrm{cod}(u).$$

The forward implication $u \in W \Rightarrow C_e(u) \simeq e$ is formal. The reverse implication is the additional detection property. We prove the equivalence with conservativity by pasting cofiber squares.

This distinction exposes an actual error in the general theorem on manuscript page 274. Retract closure of aspherical objects alone does not imply that equivalences at the initial and final vertices of a map of homotopy-pushout squares force equivalences at the two middle vertices. Our counterexample uses Hatcher's finite acyclic noncontractible complex A. Its suspension is contractible; the map from the square (A, A, CA, CA) to $(A, *, CA, CA/A)$ has three weak-equivalence components and one component $A \to *$ that is not a weak equivalence. Both squares are homotopy pushouts. We give the presentation of A, its cellular homology calculation, a nontrivial permutation representation of its fundamental group, and the suspension argument (Hatcher, 2002, Example 2.38). The related equivalence asserted in Corollary 1 therefore fails as printed. Adding cofiber detection repairs both statements, and the final Corollary 2 already has the required conservative hypothesis.

There is also a source slip in Cons 2: the edition prints *cartésien* where its argument requires *cocartésien*. A finite chain-complex example shows that the literal cartesian assertion fails even in a stable theory. The proof of the intended criterion shows that its cocartesian version follows from Cons 1 under the coherent formulation. In stable derivators the entire corrected cube calculus has a familiar expression through the Mayer–Vietoris triangle (Groth et al., 2014a, Theorems 6.1 and 7.1, arXiv v2).

The appendix's earlier circularity is a different issue. Chapter XVI identifies the dependence on the Dwyer-cofibration gluing lemma but explicitly does not give its proof there

(Grothendieck, 1991c, §3, ms. pp. 18–23). Brown's published gluing lemma, dualized, supplies the missing result (Brown, 1973, Part I, §4, Lemma 2). Thus the initial conditional proposition survives, while the later hypothesis-free generalization does not. These are distinct diagnoses, with distinct repairs.

Editorial and verification limits. The text preserves slips printed in the edition. Its one mathematical transcription correction restores the interior natural transformation α on manuscript page 235, which the transcription had drawn as an arrow between the wrong objects. The separate registers record the source's proof status, the present repair, and the evidence for each reading. Bibliography notes identify exactly which statements, proofs, or metadata were checked; in particular, the original proof of Thomason's 1979 theorem was not inspected, although its statement and a later proof were checked.

Proposition (?) ([1]). *Soit X dans* Cat*, avec b, c dans X tels que* [ms. 1]

a) $b \times c$ *est dans* X*.*

b) $\forall\ x$ *dans* X*,* $b(x)$ $(\overset{déf}{=} \mathrm{Hom}_X(x,b))$ *et* $c(x)$ *sont* $\neq \emptyset$*, i.e.* $X/b \longrightarrow X$ *et* $X/c \longrightarrow X$ *sont surjectifs sur les objets.*

Alors X *est* $\mathbf{W}_\infty$*-asphérique.* ([2])

Le fait que b soit un plus grand élément de ObX assure déjà la 0-connexité.

Commentary · Context [ms. 1]

What an ordinary pushout forgets

Grothendieck is looking for categorical gluings that preserve a homotopy type. The little span that appears throughout this appendix is a particularly severe test. Its indexing category

$$\Psi = (b_0 \longleftarrow a_0 \longrightarrow c_0)$$

has an initial object, hence a contractible nerve. Nevertheless, taking the ordinary colimit of its representable presheaves can introduce higher homotopy into the category of elements. The purpose of the examples is to locate this discrepancy precisely enough to decide which inclusions can be used in a homotopy theory on Cat.

We write $BC = |NC|$, and interpret $\mathbf{W}_\infty$ as the functors inducing weak homotopy equivalences on these classifying spaces. In this terminology "aspherical" means weakly contractible, not merely a space with vanishing higher homotopy groups. For a presheaf $F : C^{\mathrm{op}} \to \mathrm{Ens}$, the notation C/F denotes its category of elements: its objects are (c, x), and an arrow $(c, x) \to (c', x')$ is an arrow $u : c \to c'$ with $F(u)(x') = x$. Thus a represented presheaf has contractible category of elements C/c. The central phenomenon is that a colimit of represented presheaves need not retain that property.

This is already the tension described in Grothendieck (1983, §69): categorical integration gives homotopy colimits, whereas actual amalgamated sums require additional care. The letter to Thomason of 2 April 1991 explains why the two adjoints to restriction, together with their exactness properties, should be treated as the essential structure (Grothendieck, 1991a, pp. 8–9). The appendix examines the small categorical configurations behind that program. Its final gluing theorem belongs to the theory of homotopy colimits; its earlier counterexamples concern ordinary pushouts in Cat. Keeping the two operations distinct makes the apparent reversal between the examples and the closing conjecture intelligible.

There are also two different uses of asphericity for an inclusion. A functor $U \to X$ is aspherical in the usual sense if every comma category U/x is weakly contractible. An open immersion in these pages is a full sieve, and the local condition used for it is imposed on $U \to \overline{U}$, where $\overline{U}$ is its cosieve closure. Objects outside $\overline{U}$ have empty comma categories. This distinction will matter for the boundary of a subdivided square: that boundary has the homotopy type of a circle, even though the indicated local condition holds. We refer to the precise conventions of Chapter XII, §V.2 (Grothendieck, 1990–1991d), and to the commentary on Chapter II, manuscript p. 36 ("The quantifier in total asphericity") for the universal quantifier in that second notion.

Commentary · Exposition [ms. 1]

What the product actually contracts

Grothendieck begins by asking how much of a terminal object can be replaced by the existence of maps. The objects b and c are *weakly terminal*: every object admits a map to each of them, without any assertion of uniqueness. Their product $a = b \times c$ is weakly terminal as well. The argument establishes the exact conclusion needed at the first stage: the nerve NX is connected and simply connected. Here and below $BX = |NX|$, and "aspherical" in the terminology of these pages means weakly contractible, not merely a $K(\pi, 1)$.

The cancellation argument can be compressed without losing its content. For two maps $s, t : x \to a$, insert the mixed pair $(p_b s, p_c t)$. Cancellation against the now invertible projections

1. Cf. pages 11 ff. pour les contrexemples-clef.
2. Faux, cf. plus bas. X est 1-connexe, mais pas nécessairement 2-connexe.

shows that all three maps have the same image in the groupoid completion ΠX. Choose one such image $\alpha_x : x \to a$ for each object, taking $\alpha_a = 1_a$. For every arrow $u : x \to y$, both $\alpha_y u$ and α_x come from arrows $x \to a$ and therefore agree. The same identity then holds for inverse arrows and their composites. Every morphism $x \to a$ in ΠX is consequently α_x. Thus a is terminal in this groupoid, which is equivalent to the terminal groupoid. The longer zigzag induction in the text is a complete proof of this fact; its undefined a_0 and u_0 are printing slips, not a missing argument.

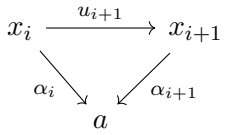
There is a significant distinction between this proposition and the later four-object example. In that example $b \amalg_a c = 1$ in the presheaf category, but a is *not* $b \times c$: at the added object there are two maps to a and only one pair of maps to (b, c). It cannot by itself refute the opening product proposition. The finite two-object category below does refute that proposition, although its first obstruction occurs in degree three. We give the calculation because the provisional degree-two calculation in the manuscript does not survive verification.

Pour la 1-connexité, prouvons que dans le groupoïde fondamental $\Pi(X)$, $a \overset{\text{déf}}{=} b \times c$ devient un élément final.

$$\begin{array}{ccc} b \times c & \longrightarrow & b \\ \downarrow & & \\ c & & \end{array}$$

Pour ceci, prouvons d'abord que $\forall$ x dans X, tous les éléments de $a(x) = b(x) \times c(x)$ sont égaux dans $\mathrm{Fl}\Pi(X)$. En effet, comme $b \times c \longrightarrow b$ est `[un]` isomorphisme, donc `[un]` monomorphisme dans $\Pi(X)$, cela montre déjà que si $\beta, \beta' \in b(x)$, $\gamma, \gamma' \in c(x)$, d'où (β, γ), (β, γ'), $(\beta', \gamma') \in b(x) \times c(x)$, on a $(\beta, \gamma) = (\beta, \gamma')$ dans $\Pi(X)$ (puisque $\mathrm{pr}_1(\beta, \gamma) = \mathrm{pr}_1(\beta, \gamma')$, et de même (en utilisant que pr_2 est `[un]` isomorphisme, donc `[un]` monomorphisme) $(\beta, \gamma') = (\beta', \gamma')$). Donc tous les $(\beta, \gamma) \in b(x) \times c(x) = a(x)$ sont égaux dans $\mathrm{Fl}\Pi(X)$. Pour achever de prouver que a est objet final de $\Pi(X)$, il suffit de voir que toute flèche *dans* $\Pi(X)$ d'un $x \in \mathrm{Ob}X$ dans a, provient d'une flèche $x \longrightarrow a$ dans X. Mais une flèche dans $\Pi(X)$ est obtenue par un chemin dans X

$$\begin{array}{ccccccccc} x = x_0 & \xrightarrow{u_1} & x_1 & \xleftarrow{u_2} & x_2 & \longrightarrow & \cdots & \xleftarrow{u_{2N}} & x_{2N} = a \\ & \searrow^{\alpha_0} & \downarrow{\scriptstyle \alpha_1} & \swarrow_{\alpha_2} & & & & & \\ & & a. & & & & & & \end{array}$$



Prenons une flèche $\alpha_0 : x \longrightarrow a_0$ dans X, je dis que la classe d'homotopie du chemin c (i.e. son image dans $\mathrm{Fl}(\Pi(X))$ est égale à celle de u_0. Pour le voir, choisissons pour tout $i \in [0, 2N]$ une flèche $\alpha_i : x_i \longrightarrow a$. (Ça existe grâce à l'hypothèse b)). Je dis que pour chaque $i \in [0, 2N]$, le triangle [ms. 2] [ed. 2]

$$\begin{array}{ccc} x_0 & \xrightarrow{c_i} & x_i \\ & \searrow^{\alpha_0} \quad \swarrow_{\alpha_i} & \\ & a & \end{array}$$

dans $\Pi(X)$ est commutatif, où c_i désigne la classe d'homotopie du chemin de x_0 à x_i définie par les u_i ($i \in [1, i]$) `[plutôt` ($i \in [1, 2N]$)`]`. Nous le faisons par récurrence sur i, l'assertion est triviale si $i = 0$ (c_0 représente l'application identitique). Le diagramme

$$\begin{array}{ccccc} & & c_{i+1} & & \\ & \overset{}{\frown} & & \overset{}{\frown} & \\ x_0 & \xrightarrow{c_i} & x_i & \xrightarrow{u_{i+1}} & x_{i+1} \\ & \searrow^{\alpha_0} \quad \swarrow_{\alpha_i} & & \swarrow_{\alpha_{i+1}} & \\ & & a & & \end{array}$$

montre qu'il suffit de prouver que pour $i \in [0, 2N-1]$ le triangle

est commutatif dans $\Pi(X)$. (**NB** u_{i+1} est en sens directe ou rétrograde, suivant que i est paire ou impaire.) Mais cela résulte du fait que l'image de $\mathrm{Hom}_X(x_i, a)$ (resp. $\mathrm{Hom}_X(x_{i+1}, a)$) dans $\mathrm{Fl}\Pi(X)$ est réduite à un seul élément. [ms. 3]

Ainsi on trouve que X *est* 1-*connexe.* Il y a donc de l'espoir! Il reste à prouver

$$H^i(X, M) = 0, \qquad i \geq 2, \quad M \text{ coefficient constant.}$$

J'ai regardé le cas lorsqu'on a ceci : $b = c$, $\mathrm{Ob}X = \{b, b \times b\}$, $\mathrm{Hom}_X(b \times b)$ [plutôt $\mathrm{Hom}(b \times b, b)$] = { réunion disjointe des ensembles $u \circ \mathrm{pr}_1$ et $u \circ \mathrm{pr}_2$, avec $u \in \mathrm{Hom}_X(b, b) = G$ un monoïde quelconque }. Alors X° est fibrée, via $I \longmapsto b^I$, sur la sous-catégorie pleine S de Ens formée de $\{0\}$ et $\{0, 1\}$, et donc X est cofibrée (en particulier propre) sur $S^\circ \overset{\text{déf}}{=} T$. (NB $S^\circ = T$ a un objet initial, mais non un objet final. Sa cohomologie à valeurs dans un préfaisceau quelconque n'est pas toujours triviale, cf. ci-dessous.)

On trouve [`On trouve' barré]

$$H^n(X, M) \Longleftarrow H^p(T, \underbrace{R^q f_*(M_X)}_{=\mathcal{H}^q}), \qquad \text{où } f : X \longrightarrow S^\circ$$

[$n = p + q$]. J'admet ici (provisoirement) ceci :

$$\begin{aligned} &H^p(T, F) = 0 \ , && \text{pour } p \geq 2, \text{ tout } F \in T^\wedge \ , \\ &H^0(T, F) = \mathrm{Ker}\delta \ , \\ &H^2(T, F) = \mathrm{Coker}\delta \ , \end{aligned}$$

ed. 3

où $\delta : F_0 \longrightarrow F_1$ est défini comme la différence $\delta = p_1^* - p_2^*$, où p_1, p_2 sont les deux projections de $\{0, 1\} \simeq \{0\}^2$ dans $T = S^\circ$. On a de plus

$$(\mathcal{H}^q)_0 = H^q(G, M), \qquad (\mathcal{H}^q)_1 = H^q(G \times G, M),$$

et

$$p_1^*, \ p_2^* \ : \ H^q(G, M) \rightrightarrows H^q(G \times G, M) \qquad \text{sont les transposés de } \mathrm{pr}_1, \ \mathrm{pr}_2 : G \times G \longrightarrow G.$$

Commentary · Exposition [ms. 3]

The finite-power category and the missing symmetries

Grothendieck now makes the product condition explicit in a category small enough to calculate. Write X_G for the category with objects $1, 2$, representing b, b^2, and

$$\mathrm{Hom}_{X_G}(m, n) = \big(\{1, \ldots, m\} \times G\big)^n.$$

A morphism lists, for each output coordinate, one input coordinate and one element of the monoid G; composition substitutes these expressions. Thus $(i, g) : b^m \to b$ means $g \circ p_i$. This convention fixes multiplication even when G is not commutative. The evident maps $2 \to 1$ exhibit 2 as the product of 1 with itself. Both objects map to 1, so the hypotheses of the opening proposition hold. For a group G, the opposite category is the full category of free G-sets of ranks one and two.

Let S be the full subcategory of finite sets on $\mathbf{1}, \mathbf{2}$, and put $T = S^{\mathrm{op}}$. The functor $X_G \to T$ forgets the monoid labels. A map $v : m \to n$ of T, equivalently a function $n \to m$, induces the

coordinate-selection homomorphism $G^m \to G^n$. The arrows with all labels equal to 1_G are chosen cocartesian lifts, so X_G is the Grothendieck construction of $n \mapsto BG^n$, where here BG^n denotes the one-object category. This proves the asserted opfibration and justifies the cohomological spectral sequence, with constant abelian coefficients M:

$$E_2^{p,q} = R^p \varprojlim_{S} F_q \implies H^{p+q}(BX_G; M), \qquad F_q(n) = H^q(BG^n; M).$$

The functor F_q is covariant on S. A modern treatment of this spectral sequence for Grothendieck constructions is Cegarra (2020, Corollaries 3–4); the underlying homotopy-colimit comparison is Thomason (1979, Theorem 1.2).

The provisional formula is already contradicted by a constant diagram $F = M$. The category T has an initial object, hence contractible nerve, and $H^{>0}(T, M) = 0$. Yet the proposed differential is $1_M - 1_M = 0$, whose cokernel is M. Changing the printed H^2 to the evidently intended H^1 does not repair this. The full category S contains two inclusions, their common retraction, and the transposition of $\mathbf{2}$; retaining only a parallel pair loses relations and higher derived limits. On the other hand the formula for H^0 is correct: a compatible pair is determined by its value at $\mathbf{1}$, and the equality of the two induced values at $\mathbf{2}$ implies compatibility with the retraction and transposition.

Commentary · Development (commentators') [ms. 3]

A small resolution for the actual base category

The point of repairing the base calculation is to retain Grothendieck's finite example, while locating its obstruction in the correct degree. The following elementary computation supplies all the derived limits used below. We did not find this calculation for the appendix's two-object category in the literature checked; the argument is included in full, without a claim of priority.

Derived-limit calculation. [ours] Let $F : S \to \mathrm{Ab}$, let $i_1, i_2 : \mathbf{1} \to \mathbf{2}$ be the inclusions, let $r : \mathbf{2} \to \mathbf{1}$ be the unique map, and let τ transpose $\mathbf{2}$. Put

$$A = F(\mathbf{1}), \quad B = F(\mathbf{2}), \quad L = \ker(F(r) : B \to A), \quad L^- = \{v \in L : F(\tau)v = -v\}.$$

Then

$$\begin{aligned} R^0 \varprojlim_{S} F &= \ker(F(i_1) - F(i_2) : A \to B), \\ R^1 \varprojlim_{S} F &= L^- / (F(i_1) - F(i_2))A, \\ R^p \varprojlim_{S} F &= \mathrm{Ext}^{p-1}_{\mathbb{Z}[C_2]}(\mathbb{Z}_{\mathrm{sgn}}, L) \qquad (p \geq 2). \end{aligned}$$

The action of C_2 on L is induced by $F(\tau)$.

Proof. Work in the abelian category of covariant functors on S. The functors $P_j = \mathbb{Z}[S(\mathbf{j}, -)]$ are projective, since $\mathrm{Hom}(P_j, F) = F(\mathbf{j})$ and evaluation is exact. The augmentation $P_1 \to \underline{\mathbb{Z}}$ gives

$$0 \longrightarrow K \longrightarrow P_1 \longrightarrow \underline{\mathbb{Z}} \longrightarrow 0.$$

Here $K(\mathbf{1}) = 0$, and $K(\mathbf{2}) = \mathbb{Z}(i_1 - i_2)$ is the sign representation; the two constant endomorphisms act as zero. This immediately gives the formula for degree zero and identifies the degree-one group as the stated cokernel, because a map $K \to F$ is precisely an element of L^-.

For completeness the higher Ext groups can be computed inside the same tiny category. Precomposition with r gives a monomorphism $P_1 \to P_2$. It has the natural retraction induced by i_1, because $ri_1 = 1$. Consequently $Q = P_2/P_1$ is projective. It is zero at $\mathbf{1}$ and is the regular representation $\mathbb{Z}[C_2]$ at $\mathbf{2}$, with basis the classes of 1 and τ; both constant maps act as zero. Any free $\mathbb{Z}[C_2]$-resolution of the sign representation therefore gives a projective resolution of K, by replacing the regular module with Q. Applying $\mathrm{Hom}(-, F)$ gives exactly the complex computing $\mathrm{Ext}^*_{\mathbb{Z}[C_2]}(\mathbb{Z}_{\mathrm{sgn}}, L)$: maps out of Q are elements annihilated by $F(r)$. Finally dimension shifting through the displayed short exact sequence proves the formula for $p \geq 2$. This also proves that no omitted higher relation is being assumed away. □

For example, take $F(\mathbf{1}) = 0$, $F(\mathbf{2}) = \mathbb{Z}$ with τ acting as -1. The formula gives $R^3 \varprojlim F \cong \mathbb{Z}/2$, from the usual alternating resolution of C_2. Thus even the claimed vanishing in all degrees at least two is false for the full base category.

On vérifie aisément que [ms. 4]

$$H^0(T, \mathcal{H}^q) = 0 \qquad \text{si } q \geq 1,$$

et il reste

$$H^n(X, M) \simeq H^1(S, \mathcal{H}^{n-1}) = \mathrm{Coker}(\delta : H^{n-1}(G) \longrightarrow H^{n-1}(G \times G)).$$

Cela donne, pour $n = 2$,

$$H^2(X, M) \simeq \mathrm{Coker}\Big(\delta : \mathrm{Hom}_{\mathrm{mon}}(G, M) \longrightarrow \underbrace{Hom_{\mathrm{mon}}(G \times G, M)}_{\mathrm{Hom}_{\mathrm{mon}}(G,M) \times \mathrm{Hom}_{\mathrm{mon}}(G,M)} \Big)$$
$$\simeq \mathrm{Coker}\Big(u \longmapsto (u, -u) : H \longrightarrow H \times H\Big),$$

où H est le groupe abélien $\mathrm{Hom}_{\mathrm{mon}}(G, M)$.

D'où

$$H^2(X, M) \;\simeq\; H = \mathrm{Hom}_{\mathrm{mon}}(G, M).$$

Donc

> X est 2-connexe si et seulement si le groupe *abélien* enveloppant du monoïde G est nul.

Ainsi, si G est un groupe abélien $\neq 0$, X *n'est pas* 2-connexe.

Commentary · Development (commentators') [ms. 4]

The counterexample survives, one degree later

Grothendieck's proposed category is indeed nonaspherical for $G = C_2$. Its degree-two cohomology, however, is zero. The distinction matters twice: it changes the audit of the first four pages, and it supplies a sound finite example for the pushouts that follow.

The actual low-degree calculation. [ours] For every monoid G, the space BX_G is 2-connected. For $G = C_2$ one moreover has

$$H^3(BX_{C_2}; \mathbb{F}_2) \cong \mathbb{F}_2.$$

In particular the opening weak-contractibility assertion is false under its exact product hypotheses.

Proof. The groupoid argument already proves simple connectivity. Use the spectral sequence and notation of the preceding two comments. The $q = 0$ row is the constant diagram M, so its terms vanish for $p > 0$. For $q > 0$ the two coordinate pullbacks

$$H^q(BG; M) \rightrightarrows H^q(BG^2; M)$$

have zero equalizer: restriction along $g \mapsto (g, 1)$ sends the first pullback to the identity and the second to zero. Thus $E_2^{0,q} = 0$ for $q > 0$.

Set $A = H^1(BG; M) = \mathrm{Hom}_{\mathrm{mon}}(G, M)$, with M regarded as an additive group. A normalized degree-one cocycle on the monoid is exactly an additive homomorphism, which proves this identification directly. A homomorphism $G^2 \to M$ is uniquely the sum of its restrictions to the two factors, so the degree-one diagram is

$$F_1(\mathbf{1}) = A, \qquad F_1(\mathbf{2}) = A \oplus A,$$

with i_1, i_2 inducing the two inclusions, r inducing addition, and τ interchanging the factors. Hence $L = \{(a, -a) : a \in A\}$, $L^- = L$, and the map $A \to L$ in the degree-one formula is an isomorphism. Thus $E_2^{1,1} = 0$. All three entries of total degree two vanish; consequently $H^2(BX_G; M) = 0$ for every abelian M. Simple connectivity and the universal coefficient theorem give $H^2(BX_G; M) = \mathrm{Hom}(H_2(BX_G; \mathbb{Z}), M)$. Taking $M = H_2(BX_G; \mathbb{Z})$ forces this group to be zero. The Hurewicz theorem now gives $\pi_2(BX_G) = 0$; see Hatcher (2002, Theorems 3.2 and 4.32).

Now put $G = C_2$ and $M = \mathbb{F}_2 = k$. The same degree-one diagram has $L = k$ with trivial C_2-action. The base calculation gives

$$E_2^{2,1} = \mathrm{Ext}^1_{\mathbb{Z}[C_2]}(\mathbb{Z}_{\mathrm{sgn}}, k) = k.$$

Indeed the free resolution of the sign module has differentials alternating between $1+\tau$ and $1-\tau$, both zero after applying $\mathrm{Hom}(-,k)$. No differential can kill this term: its sole possible incoming differential is from $E_2^{0,2}=0$ and its sole possible outgoing differential lands in $E_2^{4,0}=0$.

To identify the whole degree-three group, the only remaining possible entry is $E_2^{1,2}$. Write $H^*(BC_2;k)=k[t]$ and $H^*(B(C_2^2);k)=k[x,y]$, with all three generators in degree one; these are the usual projective-space and Künneth calculations (Hatcher, 2002, Theorems 3.15 and 3.19). In degree two, $F_2(r)$ sends each of x^2, xy, y^2 to t^2. The τ-fixed part of its kernel is therefore $k(x^2+y^2)$, exactly the image of $F_2(i_1)-F_2(i_2)$. The degree-one formula gives $E_2^{1,2}=0$. All other entries of total degree three vanish, proving the displayed isomorphism. □

This proof also explains the discrepancy in the manuscript. The abstract cokernel of $a\mapsto(a,-a)$ is indeed A, but it is not the derived limit being computed. The transposition and the common retraction replace that cokernel by the preceding resolution. For $G=C_2$ the category has two objects and $2+4+4+16=26$ arrows. It supplies the finite counterexample promised in the text, with a degree-three obstruction. The stronger assertion in footnote 2 that the general product hypotheses need not imply 2-connectivity requires a different example. The next comment verifies it with an actual product and a two-sphere.

Commentary · Development (commentators') [ms. 4]

A product whose category is a two-sphere

The correction of the monoid calculation leaves one assertion in footnote 2 to check: the exact product hypotheses may fail to force 2-connectivity. That assertion is true. One extra object supplies a smaller example in object count, and reveals geometrically the second homotopy group that the proposed monoid calculation did not produce. The construction below is our synthesis of the product condition and the elementary nerve-of-a-cone calculation; we did not locate this particular finite example in the literature searched, and make no claim of priority.

A family realizing wedges of two-spheres. [ours] For every integer $r\geq 1$ there is a category Y_r with three objects d,b,a, where b is weakly terminal and $a=b\times b$, such that

$$BY_r \simeq \bigvee^{(r-1)(r-2)/2} S^2.$$

The wedge with zero summands means a point. In particular Y_3 has 21 arrows, satisfies the opening hypotheses with $c=b$, and has the homotopy type of S^2.

Proof. Let D be an r-element set. On the two objects $b=b^1$ and $a=b^2$ use the category $T=S^{\mathrm{op}}$ already encountered, with

$$\mathrm{Hom}_T(b^m,b^n)=\{1,\dots,m\}^{\{1,\dots,n\}},\qquad m,n\in\{1,2\}.$$

These are coordinate-selection maps, composed by substitution. Add the object d, its identity, the maps

$$\mathrm{Hom}(d,b)=D,\qquad \mathrm{Hom}(d,a)=D^2,$$

and no maps from a or b to d. Composition with old arrows again selects coordinates. Substitution is associative, so this defines a category. The product bijection

$$\mathrm{Hom}(z,a)\xrightarrow{(p_1,p_2)}\mathrm{Hom}(z,b)\times\mathrm{Hom}(z,b)$$

holds for $z=a,b$ by the definition of T, and for $z=d$ it is the identity on D^2. Hence $a=b\times b$ in the enlarged category. As D is nonempty, all three objects map to b.

To see the homotopy type, consider $E=d\backslash T$. An object of E is a list of length one or two with entries in D; a morphism selects coordinates to obtain its target list. Let P be the poset of nonempty subsets of D of size at most two, ordered by reverse inclusion. Sending a list to its support defines $s:E\to P$. Choose one ordering of D and let $j:P\to E$ list each subset without repetition in that order. Coordinate selection makes j a functor and $sj=1_P$. There is a natural transformation $js\to 1_E$: from the distinct list of a support to any given list, repeat the indicated coordinates. This map is unique because each label occurs once in its source. Its uniqueness also proves naturality for every coordinate-selection arrow. Therefore $BE\simeq BP$.

For clarity, the last gluing step can be read directly on the nerve. Every nondegenerate simplex of NY_r is either wholly in NT, or starts at d and continues in T. A simplex of the second kind is precisely the cone on a simplex of $N(d\backslash T)$. Its face opposite d is obtained by forgetting the initial arrow from d. Thus NY_r is the simplicial mapping cone of $NE \to NT$. After realization it is the mapping cone of $BE \to BT$. The category T has initial object b, so BT is contractible and

$$BY_r \simeq \Sigma BE \simeq \Sigma BP.$$

The space BP is the barycentric subdivision of the complete graph on the r vertices of D. For $r \geq 1$ that graph is connected and has $\binom{r}{2} - r + 1 = (r-1)(r-2)/2$ independent cycles: collapse a spanning tree to obtain the wedge of that many circles. Suspending gives the asserted wedge of two-spheres. Finally T has 8 arrows; adding d contributes $1 + r + r^2$ arrows. For $r = 3$ the total is 21. □

This example verifies footnote 2 under the actual product assumptions, including its failure of 2-connectivity. It also keeps the two repairs distinct. The two-object category X_{C_2} first detects nonasphericity in degree three; the three-object category Y_3 detects it in degree two. The four-object category considered next in the manuscript has the latter homotopy type but satisfies only the terminal-presheaf-span condition.

Corollaire. $\Psi = \begin{array}{ccc} & \nearrow & b_0 \\ a_0 & & \\ & \searrow & c_0 \end{array}$ *n'est* pas *totalement* $\mathbf{W}_\infty$*-asphérique; i.e. si on a un dia-*

Commentary · Present state [ms. 5]

Total asphericity without a terminal object

The question concerns how far the useful gluing condition extends beyond representability. In the sense used here, a category A is totally $\mathbf{W}_\infty$-aspherical when, for every functor $f : A \to C$, the presheaf $f_!1_A$ has weakly contractible category of elements. This is the universal left-Kan-extension condition of Chapter XII, ms. 88–90; the editors explicitly distinguish it from the total asphericity of *Pursuing Stacks*. The suspicion that a terminal object is necessary is false. Filtered categories provide counterexamples; indeed Grothendieck records this correction himself in Chapter XII, ms. 109, footnote 78 (Grothendieck, 1990–1991d). Chapter II, Corollaries 2.17–2.18 (ms. 34–35), gives the underlying filtered argument (Grothendieck, 1990–1991b). We recall its mechanism because it answers the question on this page, while the commentary on Chapter II, manuscript pp. 35–36, already discusses its broader setting.

For any small A, the canonical presentation of the terminal presheaf gives

$$f_!1_A \cong \operatorname*{colim}_{a \in A} C(-, f(a)).$$

Suppose that A is filtered, and denote this presheaf by F. We verify directly that C/F is filtered. It is nonempty, since the identity of any $f(a)$ supplies an object. Given (c, x) and (d, y), choose representatives $u : c \to f(a)$ and $v : d \to f(b)$. A common successor k of a, b produces arrows from both objects to $(f(k), [\mathrm{id}_{f(k)}])$. Finally, let $r, s : (c, x) \rightrightarrows (d, y)$ be parallel arrows. Represent y by $v : d \to f(b)$. The equality $F(r)y = F(s)y$ says that vr and vs become equal at some later stage of the filtered colimit. Thus there is an arrow $b \to k$ such that its image, composed with v, equalizes r and s. This is an equalizer after postcomposition inside C/F.

The nerve of a filtered category is weakly contractible. One way to see this is to take the finitely many objects and arrows occurring in a simplicial representative of a homotopy class, choose a common target, and then equalize the finitely many competing composites. The resulting compatible cone gives a null homotopy. Equivalently, the usual finite-diagram characterization of filteredness cones off every finite simplicial diagram. Consequently C/F is weakly contractible for every f, as required. The elementary eventual-equality fact used above is the standard filtered-colimit argument (The Stacks Project Authors, 2026d, §4.19).

For a concrete infinite example take $A = (\mathbb{N}, \leq)$. It has no greatest element and hence no terminal object. The phenomenon is not a consequence of infinitude: the one-object category with endomorphism monoid $\{1, e\}$, $e^2 = e$, is filtered, since postcomposition by e equalizes any pair of endomorphisms. Its unique object is not terminal, because it has two endomorphisms. For a functor out of this category, $f_!1_A$ is the image of the induced idempotent on the represented presheaf $C(-, f(*))$. Taking $C = A$ and $f = \mathrm{id}_A$ makes this image the terminal presheaf, with one element at the unique object, whereas the sole representable has two elements there. Thus the gluing weight need not be representable. These examples settle the question as asked; they do not assert an exhaustive classification of totally aspherical categories.

Dans le diagramme

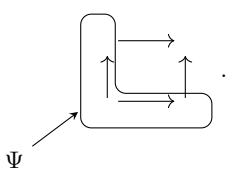
$$(*) \qquad \begin{array}{ccccc} U & \xrightarrow{\ i\ } & X & \xleftarrow{\ j\ } & T \\ {\scriptstyle p}\downarrow & \text{cocart. et cart.} & {\scriptstyle q}\downarrow & & \vdots\ \text{iso} \\ U' & \xrightarrow{\ i'\ } & X' & \xleftarrow{\ j'\ } & T', \end{array}$$

prenons

$$\begin{aligned} U = \Psi, \quad & T = \{t\} = e \text{ catégorie finale,} \\ & t \text{ objet final de } X, \\ & \text{i.e. } H_t = (u \longmapsto \mathrm{Hom}_X(u,t)) = e_U \in \mathrm{Ob}U^\wedge \ ({}^3). \end{aligned}$$

Prenons pour U' la catégorie dont il est question dans la 'proposition' hypothétique (et fausse) p. 1 avec $b = c$, plus précisément une catégorie avec deux objets b et $b \times b$, un groupe (voire un monoïde) G d'automorphismes `[(voire d'endomorphismes)]` de b, et les autres flèches celles qui s'en déduisent, en exigeant que $b \times b$ soit bel et bien le carré cartésien de b. On trouve une catégorie cofibrée (donc propre) sur la catégorie T opposée de celle des ensembles finis de la forme $\{0\} \cup \{0, 1\}$ (deux objets) avec comme fibres B_G et $B_{G\times G}$ respectivement (B_π = catégorie avec un seul objet, et monoïde d'endomorphismes π). Le foncteur

$$U = \Psi \longrightarrow U'$$



est celui donné par le diagramme

[ms. 6]

$$\begin{array}{ccccc} & & & \xrightarrow{\ \mathrm{pr}_1\ } & b \\ b \times b & & & & \\ & & & \xrightarrow{\ \mathrm{pr}_2\ } & b \end{array}$$

ed. 5

3. i.e. X déduit de $U = \Psi$ en lui rajoutant un objet final t – donc $X \simeq \mathbf{\Delta}^1 \times \mathbf{\Delta}^1$,

dans U', et les hypothèses a), b) de la page 1 assurent que la somme amalgamée $\varinjlim$ de ce diagramme dans $U'^{\wedge}$ est $e_{U'}$, i.e. que

$$p_!(e_U) = e_{U'}.$$

Il s'ensuit que dans la somme amalgamée, X' envisagée dans $(*)$, l'unique élément t' de T' est objet final de X'. On a vu que U' est 1-connexe, mais non 2-connexe si le groupe abélien enveloppant de G (i.e. $G/$(groupe des commutateurs) dans le cas où G est un groupe) n'est pas réduit à 1. L'exemple le plus économique s'obtient en prenant $G = \{\pm 1\}$ le groupe à deux éléments. C'est donc un cas où dans $(*)$ on a

$$i \in W \quad \text{(et même } i \text{ asphérique)}, \qquad \text{mais } i' \notin W,$$

et qui a l'avantage sur l'exemple plus sophistiqué de la page 103 (prop. 10) de ne mettre en jeu que des catégories finies – et même fort petites !

Commentary · Examples [ms. 6]

Adjoining a terminal object after the pushout

This construction uses the failure of asphericity to test whether an ordinary pushout preserves weak equivalences. Its mechanism is transparent on representables. For any object x of a category satisfying the opening hypotheses, put $B_x = \mathrm{Hom}(x, b)$ and $C_x = \mathrm{Hom}(x, c)$. Both sets are nonempty, and

$$B_x \amalg_{B_x \times C_x} C_x = \{*\}.$$

Every element of B_x is identified with every element of C_x, so there is exactly one equivalence class. As presheaf colimits are computed objectwise, the span $b \leftarrow b \times c \rightarrow c$ has terminal colimit. This verifies $p_! 1_\Psi = 1_{U'}$ without a homotopy assertion.

Write $\Psi^{\triangleright}$ for Ψ with a new terminal object. In the pushout $U' \amalg_\Psi \Psi^{\triangleright}$, a map from $x \in U'$ to the new object is represented by a map from x to an object of the span, modulo its two identifications. Thus the presheaf of maps to that object is precisely $p_! 1_\Psi$, and the pushout is $(U')^{\triangleright}$. The original inclusion $\Psi \rightarrow \Psi^{\triangleright}$ is aspherical: the comma category over the new vertex is Ψ, with initial object, and the comma categories over old vertices have terminal objects. After the pushout, $U' \rightarrow (U')^{\triangleright}$ is a weak equivalence exactly when BU' is weakly contractible.

Taking $U' = X_{C_2}$ therefore validates the announced failure. Both the original span and its cone are contractible, whereas $H^3(BU'; \mathbb{F}_2) = \mathbb{F}_2$. The source's asserted obstruction in π_2 must be replaced by the degree-three calculation above; the categorical pushout and its terminal object require no alteration. This is also the point where the distinction from a homotopy pushout becomes visible: a homotopy pushout along the equivalence $\Psi \rightarrow \Psi^{\triangleright}$ would retain the homotopy type of U', while the ordinary categorical pushout has become a cone.

Procédons maintenant comme dans la proposition 11, en désignant par U'' la catégorie déduite de U' en lui ajoutant un objet final, et soit [ms. 7]

$$p' : U' \longrightarrow U''$$

l'inclusion, de sorte que

$$p'_!(e_{U'}) \quad = \quad (p'p)_!(e_U) = U' \qquad \text{en tant qu'objet dans } U''^{\wedge}$$
$$\text{(sous-préfaisceau du préfaisceau final } e_{U''}).$$

Considérons

$$\begin{array}{ccccc} U & \xrightarrow{\ i\ } & X & \xleftarrow{\ j\ } & T \\ {\scriptstyle p''=p'p}\downarrow & \text{cocart. et cart.} & {\scriptstyle q''}\downarrow & & \downarrow{\scriptstyle \text{iso}} \\ U'' & \xrightarrow{\ i''\ } & X'' & \xleftarrow{\ j''\ } & T''. \end{array}$$

Cette fois U, X *et* U'' sont $\mathbf{W}_\infty$-asphériques (et même contractiles toutes trois), donc i, p'' sont dans W, pourtant X'' n'est pas $\mathbf{W}_\infty$-asphérique (donc $i'', q'' \notin \mathbf{W}_\infty$), car pour qu'elle le soit, i.e.

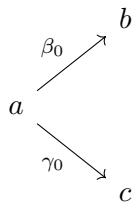
pour que $i'' \in \mathbf{W}_\infty$, il faudrait (prop. 7, cor. page 85 ([4])) que i'' soit $\mathbf{W}_\infty$-asphérique, i.e. que U''/t'' soit $\mathbf{W}_\infty$-asphérique. Mais par construction $U''/t'' \simeq U'$, qui n'est *pas* $\mathbf{W}_\infty$-asphérique.

Commentary · Exposition [ms. 7]

Two cone vertices and a suspension

Grothendieck strengthens the example by making the other map out of Ψ a weak equivalence as well. Let $C = U'$, let e be the terminal object adjoined to form $U'' = C^{\triangleright}$, and retain t for the cone vertex coming from $X = \Psi^{\triangleright}$. The left Kan extension $p'_!1_C$ is the presheaf with value one on the old objects of C and value zero at e: no map runs from the new terminal object back to C. This is the subterminal presheaf called U' in the displayed formula.

Consequently the pushout X'' consists of C with two incomparable new terminal vertices e, t, and one map from each old object to each vertex. There are no arrows between e and t. Every nondegenerate nerve simplex lies in one of the two cones; their intersection is exactly NC. Hence



$$BX'' = C(BC) \cup_{BC} C(BC) \simeq \Sigma BC.$$

This gives the omitted nonasphericity argument directly. For the finite choice $C = X_{C_2}$, suspension in reduced cohomology yields

$$\widetilde{H}^4(BX''; \mathbb{F}_2) \cong \widetilde{H}^3(BC; \mathbb{F}_2) \cong \mathbb{F}_2.$$

Thus X'' is not weakly contractible, although Ψ, X and U'' are contractible. Both maps to X'' from the latter two categories fail to be weak equivalences. No converse to Quillen's Theorem A is required. In general a noncontractible space may have contractible suspension if it is connected and acyclic, so a bare appeal to the nonasphericity of a comma category would not suffice. Here the explicit surviving cohomology class proves exactly what is needed.

Voilà un exemple encore plus simple d'un foncteur $f : \Psi \longrightarrow X$ tel que $f_!(e_\Psi)$ ne soit pas $\mathbf{W}_\infty$-asphérique, i.e. d'un diagramme

ed. 6

dans une catégorie V, telle que la limite inductive $L = b \amalg_a c$ *dans* $V^\wedge$ soit un objet non [ms. 8] asphérique de $V^\wedge$, i.e. V/L soit non asphérique. Je sais qu'il faut, pour un tel contre-exemple, que $a \longrightarrow b$ et $a \longrightarrow c$ ne soient pas des monomorphismes. L'idée, c'est de prendre un exemple universel où ces flèches ne soient pas `[des]` monomorphismes, en prenant [ms. 9]

$$V = \left(\begin{array}{ccccc} & & & & b \\ & & & \overset{\beta}{\nearrow} & \\ 0 & \underset{\mu}{\overset{\lambda}{\rightrightarrows}} & a & & \\ & & & \underset{\gamma}{\searrow} & \\ & & & & c \end{array} \right)$$

avec

$$\beta\lambda = \beta\mu \qquad \text{et} \qquad \gamma\lambda = \gamma\mu$$

les deux seules flèches non identiques, en plus des quatre flèches marquées β, γ, λ, μ.

4. pas encore démontré !

Commentary · Exposition [ms. 8]

A presheaf pushout remembers only components

Grothendieck now seeks a finite obstruction that can be inserted into a much larger category. The decisive distinction is between the ordinary pushout of three representable presheaves and the homotopy carried by its category of elements. We make that distinction explicit before using the example. Write $y(a) = \mathrm{Hom}_C(-, a)$, and let

$$L = y(b) \amalg_{y(a)} y(c)$$

for a span $b \xleftarrow{\beta} a \xrightarrow{\gamma} c$ in C. For $x \in C$, form the bipartite multigraph K_x with vertices $b(x) \amalg c(x)$ and one edge for every $u \in a(x)$, joining βu to γu. Then $L(x) = \pi_0 K_x$. An ordinary pushout has forgotten the cycles in this graph.

This description proves the assertion about monomorphisms, including the case where L is not terminal. Let E have objects (v, x, u), with $v \in \Psi$ and $u : x \to f(v)$ for the given span $f : \Psi \to C$. A morphism to (v', x', u') consists of $h : v \to v'$ and $r : x \to x'$ satisfying $f(h)u = u'r$. The projection $E \to \Psi$ has right adjoint $v \mapsto (v, f(v), 1)$, so BE is contractible. There is a canonical functor

$$P : E \longrightarrow C/L, \qquad (v, x, u) \longmapsto (x, [u]).$$

Here C/L denotes the category of elements of the presheaf L. For $(x, l) \in C/L$, the comma category $(x, l)\backslash E$ retracts up to a natural transformation onto the incidence category of the component l of K_x. Indeed an object of this comma category includes $r : x \to x'$; send it to $(v, x, u'r)$ and use the morphism given by r for the comparison with the original object. The incidence category has one object for each vertex and edge, and two arrows from each edge to its endpoints.

If β is monic, every vertex in $b(x)$ has degree at most one. Every connected component of K_x is consequently a star, possibly a single vertex, and its incidence category is contractible. Quillen's Theorem A, in its comma-category form, gives $BP : BE \simeq B(C/L)$. Thus L is aspherical. The same argument applies with b and c interchanged. This supplies the proof promised in the source; the only external ingredient is the comma-category criterion (Quillen, 1973, §1, Theorem A).

There is also a useful conclusion without a monomorphism hypothesis. If $L = e_C$, every K_x is nonempty and connected, and C is simply connected. To see this directly, work in ΠC. Put $d = [\beta][\gamma]^{-1} : c \to b$. Send a vertex $v \in b(x)$ to $[v] : x \to b$ and a vertex $w \in c(x)$ to $d[w]$. The two endpoints of an edge $u \in a(x)$ have the same image, since $d[\gamma u] = [\beta u]$. Connectedness therefore gives a single arrow $s_x : x \to b$. For every $r : x \to y$, precomposition of a vertex of K_y proves $s_y[r] = s_x$. These identities extend to all zigzags and force every arrow from x to y in ΠC to equal $s_y^{-1} s_x$. Thus ΠC is equivalent to the terminal groupoid. The correction on manuscript p. 10 is justified: the first possible obstruction is in degree two.

On trouve que

$$b \amalg_a c \xrightarrow{\sim} e_X \qquad \text{(somme amalgamée dans } V^\wedge\text{)}.$$

Pourtant V n'est pas asphérique, ni même 1-connexe : il est homotope à la sous-catégorie ouverte $V_0 = (0 \underset{\mu}{\overset{\lambda}{\rightrightarrows}} a)$, car on a une rétraction $V \xrightarrow{r} V_0$ (envoyant b et c sur a), et une flèche $ir \longrightarrow \mathrm{id}_V$ (où $i : X_0 \hookrightarrow X$ est l'inclusion). Donc V a le même type d'homotopie *que* V_0, qui est un cercle. Donc on a intérêt à prendre ce V, où $\tilde{V}$ déduit de V en rajoutant un élément final e,

$$\tilde{V} = \left(\begin{array}{ccccc} & & & & b & & \\ & & & \nearrow & & \searrow & \\ 0 & \rightrightarrows & a & & & & e \\ & & & \searrow & & \nearrow & \\ & & & & c & & \end{array} \right),$$

comme U', pour les contre-exemples pages 6 et 7.

Commentary · Examples [ms. 9]

The missing retraction and the two-sphere

The four-object category is useful because its relations can be seen as attaching two disks to the same circle. We use the notation Z of the following pages, suppressing subscripts: its objects are $0, a, b, c$, its generating arrows are $\lambda, \mu : 0 \rightrightarrows a$, $\beta : a \to b$, and $\gamma : a \to c$, and its relations identify the two composites to each of b, c. The commentary on Chapter II, manuscript p. 36 ("The retracted proposition and a visible sphere") already records the general obstruction to total asphericity. Here we need the precise attaching maps, because the next pushout will suspend this particular sphere once more.

Let $D = (0 \rightrightarrows a)$. A retraction $Z \to D$ would fix a, so it must send b to a and β to 1_a. Applying it to $\beta\lambda = \beta\mu$ would give $\lambda = \mu$, a contradiction. This is the exact point at which the proposed retraction fails. The full subcategories on $\{0, a, b\}$ and $\{0, a, c\}$ are instead the two terminal cones on D. Every composable string in Z belongs to one of them, and their intersection is D. Consequently

$$NZ = N(D^{\triangleright_b}) \amalg_{ND} N(D^{\triangleright_c}), \qquad BZ \cong \Sigma BD \cong S^2.$$

The first identity is an actual identity of simplicial sets. Realization preserves this union, and BD is the circle with two vertices and two edges. This proves the correction already supplied by footnote 7, rather than replacing one guessed homotopy type by another.

The calculation is also visible in normalized chains. There are four vertices, six nonidentity arrows, four nondegenerate 2-simplices, and no higher nondegenerate simplices. With $[u, v]$ denoting a composable pair, a fundamental cycle is

$$[\lambda, \beta] - [\mu, \beta] - [\lambda, \gamma] + [\mu, \gamma].$$

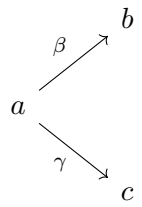
Its boundary vanishes by the two defining relations; it generates $H_2(BZ; \mathbf{Z}) \cong \mathbf{Z}$. In particular $\pi_1(BZ) = 0$ and $\pi_2(BZ) \cong \mathbf{Z}$.

The presheaf pushout nevertheless is terminal. Its pointwise calculation is

x	0	a	b	c
$\lvert a(x)\rvert$	2	1	0	0
$\lvert b(x)\rvert$	1	1	1	0
$\lvert c(x)\rvert$	1	1	0	1
$\lvert L(x)\rvert$	1	1	1	1

and all restriction maps of L are the unique maps between singletons. Thus $Z/L \cong Z$, while $L = e_Z$. The same data establish that Ψ is not totally $\mathbf{W}_\infty$-aspherical. Both arrows out of a fail to be monic, and the same pair λ, μ witnesses both failures. The word "universal" refers to the free category with these specified generators and relations; arbitrary failures of the two monomorphisms need not have a common witnessing pair.

[ms. 10]



2.6. Contre-exemples pour la totale asphéricité.

Je me suis finalement convaincu que

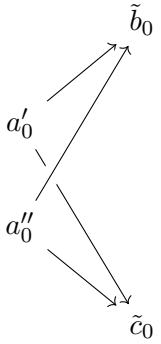
$$\Psi = \left\{ \begin{array}{ccc} & & b_0 \\ & \nearrow & \\ a_0 & & \\ & \searrow & \\ & & c_0 \end{array} \right\}$$

n'est *pas* totalement asphérique (pour le localiseur $\mathbf{W}_\infty$ – dans le présent numéro, on supposera $W = \mathbf{W}_\infty$), ou ce qui revient au même, qu'on peut avoir un diagramme de type Ψ

$(*)$

dans une catégorie $Z \in \mathrm{Ob}\,\mathrm{Cat}$, dont la limite inductive $b \amalg_a c$ dans $Z^\wedge$ soit le préfaisceau final e_Z, i.e. tel que l'on ait

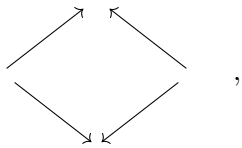
$$b(z) \amalg_{a(z)} c(z) \xrightarrow{\sim} \text{ensemble ponctuel}$$



pour tout objet z de Z (où $a(z) = \mathrm{Hom}_Z(a, z)$ `[plutôt` $\mathrm{Hom}_Z(z, a)$`]`) sans que pour autant Z soit asphérique, ni même 1-connexe ([5]). L'exemple le plus simple que j'ai trouvé, est l'exemple 'universel' d'un diagramme $(*)$ où ni l'une ni l'autre des deux flèches $a \longrightarrow b$, $a \longrightarrow c$ n'est `[un]` monomorphisme (car si elle l'est, alors on peut prouver que Z est bel et bien asphérique, comme nous verrons par la suite). C'est la catégorie

$$Z = \left\{ \begin{array}{ccccc} & & & & b_0 \\ & & & \overset{\beta_0}{\nearrow} & \\ 0_0 & \underset{\mu_0}{\overset{\lambda_0}{\rightrightarrows}} & a_0 & & \\ & & & \underset{\gamma_0}{\searrow} & \\ & & & & c_0 \end{array} \right\}$$

déduite de Ψ en lui rajoutant un objet 0_0, relié à a_0 par deux flèches distinctes λ_0, μ_0, telles que [ms. 11]



$$\beta_0\lambda_0 = \beta_0\mu_0 \qquad \text{et} \qquad \gamma_0\lambda_0 = \gamma_0\mu_0,$$

ces deux flèches composées étant, avec les quatre flèches β_0, γ_0, λ_0, μ_0 marquées sur le diagramme, les seules (six) flèches non identiques de Z. Ψ immergée dans Z comme un fermé, de complémentaire la catégorie ponctuelle réduite à 0_0. (NB L'immersion fermée $\Psi \longrightarrow Z$ n'est pas immersion de Dwyer, i.e. (comme Z est le plus petit ouvert de Z contenant Ψ) n'est pas coasphérique, car la catégorie $0\backslash\Psi$, cofibrée sur Ψ avec fibres discrètes, de cardinal 2 en a_0 et 1 en b_0 et c_0, est la catégorie

5. faux – il est 1-connexe forcément ([6]), mais non 2-connexe.
6. cf. commentaire XII, p. 101.

i.e.

,

qui a le type d'homotopie du cercle.) Ni l'immersion ouverte $\{0_0\} \longrightarrow Z$, car $\{0_0\}/a_0$ est la catégorie discrète de cardinalité 2.

Commentary · Exposition [ms. 11]

The link detects the failure of Dwyer's condition

Grothendieck is locating the obstruction where it will survive a change of ambient category. For the closed inclusion $\Psi \hookrightarrow Z$, the relevant link is $0\backslash\Psi$. Its four objects are the two arrows λ, μ to a and the unique arrows to b, c. Each of the first two objects maps to each of the last two, and there are no other nonidentity arrows. Its nerve is the square graph, hence its classifying space is S^1. Projection to Ψ is the discrete opfibration classified by the covariant functor $\mathrm{Hom}_Z(0,-)|_\Psi$, with fibre cardinalities $2, 1, 1$.

This link has neither an initial object nor a contractible nerve. The inclusion is therefore neither a closed Dwyer inclusion nor coaspherical. These are separate conclusions: Dwyer's condition asks for a left adjoint to the inclusion into the smallest open neighbourhood, equivalently for initial objects in the relevant comma categories; weak contractibility alone would be a weaker requirement. For the complementary open inclusion $\{0\} \hookrightarrow Z$, the slice over a is the discrete two-object category, so this inclusion also fails Dwyer's condition. The larger category can be simply connected while these local links retain nontrivial information. That local information, rather than the nonexistent retraction, will drive the finite pushout counterexample.

L'inclusion $i : Z_0 \longrightarrow Z$ de

$$Z_0 \;=\; (\; 0_0 \overset{\lambda_0}{\underset{\mu_0}{\rightrightarrows}} a_0 \;)$$

dans Z est un homotopisme ([7]) (car il existe une rétraction évidente r de Z sur Z_0 ([7]), et une flèche $ir \longrightarrow \mathrm{id}_Z$), donc Z est homotope à Z_0, qui a le type d'homotopie du cercle, donc n'est pas 1-connexe.

D'autre part, la vérification de [ms. 12]

$$b_0 \amalg_{a_0} c_0 \;=\; e_Z \qquad \text{dans } Z^\wedge$$

est immédiate.

On va utiliser cette flèche

$$\Psi \longrightarrow Z$$

pour construire des exemples intéressants (et déchirants) de sommes amalgamées

$$\begin{array}{ccc} U & \overset{i}{\hookrightarrow} & X \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle q} \\ U' & \overset{i'}{\hookrightarrow} & X', \end{array}$$

avec i immersion ouverte, telle qu'on ait même

$$i :\; U \longrightarrow \overline{U} \qquad \text{est asphérique, donc dans } W,$$

alors que pourtant on aura

$$i' :\; U' \longrightarrow \overline{U'} \qquad \notin W,$$

7. faux, il n'y a pas de rétraction du tout! En fait, Z est la *suspension* de la $\rightrightarrows$, qui a le type d'homotopie (topologique) du cercle, et il a donc le type d'homotopie de la 2-sphère.

et ce qui mieux (ou pis) est,

$$p \in W \qquad \text{mais} \qquad q \notin W$$

ed. 9

(et éventuellement, en même temps, $i \in W$ mais $i' \notin W$). De plus (contrairement aux constructions des propositions 10, 11 (p. 101-107)), les catégories envisagées pourront toutes être finies. Je suis particulièrement intéressé par le cas où X est un 'carré'

$$X = \Phi_n \times \Phi_m \qquad (n, m \geq 2),$$

et où U est son 'bord'

$$U = \dot{X} \overset{\text{déf}}{=} (\dot{\Phi}_n \times \Phi_m) \cup (\Phi_n \times \dot{\Phi}_m).$$

Commentary · Exposition [ms. 12]

The boundary and its categorical closure

Grothendieck wants to know whether ordinary subdivisions of a square provide attaching maps compatible with weak equivalences. The notation carries two geometries: the realization of the nerve is a genuine square, while the open and closed subsets of the category are determined by the directions of its arrows. Write

$$\Phi_n = (0 \longrightarrow 1 \longleftarrow 2 \longrightarrow \cdots \longrightarrow 2n-1 \longleftarrow 2n), \qquad \dot{\Phi}_n = \{0, 2n\}.$$

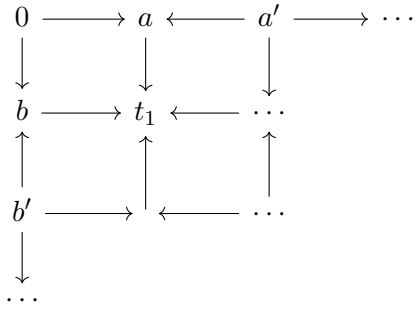
This is the convention in Chapter XII, manuscript p. 114 (Grothendieck, 1990–1991d); the commentary on directed intervals in Chapter VII, manuscript pp. 1–19, explains its relation to the underlying unoriented interval. The boundary U consists of the pairs with at least one coordinate an endpoint. It is a sieve, and

$$BX \cong [0,1]^2, \qquad BU \cong \partial[0,1]^2 \cong S^1.$$

In particular $U \to X$ is not a weak equivalence. The expression "immersion ouverte W-asphérique" in the proposition must be read in the local sense $U \to \overline{U}$: it is this induced functor to the categorical closure that is aspherical.

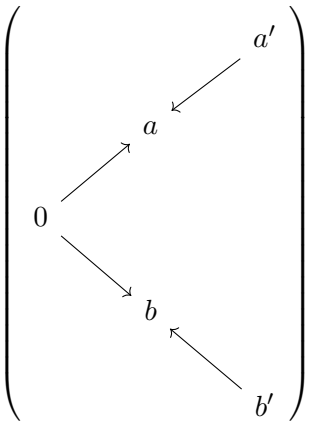
The slice calculation makes the distinction exact. Put

$$E_n = \{0, 2n\}, \qquad E_n^+ = \{0, 1, 2n-1, 2n\}.$$



The cosieve generated by U is

$$\overline{U} = (E_n^+ \times \Phi_m) \cup (\Phi_n \times E_m^+).$$



For $t \notin \overline{U}$, the slice U/t is empty. For $t \in U$ it has terminal object t. Suppose that $t \in \overline{U} \setminus U$. If exactly one coordinate is adjacent to an endpoint and the other is an interior even vertex, then U/t is a point. If that other coordinate is an odd vertex not adjacent to an endpoint, U/t is the three-object interval with a terminal middle vertex. Finally, when both coordinates are adjacent to endpoints, U/t is the five-object category $\widetilde{\Psi}$ drawn in the source. There are exactly four such t, because $n, m \geq 2$.

The nerve of $\widetilde{\Psi}$ is the path with successive vertices $a', a, 0, b, b'$. It is contractible, although neither a nor b receives a map from the other. Thus every slice over $\overline{U}$ is contractible, proving the claimed local asphericity, while the four exceptional slices have no terminal object. For a sieve of posets, Dwyer's condition is precisely the existence of these terminal objects over its generated cosieve: they assemble into the right adjoint to the inclusion. This proves both that $U \hookrightarrow X$ is not a Dwyer inclusion and that deleting the four exceptional vertices makes it one. Contractible slices suffice for a weak equivalence to the closure; an adjoint supplies the stronger structure that behaves well under arbitrary pushout.

[ms. 13]

Proposition. *Soient $n, m \geq 2$, et considérons l'inclusion $U = \partial X \overset{i}{\hookrightarrow} X$ du bord du 'carré' $X = \Phi_n \times \Phi_m$ dans X. C'est une immersion ouverte W-asphérique, de façon précise, les U/t ($t \in \dot{U} = \bar{U}\backslash U$) sont isomorphes à e (catégorie ponctuelle) ou à $\Phi =$*  *(catégorie avec élément final), sauf pour les quatre éléments t_i des quatre 'coins' de $\dot{U}$, où c'est la catégorie*

$\tilde{\Psi} =$ 

n'ayant pas d'élément final. Donc $U \overset{i}{\longrightarrow} X$ n'est pas immersion ouverte de Dwyer (mais $U \longrightarrow X\backslash\{t_1, t_2, t_3, t_4\}$ l'est …). Ceci posé, je dis que $i : U \longrightarrow X$ n'est pas une W-cofibration. ed. 10

DÉMONSTRATION. Soit

$$F \hookrightarrow U$$

l'inclusion dans $U = \partial X$ de la catégorie-coin $[V =] \begin{matrix} 0 \longrightarrow a \\ \downarrow \\ b \end{matrix}$ (cf. figure), isomorphe à Ψ. On voit aussitôt que c'est une immersion fermée de Dwyer (le plus petit ouvert de U contenant Ψ est justement la catégorie $\tilde{\Psi} = U/t_1$ de tantôt), donc une W-cofibration. Si $U \longrightarrow X$ était une W-cofibration, il en serait de même du composé $V \longrightarrow X$. On va voir que ce n'est pas le cas.

Soit $\overline{V} = \begin{matrix} 0 \longrightarrow a \\ \downarrow \quad\quad \downarrow \\ b \longrightarrow t_1 \end{matrix}$ l'adhérence de V dans X, et considérons l'inclusion [ms. 14]

$$\overline{V} \longrightarrow X,$$

je dis que [c]'est une immersion fermée de Dwyer, i.e. que pour tout $s \in W\backslash\overline{V}$, où W est le plus petit ouvert de X contenant $\overline{V}$, i.e.

$$W = \begin{matrix} 0 \longrightarrow a \longleftarrow a' \\ \downarrow \quad\quad \downarrow \quad\quad \downarrow \\ b \longrightarrow \downarrow \longleftarrow a'' \\ \uparrow \quad\quad \uparrow \quad\quad \uparrow \\ b' \longrightarrow b'' \longleftarrow c, \end{matrix}$$

la catégorie $s\backslash\overline{V}$ a un objet initial. (Les catégories $s\backslash\overline{V}$ qu'on obtient, à partir des cinq choix possibles pour s, sont $\mathbf{\Delta}^1$ (si $s = a'$ ou b') ou e (pour $s = a''$, b'' ou c)). Donc $\overline{V} \longrightarrow X$ est une W-cofibration.

Ceci posé, on sait qu'il existe, pour [?] l'inclusion (immersion ouverte)

$$V \hookrightarrow \overline{V} \qquad \text{i.e. } \Psi \hookrightarrow \mathbf{\Delta}^1 \times \mathbf{\Delta}^1,$$

un foncteur $V \longrightarrow V'$, donnant lieu à un carré cocartésien

$$(*) \qquad \begin{array}{ccc} V & \xrightarrow{i} & \overline{V} \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle \overline{p}} \\ V' & \xrightarrow{i'} & \overline{V'} \end{array}$$

avec

$$i, p \in W \text{ (car } V, V', \overline{V} \text{ } W\text{-asphérique), mais } i', \overline{p} \notin W \text{ (i.e. } \overline{V'} \textit{ pas } W\text{-asphérique).}$$

ed. 11

Je rappelle qu'on prend d'abord

$$V'_0 = \left(0' \underset{\mu}{\overset{\lambda}{\rightrightarrows}} 0 \begin{array}{l} \overset{\alpha}{\nearrow} a \\ \underset{\beta}{\searrow} b \end{array} \right) \qquad \text{avec} \quad \begin{cases} \alpha\lambda = \alpha\mu \\ \beta\lambda = \beta\mu \end{cases}$$

et l'immersion fermée 'identique' de V dans V' [plutôt V'_0]

$$p_0 : V \longrightarrow V'_0$$

(qui est telle que [ms. 15]

$$p_{0!}(e_V) = e_{V'_0} \quad),$$

puis on prend pour V' la catégorie obtenue en ajoutant un objet final à V'_0

$$V' = \left(0' \underset{\mu}{\overset{\lambda}{\rightrightarrows}} 0 \begin{array}{ccc} & \overset{\alpha}{\nearrow} a & \overset{\rho}{\searrow} \\ & & e \\ & \underset{\beta}{\searrow} b & \underset{\sigma}{\nearrow} \end{array} \right) \qquad \text{avec} \quad \begin{cases} \alpha\lambda = \alpha\mu \\ \beta\lambda = \beta\mu \\ \rho\alpha = \sigma\beta \end{cases}$$

et pour p le foncteur composé

$$V \xrightarrow{p_0} V'_0 \xrightarrow{p_1} V', \qquad p$$

où p_1 est l'inclusion (ouverte). On trouve alors le carré $(*)$, avec $\overline{V'}$ non W-asphérique, ou ce qui revient au même, $i' \notin W$. Car comme $\overline{V'}\backslash V' \simeq \overline{V}\backslash V$ est la catégorie ponctuelle, $i' \in W$ équivaut à V'/t W-asphérique ([8]) (cf. cor. 4, p. 149 dans XII). Or par construction $V'/t \simeq V'_0$, qui n'est pas W-asphérique (dans le cas, disons, où $W \subseteq W_1$, car $\pi_1(V'_0) \simeq \mathbf{Z}$).

8. moyennant (W 7 bis).

Commentary · Examples [ms. 15]

The pushout is a three-sphere

The purpose of adjoining the new terminal object e is to make the replacement V' contractible without removing the obstruction in the link of the other cone point t. It is possible to calculate the entire pushout, so the argument need not depend on the converse excision principle mentioned in footnote 8. Rename V_0' as Z and the original three-object corner as V. Thus Z is the four-object category just analysed, $V' = Z^{\triangleright_e}$, and $\overline{V} = V^{\triangleright_t}$.

Let $Q = V' \amalg_V \overline{V}$. Its objects are the four objects of Z and two further objects e, t. It contains Z as a full subcategory. For each $z \in Z$ there is exactly one arrow $z \to e$ and exactly one arrow $z \to t$; there are no arrows between e and t. To check the only nontrivial assertion, the cocone over V supplies the maps from its three objects to t. The two composites from the extra object $0'$ to t agree, because the relation $\alpha\lambda = \alpha\mu$ already identifies their composites through a. Hence there is a unique arrow $0' \to t$. This description has the pushout universal property: a functor out of Q is exactly a functor out of Z together with one cocone over Z with vertex the image of e and one with vertex the image of t; the latter is uniquely determined by its restriction to V.

Every simplex of NQ lies in one of the two cones on NZ, and their intersection is NZ. Therefore

$$BQ \cong \Sigma BZ \cong S^3, \qquad \widetilde{H}_k(BQ; \mathbf{Z}) = \begin{cases} \mathbf{Z}, & k = 3, \\ 0, & k \neq 3. \end{cases}$$

Since BV, $B\overline{V}$, and BV' are contractible, the maps i and p are weak equivalences, but i' and $\overline{p}$ are not. This is a completely finite example: Q has six objects, fourteen nonidentity arrows, sixteen nondegenerate 2-simplices, and eight nondegenerate 3-simplices. Its nerve has no higher nondegenerate simplices.

The sentence $\pi_1(V_0') \cong \mathbf{Z}$ is present in the edition and must remain in the historical text. Its correct replacement in the argument is

$$\pi_1(V_0') = 0, \qquad \pi_2(V_0') \cong \mathbf{Z}, \qquad \pi_3(Q) \cong \mathbf{Z}.$$

The example proves the required assertion for $W = \mathbf{W}_\infty$. It does not prove the printed extension to every $W \subseteq W_1$: both $V' \to Q$ and $\overline{V} \to Q$ are equivalences on 2-types. Here W_k means equivalence on homotopy groups in degrees at most k and on components.

There is a second, logically independent issue. For an arbitrary open inclusion with one-point complement, membership in $\mathbf{W}_\infty$ does not force its comma category over that point to be contractible. The referenced Chapter XII corollary explicitly assumes the inverse part of $W(7\,\text{bis})$. The acyclic-link construction in the commentary on manuscript pp. 17–18 exhibits the failure of that inverse implication for spaces. In the present example both the link and the pushout are known spheres, so the conclusion follows from the displayed nerve calculation with no appeal to this extra axiom.

Considérons alors le diagramme de carrés cocartésiens [ms. 16]

$$\begin{array}{ccccc} V & \xhookrightarrow{i} & \overline{V} & \hookrightarrow & X \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle \overline{p}} & & \downarrow{\scriptstyle q} \\ V' & \xhookrightarrow{i'} & \overline{V'} & \hookrightarrow & X' \end{array} \quad .$$

ed. 12

Comme $\overline{V} \hookrightarrow X$ est [une] immersion fermée de Dwyer, le carré de droite est W-cocartésien, donc $(\overline{p} \in W) \iff (q \in W)$, donc (comme $\overline{p} \notin W$) on a

$$p \in W, \qquad \text{mais} \qquad q \notin W,$$

ce qui montre bien que $V \longrightarrow X$ n'est pas une W-cofibration. Factorisant $V \longrightarrow X$ par U (au lieu de $\overline{V}$), on trouve

$$\begin{array}{ccccc} V & \longrightarrow & U & \longrightarrow & X \\ {\scriptstyle p\in W}\downarrow & & \downarrow{\scriptstyle q_U \in W} & & \downarrow{\scriptstyle q \notin W} \\ V' & \longrightarrow & U' & \longrightarrow & X' \end{array} \quad ,$$

où $q_U \in W$ puisque $p \in W$ et $V \longrightarrow U$ est [une] immersion de Dwyer. Cela rend explicite que $U \longrightarrow X$ n'est pas une W-cofibration, puisque

$$q_U \in W, \qquad \text{mais} \qquad q \notin W,$$

q.e.d.

Commentary · Exposition [ms. 16]

Carrying the local obstruction to the boundary

The last step places the six-object defect inside the subdivided rectangle. Grothendieck has chosen the corner so that the two surrounding inclusions are closed Dwyer inclusions. We record their adjoints, because they explain exactly which pushouts preserve homotopy and complete the logical step in the proof.

Use coordinates $0 = (0,0)$, $a = (1,0)$, $b = (0,1)$, and $t_1 = (1,1)$. The smallest open neighbourhood of $V = \{0, a, b\}$ in U consists of these three points and $a' = (2,0), b' = (0,2)$. Its inclusion of V has the left adjoint fixing V and sending a' to a and b' to b. Indeed these images are the least points of V above the corresponding objects. The inclusion $V \hookrightarrow U$ is a cosieve, so it is a closed Dwyer inclusion.

Similarly $\overline{V} = \{0,1\} \times \{0,1\}$ is a cosieve of X. Its smallest open neighbourhood is $\{0,1,2\}^2$. Define $r_0(0) = 0$, $r_0(1) = r_0(2) = 1$; then $r_0 \times r_0$ is left adjoint to the inclusion of $\overline{V}$ into this neighbourhood. Thus $\overline{V} \hookrightarrow X$ is also a closed Dwyer inclusion. This gives the source's five comma categories explicitly: $a'\backslash\overline{V}$ and $b'\backslash\overline{V}$ are two-object chains, whereas the other three are points.

Thomason's pushout theorem, applied after taking opposite categories, now identifies the nerves of the relevant categorical pushouts with homotopy pushouts (Thomason, 1980, Proposition 4.3 and Corollary 4.4). One additional observation is needed for the reverse implication written in the source: $\overline{V} \to X$ is itself a weak equivalence, since both classifying spaces are contractible. Consequently its pushout $Q \to X'$ is a weak equivalence. In the commutative square

$$\begin{array}{ccc} \overline{V} & \xrightarrow{\sim} & X \\ {\scriptstyle \overline{p}}\downarrow & & \downarrow{\scriptstyle q} \\ Q & \xrightarrow{\sim} & X' \end{array}$$

two-out-of-three gives $\overline{p} \in \mathbf{W}_\infty$ if and only if $q \in \mathbf{W}_\infty$. Since $BQ \simeq S^3$, we obtain $BX' \simeq S^3$ and $q \notin \mathbf{W}_\infty$. A homotopy pushout by itself would not justify the converse: the two horizontal equivalences are the missing reason in this particular square.

Finally let $U' = U \amalg_V V'$. The other closed Dwyer inclusion, $V \to U$, ensures that $q_U : U \to U'$ is a weak equivalence because $p : V \to V'$ is one. Associativity of ordinary pushout identifies $X \amalg_U U'$ with the same X'. Thus the cobase-change functor along $U \to X$ takes the weak equivalence q_U to the map q which is not a weak equivalence. This proves exactly the definition of failure of a W-cofibration used in Chapter XII: the functor $U\backslash\mathrm{Cat} \to X\backslash\mathrm{Cat}$ fails to preserve weak equivalences. In modern terminology, this inclusion is not an h-cofibration. The target replacement still satisfies $BU' \simeq S^1$; the change in the ambient category is detected by its new third homology group.

Commentary · Later developments [ms. 16]

Dwyer maps, homotopy pushouts, and products

Grothendieck's distinction between contractible links and adjoint neighbourhoods remains useful in the modern theory. Thomason's original Dwyer condition guarantees that the comparison from a pushout of nerves to the nerve of a categorical pushout is a weak homotopy equivalence. It therefore controls the entire change-of-base operation, rather than merely the homotopy type of the initial inclusion. One should not identify Dwyer maps with all cofibrations in the Thomason model structure: Cisinski (1999, Lemma 4 and Proposition 2) corrected the claim that the original Dwyer class is closed under retracts. His larger class of pseudo-Dwyer maps retains the required pushout property.

The later result of Hackney et al. (2024, Theorems 1.5–1.6) strengthens the comparison to an equivalence of $(\infty,1)$-categories. Thus pushouts along Dwyer maps preserve more than the

classifying-space homotopy type. Our two uses of closed Dwyer maps are obtained by passing to opposites; the reversal changes the direction of the neighbourhood adjunction but does not change the classifying-space conclusion.

The negative product phenomenon also has a precise later form. Pavlov (2024, Definition 2.6) uses h-cofibration for the preservation condition Grothendieck calls W-cofibration. In the same paper, Proposition 4.3 proves that no model structure on Cat with Thomason weak equivalences can be cartesian. Its proof uses a different finite cube construction, credited in Proposition 4.2 to Maltsiniotis. The present appendix supplies a particularly transparent earlier obstruction: the boundary of a product of alternating intervals can have contractible links in its closure and still fail the preservation condition. These are results about strict categorical pushouts; homotopy pushouts of spaces retain their usual invariance.

Commentary · Development (commentators') [ms. 16]

The same defect on higher cubical boundaries

The rectangle argument is local enough to survive in every higher dimension. This gives a concrete continuation of Grothendieck's construction: the defect need not grow with the dimension of the ambient cube. The literature checked for this extension comprised Thomason's pushout theorem, Cisinski's correction, the Dwyer pushout comparison of Hackney–Ozornova–Riehl–Rovelli, and Pavlov's distinct cube obstruction. We did not locate the following precise family there; the proposition is an elementary extension of the appendix, without a claim of priority.

Proposition (one fixed obstruction in every dimension). [ours] Let $d \geq 2$, let $n_j \geq 2$, and put

$$X_d = \prod_{j=1}^{d} \Phi_{n_j}, \qquad U_d = \bigcup_{j=1}^{d} \Phi_{n_1} \times \cdots \times \dot{\Phi}_{n_j} \times \cdots \times \Phi_{n_d}.$$

There is a finite weak equivalence $U_d \to U'_d$ whose pushout along $U_d \hookrightarrow X_d$ has target X'_d with $BX'_d \simeq S^3$. In particular every inclusion $U_d \hookrightarrow X_d$ fails to be a $\mathbf{W}_\infty$-cofibration.

Proof. Fix the sink 1 in each of the last $d-2$ factors. Let V be the three-object full subposet with first two coordinates $(0,0), (1,0), (0,1)$ and all other coordinates 1. Let S add the point $(1,1,1,\ldots,1)$. Thus $V \cong \Psi$ and $S \cong [1] \times [1]$. Every point of V lies in U_d, while the fourth point of S does not. Since each coordinate 1 is maximal in its alternating interval, all successors of S remain in S; all successors of V that remain in U_d remain in V. Hence $S \hookrightarrow X_d$ and $V \hookrightarrow U_d$ are closed inclusions.

Their Dwyer structures can be given without induction. The smallest open neighbourhood of S is $\{0,1,2\}^d$. Map its first two coordinates by $r_0(0) = 0$, $r_0(1) = r_0(2) = 1$, and map every remaining coordinate to 1. This sends an object to the least element of S above it, and is therefore left adjoint to the inclusion of S. The smallest open neighbourhood of V in U_d is

$$\big(\{0,1,2\} \times \{0\} \;\cup\; \{0\} \times \{0,1,2\}\big) \times \{0,1,2\}^{d-2}.$$

The same map lands in V and is its left adjoint. Both inclusions are closed Dwyer inclusions.

Use the finite weak equivalence $p : V \to V' = Z^{\triangleright_e}$ constructed above. Put

$$U'_d = U_d \amalg_V V', \quad Q = S \amalg_V V', \quad X'_d = X_d \amalg_V V'.$$

The first Dwyer pushout gives $U_d \simeq U'_d$. Both BS and BX_d are contractible, so $S \to X_d$ is a weak equivalence as well as a closed Dwyer inclusion. Its pushout gives a weak equivalence $Q \to X'_d$. The calculation on manuscript p. 15 identifies $BQ \simeq S^3$, so $BX'_d \simeq S^3$. Finally associativity of pushouts gives $X'_d = X_d \amalg_{U_d} U'_d$. The resulting map from the contractible BX_d to BX'_d is not a weak equivalence, proving the assertion. All categories involved are finite, since the displayed pushouts are obtained by the same finite gluing constructions. □

Commentary · Exposition [ms. 17]

The arrows which join the two pieces

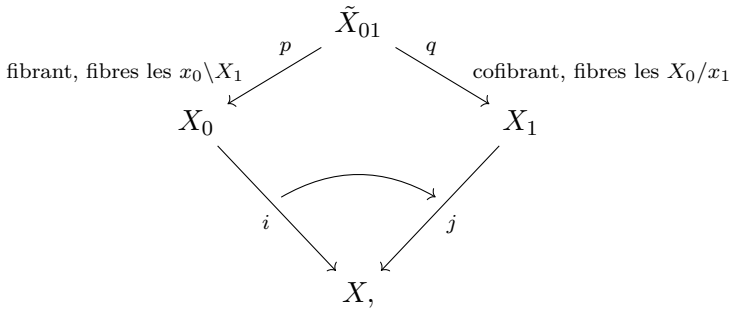
Grothendieck now turns from unsuccessful pushouts to a decomposition which retains the attaching data. An open subcategory $A = X_0$ is a full sieve; its complementary closed subcategory $B = X_1$ is a full cosieve. Thus every object belongs to exactly one piece, and there are no arrows from B to A. The additional information in X is the functor

$$M : A^{\mathrm{op}} \times B \longrightarrow \mathrm{Ens}, \qquad M(a,b) = \mathrm{Hom}_X(a,b).$$

In the language of distributors, X is the collage of M; this description, and its simplicial counterpart, are given in Joyal (2008, §§7.1–7.2, pp. 309–311). The direction of these attaching arrows is the feature that permits the argument below.

Write $E = \widetilde{X}_{01}$. Its objects are arrows $f : a \to b$ with $a \in A$ and $b \in B$; a morphism $f \to f'$ is a commuting square

$$(u,v) : f \longrightarrow f', \qquad u : a \to a', \quad v : b \to b', \quad vf = f'u.$$



Both vertical sides point in their ordinary directions. In particular E is the ordinary crossing-arrow category, not a twisted-arrow category. The projection $p : E \to A$ is a split Grothendieck fibration: pullback along $u : a \to a'$ sends $f' : a' \to b$ to $f'u : a \to b$. Its fibre is $a\backslash B$. Dually, $q : E \to B$ is a split opfibration, with fibre A/b and transport given by postcomposition. The arrows f themselves constitute a natural transformation $ip \Rightarrow jq$.

After realization this natural transformation provides a specified homotopy between the two maps $BE \rightrightarrows BX$, where $BC = |NC|$. Consequently it defines a map from the double mapping cylinder of $BA \leftarrow BE \to BB$ to BX. This is the comparison whose weak equivalence is at issue. The ordinary square does not commute strictly, and replacing its specified homotopy by an arbitrary one would change the question.

The easy cases stated in the manuscript have a useful explanation. If i is aspherical, every A/b is contractible, hence q is a weak equivalence; the homotopy pushout then has the homotopy type of BA, which maps equivalently to BX. If j is coaspherical, the dual argument uses the fibres $a\backslash B$ of p. The general argument must retain these fibres rather than assume their contractibility.

Question. *Ce diagramme*

(∗)

ed. 13

est-il W-cocartésien?

OK si i W-asphérique ou j W-coasphérique, i.e. $X \longrightarrow \mathbf{\Delta}^1$ lisse ou propre – c'est un cas où on a soit $X_0 \xrightarrow{W} X$, soit $X_1 \xrightarrow{W} X$. Mais même en supposant i ou j dans W, et de plus X asphérique (donc X_0 et X asphériques, ou X_1 et X asphériques), et $W = \mathbf{W}_\infty$, je n'ai pu prouver que le diagramme est cocartésien, i.e. $q \in W$ resp. $p \in W$ ([9]). (Pas non plus si

9. Je suppose que W satisfait Loc (6).

$X_0 \simeq e$, X, X_1 W-asphérique $\Longrightarrow$ $e\backslash X$ W-asphérique, i.e. $X_1 \longrightarrow X$ W-coasphérique ...)
Mais j'ai prouvé du moins, dans tous les cas, que

$$(**) \qquad \mathcal{X} \overset{\text{déf}}{=} \int \tilde{X}_{01} \begin{array}{c} \nearrow X_0 \\ \searrow X_1 \end{array} \xrightarrow{\varphi} X$$

est dans $\mathbf{W}_1$.

Chose *fausse* (sauf si i ou j dans $W = \mathbf{W}_\infty$) si on remplace $\tilde{X}_{01}$ par $\tilde{X}'_{01}$, formée des triples (x_0, x_1, c), avec $x_0 \in \mathrm{Ob}\, X_0$, $x_1 \in \mathrm{Ob}\, X_1$, $c : x_0 \dashrightarrow x_1$ un *chemin* de x_0 à x_1 dans X! On a donc une situation 'topologique' tout à fait spéciale à la catégorie de modèles Cat, qui [ms. 18]
ne semble pas avoir d'analogue dans des catégories telles que Esp ou $\mathbf{\Delta}^\wedge$, où pourtant les notions d'ouvert et de fermé complémentaire (avec grain de sel dans $\mathbf{\Delta}^\wedge$) ont un sens.

Commentary · Development (commentators') [ms. 17]

Acyclic links and a false converse

The proposed $\mathbf{W}_\infty$ gluing formula and the opposite-side reflection invoked by the manuscript's "i.e." have different strengths. The formula is true. Footnote 9 adds Loc (6), a numbered hypothesis which requires qualification. If it uses the full reversible convention of Chapter XVI, Corollary 3.7, then cocartesianness together with $i \in W$ does imply $q \in W$, and dually for j, p: this is the additional condition Loc (6C) (Grothendieck, 1991c, §3, Corollary 3.7, ms. 26). Under that interpretation the conditional inference is valid, but its specialization to $\mathbf{W}_\infty$ is incompatible with the axiom. The following construction proves the failure for ordinary weak homotopy equivalences.

Proposition (a contractible union with a noncontractible link). [ours] There is a finite poset X, a one-object sieve $A = \{a\}$, and its complementary cosieve B, such that BA, BB, and BX are contractible, whereas $B\widetilde{X}_{01}$ is not contractible. In particular neither p nor q need be a weak equivalence, even when both i and j are weak equivalences. Moreover, $\mathbf{W}_\infty$ fails Loc (6b) in the convention of Chapter XVI.

Proof. We first choose a connected acyclic finite complex P with nontrivial fundamental group. A standard source of such complexes is Hatcher (2002, Example 2.38). For explicitness, take the presentation complex

$$\langle s, t \mid s^3(st)^{-2},\ t^5(st)^{-2} \rangle.$$

It has one vertex, two edges and two two-cells. Its cellular differential in positive degrees is

$$0 \longrightarrow \mathbb{Z}^2 \xrightarrow{\left(\begin{smallmatrix} 1 & -2 \\ -2 & 3 \end{smallmatrix}\right)} \mathbb{Z}^2 \longrightarrow 0.$$

The determinant is -1, so its reduced integral homology vanishes. The assignments $s \mapsto (1\,2\,3)$ and $t \mapsto (1\,4\,3\,2\,5)$ define a nontrivial homomorphism to A_5: their product is $(1\,4)(2\,5)$, and both relations hold. Thus P is not simply connected. By the finite form of the simplicial replacement theorem (Hatcher, 2002, Theorem 2C.5), choose a finite simplicial complex $L \simeq P$ and let K be its poset of nonempty faces. Its order complex is the barycentric subdivision of L, so $BK \simeq P$.

Adjoin two incomparable new elements a, b to K, each smaller than every element of K, and call the resulting poset X. Set $A = \{a\}$ and $B = \{b\} \cup K$. Then A is a sieve and B is its complementary cosieve; b is initial in B. The nerve of X is the union of two cones on NK, along NK itself. Hence

$$BX \cong \Sigma BK.$$

This suspension is simply connected because BK is connected, and its reduced homology vanishes by the suspension isomorphism. The simply connected homology form of Whitehead's theorem therefore makes it contractible (Hatcher, 2002, Corollary 4.33).

The crossing arrows are exactly the unique arrows $a \to k$, for $k \in K$. Their commuting squares are exactly the order relations of K. Thus $E \cong K$, $p : K \to \{a\}$, and $q : K \hookrightarrow \{b\} \cup K$. Neither map is a weak equivalence, since $\pi_1(BK)$ is nontrivial.

For the last assertion, consider the full sieves

$$U = (\{a\} \cup K)^{\mathrm{op}}, \qquad V = (\{b\} \cup K)^{\mathrm{op}} \quad \text{in } X^{\mathrm{op}}.$$

They cover X^{op} and intersect in K^{op}. Map their Mayer–Vietoris square to the square whose four vertices are the terminal category. The component maps from U, V, X^{op} are weak equivalences: their classifying spaces are two cones and the contractible suspension. The component from K^{op} is not. This violates precisely the inverse cube implication Loc (6b); the full axiom includes that implication (Grothendieck, 1991c, §3, ms. 16′–17′, footnote 13). □

For $\mathbf{W}_\infty$, this also answers negatively the subsidiary question with $X_0 \simeq e$ and X, X_1 aspherical. Its intended comma category is $a\backslash X_1 = K$; the printed $a\backslash X$ would contain the initial object id_a and would be automatically contractible. The example does not contradict the gluing conjecture: its homotopy pushout is exactly the contractible suspension ΣBK. It disproves opposite-side reflection for $\mathbf{W}_\infty$, while leaving the stronger conditional principle intact.

The axiom labels cannot be identified solely by their numbers. Chapter XV, §9, ms. 117, calls a fibration axiom Loc (6) (Grothendieck, 1990–1991k) and refers to Chapter XII, §IV, ms. 53–59; there, variant a′ is a pullback condition for W_ω-perfect functors (Grothendieck, 1990–1991f). Chapter XVI instead writes the forward Mayer–Vietoris condition as Loc (6′a), whereas the appendix's last line prints Loc (6a′) (Grothendieck, 1991c, §3, ms. 17′). We retain these distinct labels and cannot certify that footnote 9 invokes the later reversible convention. We checked the standard acyclic-complex construction and the homotopy-colimit sources cited below; we did not locate this precise finite-poset application there. The marker records our worked application, without a claim of priority.

L'argument catégorique quasi-trivial qui établit que $(**)$ est dans $\mathbf{W}_1$, i.e. induit une équivalence de catégories entre $\mathrm{Rev}(X)$ et

$$\mathrm{Rev}(\mathcal{X}) \;\simeq\; \mathrm{Rev}(X_0) \overset{2}{\times}_{\mathrm{Rev}(\tilde{X}_{01})} \mathrm{Rev}(X_1),$$

me semble devoir s'étendre aux dimensions supérieures, à coups de n-gerbes sur X – mais les fondements sur la théorie des n-gerbes manquent. (Et je n'ai pas eu le courage d'expliciter l'argument même pour $n = 2$ (où pourtant Giraud fournit ce qu'il faut) ([10]).) Aussi je conjecture que φ est tout au moins dans $\mathbf{W}_\infty$, i.e. que le diagramme $(*)$ est W-cocartésien si $W \supseteq \mathbf{W}_\infty$ (et satisfait Loc (6 a′)).

Commentary · Development (commentators') [ms. 18]

The open–closed gluing formula

The final conjecture $\varphi \in \mathbf{W}_\infty$ has an affirmative answer. Its proof comes from the fact that a simplex in NX crosses from A to B at most once. We give the precise specialization of Thomason's homotopy-colimit comparison that settles this question. We did not locate this exact formulation in the checked sources; the result below is presented as a consequence of an established theorem, without a claim of priority.

Proposition (directed gluing). [ours] For every small category X with a full sieve A and complementary full cosieve B, let E be its crossing-arrow category. The natural transformation $ip \Rightarrow jq$ induces a weak homotopy equivalence

$$\mathrm{hocolim}(BA \longleftarrow BE \longrightarrow BB) \longrightarrow BX.$$

Consequently the comparison $\varphi : \mathcal{X} \to X$ of the manuscript belongs to $\mathbf{W}_\infty$.

Proof. To keep track of the unique crossing, introduce the bisimplicial set

$$S_{r,s} = \left\{ a_0 \longrightarrow \cdots \longrightarrow a_r \xrightarrow{f} b_0 \longrightarrow \cdots \longrightarrow b_s \;\middle|\; a_i \in A,\ b_j \in B \right\}, \qquad r, s \geq 0.$$

Its faces compose or omit arrows on the indicated side, and its degeneracies insert identities. The last horizontal face precomposes f; the first vertical face postcomposes f. Thus S is the simplicial replacement of the contravariant functor

$$A^{\mathrm{op}} \longrightarrow \mathrm{Cat}, \qquad a \longmapsto a\backslash B.$$

10. Mais j'ai fait quand même une esquisse de vérification pour $n = 2$, qui me convainc qu'on a bien $\varphi \in \mathbf{W}_2$. Et je n'ai pas guère de doute qu'on a même $\varphi \in \mathbf{W}_\infty$.

Its Grothendieck construction, with cartesian variance, is exactly E: a morphism over $u : a \to a'$ is a map $f \to f'u$ in $a\backslash B$, namely a v with $vf = f'u$.

There is a comparison $\theta : \operatorname{diag} S \to NE$. On an n-simplex it gives the chain of crossing arrows

$$a_i \longrightarrow a_n \xrightarrow{f} b_0 \longrightarrow b_i, \qquad 0 \le i \le n,$$

whose successive morphisms have sides $a_i \to a_{i+1}$ and $b_i \to b_{i+1}$. This is Thomason's comparison for the preceding contravariant functor. It is a weak equivalence; the precise variance and this formula are verified in Cegarra (2020, §3.1, equation (9), and Theorem 3), which gives an independent proof of the comparison originally due to Thomason (1979, Theorem 1.2). Both endpoint maps commute with θ: they simply forget the b-chain or the a-chain.

It remains to identify what the mixed simplices assemble to. Let $R = \|S\|$ be the double geometric realization. It has maps $r_A : R \to BA$ and $r_B : R \to BB$ obtained by forgetting one side. The natural diagonal-to-double-realization homeomorphism identifies R with $|\operatorname{diag} S|$. Form

$$D(R) = \big(BA \amalg (R \times [0,1]) \amalg BB\big)/\big((z,0) \sim r_A(z),\ (z,1) \sim r_B(z)\big).$$

For a mixed simplex as above, send $(u, v, t) \in \Delta^r \times \Delta^s \times [0,1]$ to the point of Δ^{r+s+1} with coordinates

$$((1-t)u_0, \dots, (1-t)u_r, tv_0, \dots, tv_s).$$

This respects faces and degeneracies, and respects the endpoint identifications. It supplies a homeomorphism $D(R) \cong BX$. Indeed, in a point with positive total weight on both pieces, t is the total weight on the B vertices; dividing the two sets of coordinates by $1 - t$ and t recovers u, v. At $t = 0, 1$ precisely the identifications defining $D(R)$ occur. This description is compatible with the realization quotient topology because it is the usual simplex-join homeomorphism on every simplex. Pure simplices give the two endpoint spaces.

The double mapping cylinder computes a homotopy pushout. Replacing its middle space R by the weakly equivalent CW complex BE therefore preserves its homotopy type, by homotopy invariance of this construction. The resulting map to BX is the canonical one: the homotopy obtained from $ip \Rightarrow jq$, after composition with θ, is homotopic relative to its endpoints to the displayed barycentric homotopy. On each prism, both lie in the same mixed simplex, and linear interpolation supplies compatible homotopies on its faces. Thus the canonical comparison, and not merely an abstract map between the same homotopy types, is a weak equivalence.

Finally, let J be the span category with arrows $* \to 0$ and $* \to 1$, and take its covariant diagram with values E, A, B and structure maps p, q. Its Grothendieck construction models $\mathcal{X}$. A comparison to X sends its A- and B-objects to themselves and its E-object $f : a \to b$ to a; the arrows towards the B-part use f. Thomason's theorem identifies its classifying space with the preceding homotopy pushout, compatibly with this cocone. Hence $B\varphi$ is a weak equivalence. □

The cases $A = \varnothing$ or $B = \varnothing$ are included: then E is empty and the assertion reduces to the other piece. For every localizer W containing $\mathbf{W}_\infty$, the comparison just proved also lies in W. If the span Grothendieck construction represents the W-homotopy pushout, this proves W-cocartesianness as well. For a fundamental localizer, Chapter XVI explicitly supplies that interpretation under its forward axiom Loc (6′a) (Grothendieck, 1991c, §3, ms. 24, footnote 15). This comparison hypothesis requires no opposite-side reflection. The manuscript cites Loc (6a′) for its general-W interpretation; because of the numbering ambiguity just documented, we do not silently identify that label with the distinct forward or full axioms of Chapter XVI. The theorem for $\mathbf{W}_\infty$ is independent of that identification.

The proof also clarifies the preceding observation about a phenomenon peculiar to categories. Its realization is an explicit topological double mapping cylinder, and the mixed-simplex construction has a directed simplicial formulation. What a bare pair of complementary topological subsets does not supply is the specified category of attaching arrows.

Commentary · Examples [ms. 18]

Why replacing arrows by all paths changes the answer

Grothendieck's caution about paths concerns the attaching information, rather than an insufficiency of path spaces as models of homotopy types. A bridge of directed arrows records how the

two pieces were assembled. A bridge of all paths in the already assembled space usually records a homotopy pullback instead. These two bridges can differ even in the smallest example with a loop.

Let X have objects a, b and precisely two nonidentity arrows $\lambda, \mu : a \rightrightarrows b$. Take $A = \{a\}$ and $B = \{b\}$. There are no nonidentity commuting squares between its two crossing arrows, so E is the discrete two-point category. The nerve of X has two vertices and two edges and no nondegenerate higher simplices. Thus

$$BX \cong S^1, \qquad \operatorname{hocolim}(* \longleftarrow \{\lambda, \mu\} \longrightarrow *) \cong S^1.$$

Now replace the bridge by a model of the space of all paths from a to b in BX. Choosing one reference path identifies this space up to homotopy with ΩS^1, whose components are contractible and indexed by $\mathbb{Z}$. The new homotopy pushout is therefore the graph with two vertices and one edge e_k for each $k \in \mathbb{Z}$. Collapsing e_0 gives

$$\bigvee_{k \in \mathbb{Z} \setminus \{0\}} S^1.$$

The comparison to S^1 sends the loop represented by $e_k e_0^{-1}$ to the integer k. Its map on fundamental groups is the homomorphism from the free group on these generators to $\mathbb{Z}$ which sends the generator indexed by k to k. It is surjective but not injective; for example the word consisting of the generator indexed by 2 followed by the inverse square of the generator indexed by 1 lies in its kernel and is a nonempty reduced word. Thus even the $\mathbf{W}_1$ conclusion fails.

More generally, when a path category models $BA \times^h_{BX} BB$, the exception stated in the manuscript is valid: if $BA \to BX$ is a weak equivalence, its projection to BB is a weak equivalence, so the associated homotopy pushout maps equivalently to BX; the other case is dual. This is a sufficient condition, not a characterization of every exceptional case. The manuscript specifies the objects of $\widetilde{X}'_{01}$ but does not spell out its morphisms. Our computation concerns the usual homotopically correct all-paths interpretation; it does not assert an equivalence for an unspecified raw category of paths.

Commentary · Later developments [ms. 18]

From covering descent to higher local systems

The last paragraph identifies the right source of confidence in the conjecture: a local system can be reconstructed from its restrictions to the two pieces and its transport across every attaching arrow. We can make the argument for coverings completely explicit before passing to higher coefficients.

Use covariant transport to identify $\mathrm{Rev}(C)$ with the category of functors $C \to \mathrm{Ens}$ which send every arrow to a bijection. An object of

$$\mathrm{Rev}(A) \underset{\mathrm{Rev}(E)}{\overset{2}{\times}} \mathrm{Rev}(B)$$

is a pair L_A, L_B with an isomorphism $\alpha : p^* L_A \xrightarrow{\sim} q^* L_B$. Define L on the two full subcategories by L_A, L_B, and on a crossing arrow $f : a \to b$ by $L(f) = \alpha_f$. To check functoriality, there are only two mixed cases. The squares $(u, \mathrm{id}) : fu \to f$ and $(\mathrm{id}, v) : f \to vf$ in E give

$$\alpha_{fu} = \alpha_f L_A(u), \qquad \alpha_{vf} = L_B(v) \alpha_f.$$

They are exactly the two composition laws needed in X, since a composable chain cannot cross from A to B twice. All transports are bijective. A compatible pair of morphisms between such descent data gives a natural transformation of the reconstructed functors, and restriction is inverse to this construction. This proves the equivalence of covering categories in the manuscript; applying the same gluing description to the categorical mapping cylinder gives its displayed formula for $\mathrm{Rev}(\mathcal{X})$.

This argument also identifies the fundamental groupoid directly. Its generators are the arrows internal to the two pieces and the crossing arrows, now formally invertible; the equations just verified supply all mixed composition relations. Consequently the comparison φ induces an equivalence of fundamental groupoids. The source offers a sketch of this $\mathbf{W}_1$ assertion and reports a further sketch for $\mathbf{W}_2$; the preceding mixed-simplex proof establishes all degrees at once.

The contemporary interpretation of the proposed higher-gerbe argument uses local systems valued in spaces or in n-groupoids. If $\mathcal{S}$ denotes the ∞-category of spaces, define $\mathrm{Loc}(C) = \mathrm{Fun}(BC, \mathcal{S})$, viewing BC as its homotopy type. The proved pushout formula, by the universal property of a colimit, yields

$$\mathrm{Loc}(X) \simeq \mathrm{Loc}(A) \times^{h}_{\mathrm{Loc}(E)} \mathrm{Loc}(B).$$

One can restrict the values to n-truncated spaces to obtain every finite stage. Straightening gives the precise realization of space-valued coefficients, and higher descent formalizes such pullbacks of coefficient categories; see Lurie (2009, Theorem 2.2.1.2, Corollary 3.3.4.6, and Theorem 6.1.3.9). Giraud's theory supplied the stack and gerbe language for the first nonabelian stages (Giraud, 1971); the claim here is about locally constant higher coefficients, not an identification of all stacks with local systems. The categorical question of the appendix is therefore settled without requiring a separate construction and comparison of n-gerbes for each n.

Overview · XIIapp

Grothendieck's appendix to Chapter XII examines a difficulty that becomes visible as soon as one tries to use small categories as models for spaces: an ordinary categorical pushout can discard the homotopy information that a homotopy pushout must retain. The investigation begins with a proposed contractibility criterion, passes through explicit finite counterexamples, and ends with a conjectural gluing theorem. Its exploratory order matters. An unsuccessful cohomology calculation and an impossible retraction are part of the route to the examples; correcting them changes some intermediate claims without destroying the main obstruction. The electronic edition already marks several of these revisions (Grothendieck, 1990–1991g).

Throughout these pages $BC = |NC|$ denotes the classifying space of a small category. The localizer $\mathbf{W}_\infty$ consists of the functors inducing weak homotopy equivalences. The word "aspherical" means weakly contractible in this usage. A presheaf $F : C^{\mathrm{op}} \to \mathrm{Ens}$ has a homotopy type through its category of elements C/F. In particular, a representable presheaf is aspherical, since its category of elements is a slice C/c with a terminal object. These conventions connect the appendix to the integration of homotopy types described in *Pursuing Stacks*, §69, and to the adjoints-to-restriction viewpoint of the 1991 letter to Thomason (Grothendieck, 1983, 1991a).

The opening hypothesis asks for two weakly terminal objects b, c, meaning that every object admits a map to each, and for their categorical product $a = b \times c$. The source proves that BC is simply connected. Its proof is sound: in the groupoid completion, cancellation against the two projections identifies all maps from an object to a; those unique classes are compatible with every arrow and its inverse. The completion is therefore equivalent to the terminal groupoid. The proposed stronger conclusion, weak contractibility, is false, but the first example in the manuscript needs a different calculation from the one printed.

That example is the category X_G of the first two formal powers of an object with endomorphism monoid G:

$$\mathrm{Hom}_{X_G}(b^m, b^n) = \big(\{1, \dots, m\} \times G\big)^n, \qquad m, n \in \{1, 2\}.$$

It is an opfibration over the opposite of the full finite-set category on a singleton and a two-element set, with fibres the one-object categories of G and G^2. The resulting cohomological spectral sequence is legitimate. The provisional derived-limit formula used to evaluate it is not: the transposition of the two-element set and the common retraction of its two inclusions supply relations that the proposed two-term complex has omitted. Even a constant coefficient diagram contradicts the displayed cokernel formula.

The commentary gives an explicit projective resolution for the actual indexing category. It proves that BX_G is 2-connected for every monoid G, while

$$H^3(BX_{C_2}; \mathbb{F}_2) \cong \mathbb{F}_2.$$

Thus the two-object, twenty-six-arrow category remains a finite counterexample to the opening proposition. Its obstruction occurs one degree later than the manuscript asserts. The repaired computation is supplied as a commentators' development, with complete proofs and a separate normalized-nerve verification. The standard spectral-sequence and homotopy-colimit ingredients are identified explicitly (Cegarra, 2020; Thomason, 1979).

A second development supplies the degree-two counterexample promised by footnote 2 under the exact product hypotheses. For an integer $r \geq 1$, adjoin a new source d to the category of the first two powers for the trivial monoid, with r maps $d \to b$ and the corresponding r^2 maps $d \to b^2$. Composition selects coordinates. The product remains an actual categorical product, and its new source link retracts up to homotopy onto the poset of nonempty subsets of an r-element set of cardinality at most two. Its nerve is the subdivided complete graph.

The resulting three-object category Y_r satisfies

$$BY_r \simeq \bigvee^{(r-1)(r-2)/2} S^2.$$

For $r = 3$ this gives a twenty-one-arrow model of S^2. It verifies the footnote without confusing the opening product condition with the weaker presheaf condition used subsequently.

The persistent indexing shape is the span $\Psi = (b_0 \leftarrow a_0 \rightarrow c_0)$. For a span of representables in $C^\wedge$, its value at x is the set of components of a bipartite graph: the vertices are the maps $x \to b$ and $x \to c$, and the edges are the maps $x \to a$. A terminal ordinary pushout says that all these graphs are connected. It does not say that their cycles vanish. The commentary proves both useful consequences stated in the source: a terminal pushout forces simple connectivity of BC, and if either arrow out of a is monic, the presheaf pushout is aspherical. The latter follows because the graph components are then stars, and Quillen's Theorem A applies to their incidence categories (Quillen, 1973).

The four-object example Z makes the missing cycles visible. It has two parallel arrows $0 \rightrightarrows a$, followed by arrows $a \to b, c$ which equalize them. Its presheaf pushout $b \amalg_a c$ is terminal. Its nerve, however, is two cones on the parallel-arrow circle, and hence $BZ \cong S^2$. The proposed retraction onto the circle cannot be a functor: applying it to either equalizing relation would identify the two distinct arrows. Footnote 7 corrects the homotopy type, but the later statement $\pi_1(Z) \cong \mathbb{Z}$ repeats the earlier error. We retain both printed readings and explain their mathematical status.

Adding two incomparable cone vertices to Z gives the six-object category Q with $BQ \cong S^3$. This is the reliable finite obstruction in the later pushout square: its three input categories are contractible, while its ordinary categorical pushout is not. The assertion is established directly from the nerve, without an unrestricted converse to a comma-category theorem. Such a converse would be false: a connected acyclic noncontractible link can have contractible suspension. The appendix's extension to arbitrary $W \subseteq W_1$ therefore does not follow from this example; the obstruction for this pushout lies in degree three.

Grothendieck then inserts this local defect into the boundary of a product $\Phi_n \times \Phi_m$ of alternating directed intervals. The boundary has classifying space S^1, while the product is contractible. Its slices over its categorical closure are contractible, but four of them have no terminal object. Accordingly the boundary inclusion satisfies the local asphericity condition of Chapter XII and fails the stronger Dwyer neighbourhood-adjoint condition. Two surrounding closed Dwyer inclusions allow the six-object defect to survive the enlargement. The necessary pushout comparison is Thomason's; Cisinski's later correction distinguishes Dwyer maps from their retracts (Thomason, 1980; Cisinski, 1999). The resulting inclusion fails to preserve weak equivalences under cobase change. In contemporary terminology it is not an h-cofibration.

The same construction extends, with proof here, to the boundary of every product of at least two such intervals: fixing interior sinks in the remaining coordinates carries the same S^3 defect into higher dimensions. Later theory gives two complementary perspectives. Pushouts along Dwyer maps are preserved even as $(\infty, 1)$-categorical pushouts (Hackney et al., 2024); no model structure on Cat with Thomason weak equivalences can be cartesian (Pavlov, 2024, Proposition 4.3). These results explain the continuing significance of the appendix's distinction between contractible links and actual adjoint neighbourhoods.

The question whether total asphericity forces a terminal object has a simpler answer. Here "total" quantifies over every left Kan extension $f_!1_A$, a convention expressly distinguished in the edition from the total asphericity of *Pursuing Stacks*. Filtered categories satisfy this condition, because the category of elements of a filtered colimit of representables is filtered. Grothendieck already records the correction elsewhere in the manuscript (Grothendieck, 1990–1991b, Chapter II, Corollaries 2.17–2.18). Both $(\mathbb{N}, \leq)$ and the one-object category of an unsplit idempotent give examples without a terminal object. The surrounding classification

is discussed in the commentary on Chapter II, manuscript pages 35–36, and is not repeated here.

The closing conjecture concerns a different, homotopically correct gluing. If A is a full sieve of X, B its complementary full cosieve, and E the category of arrows from A to B with ordinary commuting squares, then

$$BX \simeq \operatorname{hocolim}(BA \longleftarrow BE \longrightarrow BB).$$

The comparison is defined by the natural transformation supplied by the crossing arrows. We prove the formula using mixed simplices of the nerve: each crosses from A to B once, and its barycentric coordinates split into a point on each side and an interval coordinate. Thomason's comparison identifies the resulting bisimplicial bridge with BE. This settles the $\mathbf{W}_\infty$ conjecture and supplies the whole hierarchy of local-system descent statements at once. The exact specialization is worked out here; the general comparison theorem predates the manuscript, and no claim about priority for this formulation is made.

Two qualifications are mathematically necessary. First, for $\mathbf{W}_\infty$, the true gluing formula does not imply the subsidiary assertion that one of its bridge projections must be a weak equivalence whenever a boundary inclusion is. The acyclic-link example disproves that implication even for finite posets with contractible pieces and union. A stronger reversible localizer axiom would supply the implication, but $\mathbf{W}_\infty$ does not satisfy that axiom. The numbered references in the appendix require caution: Chapters XV and XVI use different Loc (6) conventions, and the positions of the primes in their variants differ. The detailed commentary records the checked formulations without certifying which convention the appendix intended (Grothendieck, 1990–1991k, 1991c). Second, replacing crossing arrows by all paths in the completed space changes the bridge: for the parallel-arrow circle, two crossing arrows give S^1, whereas an all-paths bridge gives a countable wedge of circles. The source's covering-descent argument is fully justified by gluing locally constant set-valued functors across commuting squares; higher local systems give its contemporary extension (Lurie, 2009). The explicit directed attaching data are what make the final formula work.

[page 1]

Je veux d'abord donner une variante affaiblie de la notion de triple de Quillen ("model category" de Quillen). Ce ne sera pas une notion tout-à-fait autoduale – ainsi il y aura *deux* variantes affaiblies, duales l'une de l'autre.

Commentary · Exposition [ms. 1]

Two calculi behind a model structure

Grothendieck begins by separating the machinery that constructs replacements from the equivalences those replacements are meant to respect. This separation will make it possible to ask whether the homotopy theory belongs to the pair $(\mathcal{M}, W)$ itself. The first section therefore contains no weak equivalences: its subject is the elementary calculus of lifting and factorization.

For arrows $i : A \to B$ and $p : X \to Y$, write $i \,\square\, p$ when every commutative square with these vertical sides admits a diagonal $h : B \to X$, satisfying $hi = a$ and $ph = b$, where $a : A \to X$ and $b : B \to Y$ are its horizontal sides. No uniqueness is required. In current notation Grothendieck's Φ_* is $\Phi^{\square}$, and Ψ^* is ${}^{\square}\Psi$. Consequently

$$\Phi \subseteq {}^{\square}\Psi \quad \Longleftrightarrow \quad \Psi \subseteq \Phi^{\square}.$$

This is an order-reversing Galois connection between classes of arrows. The arrows in the two displayed boxes operate on classes, rather than on individual morphisms; the editors' correction is mathematically essential, while the missing parenthesis in that correction is merely typographical. For a large category we work relative to universes, or speak of classes instead of forming an unrestricted set of all its subclasses.

There are already two different closure notions in view. A class is *left lifting closed* when it has the form ${}^{\square}\Psi$. Later, a class will be enlarged by isomorphisms, pushouts, transfinite composites and retracts; this is its *weak saturation* in current model-category language. These operations agree for the closure generated by a set in a locally presentable category, by the small object argument. Their identification requires that theorem; it is not a consequence of the Galois connection alone. Conversely, Grothendieck's phrase "W faiblement saturée" on manuscript p. 7 means two-out-of-three together with the isomorphisms. Keeping these uses separate prevents a genuine ambiguity in the conjectural argument below.

Mais avant encore, un sorite sur les LLP (left lifting property) et RLP (right lifting property) ([1]). Soit $\mathcal{M}$ une catégorie quelconque (le plus souvent, $\mathcal{M}$ sera grande). On considère des parties

Commentary · Exposition [ms. 3]

Closure, transfinite lifting and the retract argument

Grothendieck wants the formal part of Quillen's method to be available before choosing any examples. Proposition 1 provides exactly this preparation. To see its content directly, let $L(R) = {}^{\square}R$ and $R(L) = L^{\square}$. Antitonicity follows by adding lifting problems. Every arrow of L lifts against every arrow of $R(L)$, so $L \subseteq L(R(L))$. Applying antitonicity gives $R(L(R(L))) \subseteq R(L)$, while the reverse inclusion is the same elementary observation with the two roles exchanged. Thus $RLR = R$ and $LRL = L$. These identities prove idempotence, describe the fixed points and show that the two fixed-point posets are oppositely isomorphic. For instance,

$$R\left(\bigcap_i L_i\right) = \overline{\bigcup_i R(L_i)}$$

when each L_i is left lifting closed. The hypothesis matters: the right side is the join in the lattice of right lifting closed classes, not their ordinary union.

The stability assertions in Proposition 2 express how to transport a chosen solution. Isomorphisms lift by inversion. A lifting problem for a composite is solved successively. A lifting problem for a pushout is equivalent, by its universal property, to one for the original map. For a continuous ordinal chain, begin with the prescribed map on its initial object, extend at each successor, and take the unique induced map at each limit. Transfinite recursion then supplies the diagonal against the composite. The existence of the colimits appearing in the chain is the only colimit hypothesis used here; no presentability has yet entered.

The retract assertion deserves an explicit formulation, since it is the bridge from a constructed factorization to a lifting characterization. Suppose $f : A \to B$ factors as $A \xrightarrow{i} E \xrightarrow{p} B$, and suppose $f \,\square\, p$. Apply this lifting property to the square with top i and bottom 1_B. The resulting $s : B \to E$ satisfies $sf = i$ and $ps = 1_B$. In the arrow category, the morphisms $(1_A, s) : f \to i$ and $(1_A, p) : i \to f$ have composite 1_f. Hence f is a retract of i. In particular, a factorizing pair (L, R) with $L \,\square\, R$ becomes a weak factorization system as soon as both classes are retract closed. This is the content of the standard retract argument; compare Riehl (2014, Lemmas 11.1.4 and 11.2.3). It is this system of two classes of arrows that the manuscript calls a *couple de Quillen*. A modern *Quillen adjunction* is a different notion, involving two model categories and an adjoint pair of functors.

Proposition 2. *Soit* Φ *une partie close à gauche de* $\mathrm{Fl}(\mathcal{M})$. *Alors* Φ *satisfait les conditions* a) b) c) *ci-dessous :*

a) Φ *contient les isomorphismes, et est stable par composition, et par cochangement de base (*i.e. *si on a* $\begin{array}{ccc} A & \xrightarrow{i} & B \\ \downarrow & & \downarrow \\ A' & \xrightarrow{i'} & B' \end{array}$ *carré cocartésien dans* $\mathcal{M}$, *avec* $i \in \Phi$, *on a* $i' \in \Phi$*).*

b) Φ *stable par facteurs directs (en tant que partie de l'ensemble des objets de* $\underline{\mathrm{Fl}}(\mathcal{M})$*).*

c) Φ *"stable par limites inductives ordinales", dans le sens suivant : Soit* I *un ensemble bien ordonné,* $(A_i)_{i\in I}$ *un système inductif dans* $\mathcal{M}$, *tel que les* $u_{ji} : A_i \longrightarrow A_j$ *soient dans* Φ, *et* $A_{i_0} \xleftarrow{\sim} \varinjlim_{i<i_0} A_i$ *si* $i_0 \in I$ *est un élément limite. Supposons que* $A = \varinjlim_I A_i$ *existe. Alors* $\forall\ i_0 \in I$, *la flèche canonique* $A_{i_0} \longrightarrow A$ *est dans* Φ.

Il y a un énoncé dual pour une partie Ψ close à droite; elle contient les isomorphismes, est stable par composition et par changement de base, par facteurs directs, et enfin stable par limites projectives ordinales.

On aura une réciproque partielle dans les catégories accessibles. C'est pour l'énoncé de [page 5] cette réciproque que j'ai mis à part la condition *b*) de stabilité par facteurs directs, au lieu de la bloquer avec *a*).

2. Donner définition en forme.
3. de façon précise, $\bigcap_i(\Psi_i^*) = (\bigcup_i \Psi_i)^*$
4. de façon précise, on a $\bigcap_i(\Phi_{i*}) = (\bigcup_i \Phi_i)_*$

Définition 1.

a) (Pour mémoire.) RLP, LLP, la relation $\Phi \longleftrightarrow \Psi$ entre parties de $\mathrm{Fl}(\mathcal{M})$ (relation non symétrique!).

b) (Pour mémoire.) Partie de $\mathrm{Fl}(\mathcal{M})$ close à gauche, close à droite.

c) Soit $\Phi \longleftrightarrow \Psi$. On dit que le couple (Φ, Ψ) a la *propriété de factorisation de Quillen*, si *toute* flèche f de $\mathcal{M}$ se factorise en

$$f = pi, \qquad i \in \Phi,\ p \in \Psi.$$

On dit que (Φ, Ψ) est un *couple de Quillen* si c'est un couple associé par `[les]` propriétés LLP et RLP ($\Phi \longleftrightarrow \Psi$), et `[si]` elles `[les parties` Φ `et` Ψ`]` sont closes (*i.e.* $\Phi = \Psi^*$, $\Psi = \Phi_*$), et si elles ont la propriété de factorisation de Quillen.

J'énonce dès maintenant le résultat technique essentiel, assurant l'existence de beaucoup de couples de Quillen :

Commentary · Examples [ms. 5]

A weak factorization system in sets

The elementary example of injections and surjections makes the preceding abstraction concrete. We work in sets with the axiom of choice. Every injection $i : A \hookrightarrow B$ lifts against every surjection $p : X \twoheadrightarrow Y$: retain the given map on A, and choose a preimage in X of the prescribed image of each point of $B \setminus A$. Conversely, lifting against $\varnothing \to \{*\}$ characterizes surjections. If a map i has the left lifting property against all surjections, factor it as

$$A \xrightarrow{\iota} A \amalg B \xrightarrow{[i,1_B]} B.$$

The second arrow is surjective, so the retract argument makes i a retract of the injection ι, hence an injection. Thus $(\mathrm{Mono}, \mathrm{Surj})$ is a weak factorization system, generated by the single arrow $\varnothing \to \{*\}$.

The factorization displayed above is functorial: a square $(u, v) : i \to i'$ acts on its middle object by $u \amalg v$. The diagonal in an arbitrary lifting problem need not be unique or functorially chosen. This is why functorial factorization and a specified coherent family of fillers are additional kinds of structure, even though both are useful in later developments. Nor should this factorization be confused with the familiar image factorization, whose left class is surjections and whose right class is injections. The same two classes occur in opposite order, with a different lifting relation. The asymmetry noted in Definition 1(a) is already visible in this example.

Théorème 1. *Supposons que* $\mathcal{M}$ *soit* accessible, *et stable par (petites) limites inductives. (Il doit suffire stabilité par sommes amalgamées, et par* $\varinjlim$ *filtrantes, voire ordinales …). Soit* Φ_0 *une* petite *partie de* $\mathrm{Fl}(\mathcal{M})$, $\Psi = (\Phi_0)_*$, *et* Φ *une partie de* $\mathrm{Fl}(\mathcal{M})$ *telle que* p. 4 [page 6]

$$\Phi_0 \ \subset\ \Phi\ \subset \Psi^*\ (= \widetilde{\Phi}_0).$$

Alors :

a) *Pour que* Φ *soit close à gauche,* i.e. $\Phi = \widetilde{\Phi}_0$, *il faut et il suffit qu'elle satisfasse les conditions* a) b) c) *de la proposition 2. Quand il en est ainsi, le couple* (Φ, Ψ) *est un couple de Quillen.*

b) *Supposons seulement que* Φ *satisfasse aux conditions* a), c) *de la proposition 2 (à l'exclusion de la condition* b) *des facteurs directs) – donc on ne peut affirmer que* Φ *soit close à gauche. Néanmoins,* $(\Phi, \underbrace{\Psi}_{=\Phi_*})$ *satisfait à la propriété de factorisation de Quillen.*

Commentary · Exposition [ms. 6]

The small object theorem and its precise input

Theorem 1 is sound under its stated cocompleteness and accessibility hypotheses, understood in the usual locally small sense: an accessible cocomplete category is locally presentable. Its proof explains why the small generating family and the separate retract condition have been singled out. Let $I = \Phi_0$, choose a regular cardinal κ such that the domains of all arrows in I are κ-presentable, and fix $f : X \to Y$. Start with $X_0 = X$. At stage α, take every square

$$\begin{array}{ccc} A & \longrightarrow & X_\alpha \\ {\scriptstyle j}\downarrow & & \downarrow \\ B & \longrightarrow & Y \end{array} \qquad (j \in I)$$

and attach one copy of B along its specified map from A. This is a set of squares because I is small and the category is locally small. Their coproduct and pushout give $X_\alpha \to X_{\alpha+1}$ over Y. At limit stages take colimits. After κ stages put $E = \operatorname{colim}_{\alpha<\kappa} X_\alpha$.

Every map $A \to E$ with A a chosen domain factors through some X_α, since the ordinal κ is κ-filtered. A square $j \to (E \to Y)$ is therefore one of the squares attached at the next stage; its attaching cell supplies a filler into E. Hence $E \to Y$ belongs to $I^{\square} = \Psi$. The arrow $X \to E$ is an I-cell complex. The construction is functorial if every square is attached, without making choices of representatives depending on f.

For the theorem's slightly unusual formulation, coproducts of attaching maps cause no problem. A simultaneous attachment indexed by a set can be replaced, after well ordering that set, by successive pushouts. Thus closure under pushouts and continuous transfinite composition already puts every I-cell complex in Φ. This proves part (b). Moreover

$$I \subseteq \Phi \subseteq {}^{\square}(I^{\square}) \quad \Longrightarrow \quad \Phi^{\square} = I^{\square}.$$

If Φ is also retract closed, any $g \in {}^{\square}(I^{\square})$ is a retract of the left factor of its cellular factorization. Consequently $g \in \Phi$ and $\Phi = {}^{\square}(I^{\square})$, proving part (a). This proof supplies the theorem only stated here; a modern account is Riehl (2014, Theorem 12.2.2 and Corollary 12.2.4).

The parenthetical weakening of cocompleteness can also be made precise. For this construction it suffices to have the needed pushouts, ordinal colimits, local smallness and one regular cardinal giving the required smallness of the generating domains relative to the cellular chains. Pushouts together with ordinal colimits construct each set of attachments successively from the existing object X_α, so a separately postulated empty coproduct is unnecessary. What cannot be dropped is the smallness condition guaranteeing that a lifting problem has appeared before the construction ends.

Remarque. Dans la démonstration, l'existence de $\Phi_0 \subset \Phi$, qui joue le rôle d'un petit ensemble de "générateurs" (à gauche) pour Φ, joue un rôle essentiel. Il y aurait lieu de développer la notion de *parties accessibles* de $\mathrm{Fl}(\mathcal{M})$, qui impliquerait l'existence d'un petit [page 7] ensemble $\Phi_0 \subset \Phi$ tel que $\Phi \subset \widetilde{\Phi}_0$, et qui aurait la propriété que

$$\begin{aligned} \Phi \text{ accessible} \quad &\Longrightarrow \quad \Phi_* \text{ accessible} \\ \Psi \text{ accessible} \quad &\Longrightarrow \quad \Psi^* \text{ accessible.} \end{aligned}$$

Tout couple (Φ, Ψ) de parties closes associées ($\Phi = \Psi^*$, $\Psi = \Phi_*$) et accessible, serait donc un couple de Quillen.

Commentary · Examples [ms. 7]

Accessibility does not supply generating arrows

Grothendieck's proposed notion of an accessible class is meant to make the small object theorem reusable without displaying its generators. Modern terminology separates three properties: accessibility of a full subcategory of the arrow category, accessibility of a chosen factorization functor, and generation of its right lifting class by a set of arrows. The following known example shows why these cannot be substituted for one another; see Rosický (2021, Introduction and Examples 3.7).

Let $\mathcal{M} = \mathrm{Pos}$, and let L consist of the order embeddings. This is a left lifting closed class. Indeed, a monotone map from a subposet $A \subseteq B$ to the two-element chain $2 = \{0 < 1\}$ extends to B by taking the upward closure of the inverse image of 1. Thus every order embedding lifts against $2 \to 1$. Conversely, if $u : A \to B$ is not an order embedding, there exist $a, a' \in A$ with $u(a) \leq u(a')$ but $a \not\leq a'$. This also detects failure of injectivity by choosing the appropriate ordered pair of distinct points with the same image. The characteristic function of the principal upper set $\{x \mid a \leq x\}$ takes a to 1 and a' to 0, and cannot extend over u. Hence

$$L = {}^{\square}\{2 \to 1\}.$$

One can even construct the associated factorization. Embed A into the complete lattice $2^{\mathrm{Up}(A)}$ by recording membership in all its upper sets, and factor $f : A \to B$ through its graph in $B \times 2^{\mathrm{Up}(A)}$. Projection to B lifts against order embeddings, because a monotone map into a complete lattice extends by taking joins of the images of elements below the new point. Thus $(L, L^{\square})$ is a weak factorization system.

As a full subcategory of $\mathrm{Pos}^{[1]}$, L is accessible and accessibly embedded. Filtered colimits preserve order reflection: any relation between images is witnessed at a finite stage, where it already reflects. Every embedding is a filtered union of its finite subembeddings; such finite arrows are finitely presentable in the arrow category and remain so in this full subcategory.

Nevertheless no set $I \subseteq L$ satisfies $I^{\square} = L^{\square}$. Choose an infinite regular κ larger than the cardinalities of all domains and codomains in I, and let P be the poset of subsets of κ of cardinality less than κ. A map $h : A \to P$ extends along every $i : A \hookrightarrow B$ in I by

$$\bar{h}(b) = \bigcup_{i(a) \leq b} h(a).$$

Regularity makes this union an element of P, and order reflection gives $\bar{h}(i(a)) = h(a)$. Therefore $P \to 1$ belongs to $I^{\square}$. Now embed the discrete poset on κ into the poset obtained by adjoining a top element. The map $a \mapsto \{a\}$ cannot extend to that top, since its image would have to contain all of κ. Thus $P \to 1 \notin L^{\square}$. The proposed generating-set conclusion fails even for an accessible, left lifting closed class having factorizations. This does not refute the possibility of defining the stronger notion Grothendieck wants; it identifies what such a definition would have to add.

2 Catégories de Quillen faibles, et construction d'icelles (Théorème-scholie conjectural)

Dans toute la suite, on se donne une *catégorie de modèles*

$$\begin{cases} (\mathcal{M}, W), \text{ où } W \subset \mathrm{Fl}(\mathcal{M}) \\ \\ W \textit{ faiblement saturée } ({}^{5}) : \begin{array}{ll} a) & W \text{ contient les isomorphismes.} \\ b) & \text{Si deux parmi } f,\ g,\ gf \texttt{ [sont] dans } W, \\ & \text{le troisième aussi.} \end{array} \end{cases}$$

On veut décrire des données supplémentaires un peu plus faibles que celles d'une catégorie de modèles de Quillen. On suppose données des parties p. 5

$$C,\ F,\ TC,\ TF\ \subset\ \mathrm{Fl}(\mathcal{M}),$$

avec les propriétés suivantes. Comme axiome préliminaire, je pose

M 0 Stabilité de $\mathcal{M}$ par $\varprojlim$ finies et $\varprojlim$ [plutôt $\varinjlim$] finies.

M 1 Propriété de relèvement-prolongement

$$C \longleftrightarrow TF, \qquad TC \longleftrightarrow F. \qquad \text{[page 8]}$$

5. C'est l'axiome M 5 de Quillen.

M 2 Propriété de factorisation pour (C, TF), (TC, F).

M 3 Stabilité de F par composition et par changement de base, de C par composition et cochangement de base, F et C contiennent les isomorphismes.

M 4 Stabilité de TF par composition et changement de base, de TC par composition et cochangement de base, et TF et TC contiennent les isomorphismes.

M′ $TC \subset C \cap W$, $TF \subset F \cap W$.

M″ $C \subset \underbrace{\mathrm{Cof}_W}_{W\text{-cofibrations}}$, $F \subset \underbrace{\mathrm{Fib}_W}_{W\text{-fibrations}}$.

[Un morphisme $p : X \longrightarrow Y$ de $\mathcal{M}$ est une W-fibration si pour tout diagramme de carrés cartésiens de la forme :

$$\begin{array}{ccccc} X & \longleftarrow & X' & \xleftarrow{t} & X'' \\ {\scriptstyle p}\downarrow & & \downarrow & & \downarrow \\ Y & \longleftarrow & Y' & \xleftarrow[s]{} & Y'' , \end{array}$$

si $s \in W$, alors $t \in W$. La notion de W-cofibration est la notion duale.]

Dans le cas de Quillen (Q-*catégories de modèles*), M′ est renforcé en

$$TC = C \cap W, \qquad TF = F \cap W,$$

et il n'y a pas d'axiome M″. L'axiome M″ équivaut à la propriété de "propriety", correspondant aux Q-catégories de modèles *propres.*

Commentary · Exposition [ms. 8]

Relative equivalences and properness

The additional four classes serve two purposes: they furnish replacements and make ordinary base change behave homotopically. In modern language $(\mathcal{M}, W)$ is first a relative category with two-out-of-three. It is not yet a Quillen model category. Axiom M 2 supplies both factorizations, and M 1 supplies the corresponding lifting relations; without retract closure these pairs need not yet be weak factorization systems. The strict inclusions allowed in M′ deliberately leave open whether the chosen trivial cofibrations exhaust $C \cap W$, and similarly for fibrations.

The intrinsic class Fib_W has a stronger universal quantifier than the assertion that one pullback preserves weak equivalences. A map $p : X \to Y$ belongs to it precisely when, after every base change $Y' \to Y$, the functor

$$(p')^* : \mathcal{M}/Y' \longrightarrow \mathcal{M}/(X \times_Y Y')$$

takes weak equivalences to weak equivalences. Its dual is Cof_W. For an ordinary model structure, pullbacks of fibrations are again fibrations. Therefore right properness says exactly that $F \subseteq \mathrm{Fib}_W$; left properness similarly gives $C \subseteq \mathrm{Cof}_W$. The identification in the manuscript is correct, with the customary completeness and retract conventions supplied when translating to a modern closed model category.

There is a useful unconditional inclusion

$$W_{\mathrm{univ}} \subseteq \mathrm{Fib}_W \cap W, \qquad W^{\mathrm{univ}} \subseteq \mathrm{Cof}_W \cap W.$$

For the first, put a universally weak equivalence vertically in a cartesian square. Both vertical sides are in W. If the bottom horizontal arrow is in W, two-out-of-three puts the top arrow in W; apply the same argument after any further base change. The reverse inclusions require the factorization argument of Proposition 4. This logical dependence explains why Proposition 3 first invokes the displayed equality and then proves the result which justifies it. There is no circularity: Proposition 4 uses factorization and the intrinsic fibrations only, not Proposition 3's saturation construction.

Proposition 3. *Supposons les conditions* M 0 *(pour mémoire),* M 1, M 2, M′, M″ *satisfaites. Alors en remplaçant C, TC par les saturés pour les propriétés de stabilité de contenir les* p. 6 [page 9]

isomorphismes, d'être stable par composition et par cochangement de base, et F, TF par celles de contenir les isomorphismes et d'être stable par composition et par changement de base, on trouve C', TC', F', TF' satisfaisant à tous les axiomes M 1 à M 4, M′, M″.

Démonstration. La proposition 2 nous assure que M 1 continue à être satisfait, et pour M 2 c'est trivial. M 3 et M 4 seront valables par construction. D'autre part, M″ reste valable, car Cof_W a les stabilités requises pour C', et Fib_W celles requises pour F'. Reste à prouver M′, *i.e.*

$$TC' \subset C' \cap W, \qquad TF' \subset F' \cap W,$$

et pour ceci il suffit de voir que $C' \cap W$ resp. $F' \cap W$ a les stabilités requises pour TC' resp. TF'. Cela résulte du

Lemme. *Soit C une partie de Cof_W. Si C contient les isomorphismes, il en est de même de $C \cap W$. Si de plus C est stable par composition resp. par cochangement de base, il en est de même* [de] *$C \cap W$. Énoncé dual pour une partie F de Fib_W.*

Cela provient du fait que

$$\boxed{\mathrm{Cof}_W \cap W = W^{\mathrm{univ}}\ (^6)} \overset{\text{déf}}{=} \begin{array}{l}\text{ensemble des flèches } A \longrightarrow B \text{ telles que pour tout} \\ A \longrightarrow A',\ A' \longrightarrow B' = A' \vee_A B \ \text{ est dans } W.\end{array}$$

est lui-même stable par composition et par cochangement de base, et que l'on a bien sûr, si $C \subset \mathrm{Cof}_W$,

$$C \cap W \ = \ C \cap (\mathrm{Cof}_W \cap W) \ = \ C \cap W^{\mathrm{univ}}.$$

Donc il reste à prouver le [page 10]

Corollaire 1. *Supposons qu'il existe des parties C, F, TC, $TF \subset \mathrm{Fl}(\mathcal{M})$ satisfaisant* M 2, M′ (7), M″. *Alors*

$$\begin{aligned}\mathrm{Cof}_W \cap W \ &= \ W^{\mathrm{univ}} \\ \mathrm{Fib}_W \cap W \ &= \ W_{\mathrm{univ}} \ \ (^8).\end{aligned}$$

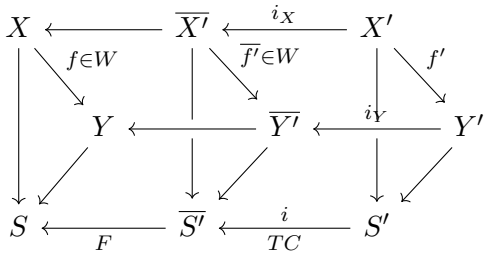
Pour voir ceci, montrons p. ex. le deuxième (le premier s'en déduira par dualité).

$$\begin{array}{ccc} X & \longleftarrow & X' \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle f'} \\ Y & \longleftarrow & Y' \end{array} \qquad\qquad f \in \mathrm{Fib}_W,\ f \in W \Longrightarrow f' \in W.$$

On a mieux :

Proposition 4. *Supposons que toute flèche de $\mathcal{M}$ se factorise en pi, avec $i \in W$ et* p. 7 *$p \in \mathrm{Fib}_W$. Alors, si X, Y sont dans $\underline{\mathrm{Fib}}_W S \subset \mathcal{M}/S$* [sous-catégorie pleine de $\mathcal{M}/S$ formée des $r : Z \longrightarrow S$, où $r \in \mathrm{Fib}_W$], *alors toute $f : X \longrightarrow Y$ dans $\mathcal{M}/S$ qui est dans W_S* [formé des flèches au-dessus de S qui sont dans W] *est dans W_S^{u},* i.e. *elle reste dans W après tout changement de base $S' \longrightarrow S$.*

$$\begin{array}{ccc} X & \xrightarrow{\ f\ } & Y \\ & {\scriptstyle p}\searrow \quad \swarrow{\scriptstyle q} & \\ & S & \end{array} \qquad\qquad p, q \in \mathrm{Fib}_W$$



Énoncé dual pour les flèches de $S\backslash\underline{\mathrm{Cof}}_W \subset S\backslash\mathcal{M}$ [sous-catégorie pleine de $S\backslash\mathcal{M}$ formée des $i : S \longrightarrow Z$, où $i \in \mathrm{Cof}_W$], *une telle flèche qui est dans W est S-coüniversellement dans W, si toute flèche de $\mathcal{M}$ se factorise en qj, avec $j \in \mathrm{Cof}_W$ et $q \in W$.*

6. flèches *coüniversellement* dans W, ou *W-équivalences coüniverselles*.

7. On n'a pas besoin de tout M′, seulement de $TC \subset W$, $TF \subset W$. [page 11]

8. Flèches $f : X \longrightarrow Y$ *universellement* dans W, *i.e.* telles que pour tout $Y' \longrightarrow Y$, $f' : X' = X \times_Y Y' \longrightarrow Y'$ soit dans W.

Démonstration.

On factorise $S' \longrightarrow S$ en $S' \xrightarrow{i} \overline{S'} \xrightarrow{p} S$, avec $i \in W$, $p \in \mathrm{Fib}_W$, par M 2. Donc $f \in W \Longrightarrow \overline{f'} \in W$. Comme $X, Y \in \mathrm{Ob}\,\underline{\mathrm{Fib}}_W S$, on a $\overline{X'}, \overline{Y'} \in \mathrm{Ob}\,\underline{\mathrm{Fib}}_W \overline{S'}$, et comme $i : S' \longrightarrow \overline{S'}$ est dans W, donc aussi i_X, i_Y, on a $f' \in W$ par M 5 (saturation faible de W).

Commentary · Exposition [ms. 11]

Why weak equivalences between fibrations survive base change

Proposition 4 turns the factorization machinery into a statement about W alone. Its proof is short, but each use of the intrinsic fibration condition has a different role. Given a weak equivalence $f : X \to Y$ over S, with $X \to S$ and $Y \to S$ in Fib_W, factor a proposed base change as

$$S' \xrightarrow{i} \overline{S} \xrightarrow{q} S, \qquad i \in W, \quad q \in \mathrm{Fib}_W.$$

Pulling f back along q gives $\bar{f} \in W$: it is a pullback of the weak equivalence f along the base change $Y \times_S \overline{S} \to Y$ of q. Next, the maps $X \times_S \overline{S} \to \overline{S}$ and $Y \times_S \overline{S} \to \overline{S}$ remain intrinsic fibrations. Pulling i back along them gives weak equivalences

$$X \times_S S' \longrightarrow X \times_S \overline{S}, \qquad Y \times_S S' \longrightarrow Y \times_S \overline{S}.$$

The commutative square with these sides and $\bar{f}$ then places $f \times_S S'$ in W by two-out-of-three. No lifting property, functorial choice of factorization, or retract argument is used.

For Corollary 1 apply this assertion in the slice over the codomain of $f \in \mathrm{Fib}_W \cap W$, comparing f with the identity fibration. The converse inclusion was proved above. Duality gives the cofibration equality. Now Proposition 3 can be completed: adjoining the specified composition and base-change operations preserves lifting by Proposition 2 and preserves available factorizations because the four classes only grow. The intrinsic classes have the same finite closure properties. Finally $C' \cap W = C' \cap W^{\mathrm{univ}}$ is stable under pushout and composition, and therefore contains the closure of TC; the fibration side is dual. The strengthening by retracts on manuscript p. 11 is valid if W is retract closed, since pullback and pushout transport retract diagrams to retract diagrams.

Commentary · Development (commentators') [ms. 11]

The factorization hypothesis seen on three objects

Grothendieck's intrinsic classes make it possible to isolate the role of factorization without any topology. The following small calculation shows exactly what would go wrong if Corollary 1 were read as a formal property of two-out-of-three alone. We checked the comparisons with relative-category and factorization-system treatments in Riehl (2014); Rosický (2021); we did not find this particular three-object calculation there. Its purpose is to clarify the hypothesis, not to claim a new general phenomenon.

A weak equivalence which is an intrinsic fibration but is not universal. [ours] Let $\mathcal{M}$ be the chain $0 < 1 < 2$, regarded as a category, and let W consist of the identities and the arrow $w : 0 \to 2$. Then W has two-out-of-three, $w \in \mathrm{Fib}_W$, but $w \notin W_{\mathrm{univ}}$.

Proof. The only composite of two nonidentity arrows is $0 \to 1 \to 2$. Only its composite is in W, so two-out-of-three imposes no further weak equivalence; composites involving identities satisfy the condition. Pullback in this chain is minimum. Every base change of w is $0 \to y$ for $y \in \{0, 1, 2\}$. Below $y = 0$ or 1, the only weak equivalences are identities. Below 2, the sole additional test is

$0 \to 2$, whose pullback along $0 \to 2$ is 1_0. Thus all base changes of w preserve weak equivalences and $w \in \mathrm{Fib}_W$. Its pullback along $1 \to 2$ is $0 \to 1$, which is not in W. This proves the assertion.

The missing factorization can also be located. The map $1 \to 2$ is not in Fib_W, since it pulls w back to $0 \to 1$. A factorization of $1 \to 2$ with first factor in W must have first factor 1_1, leaving precisely this nonfibration as second factor. Thus the hypothesis of Proposition 4 fails for a specified arrow. This finite category has all small limits and colimits; filtered diagrams of arrows have colimits attained in their finite directed image. Hence W is even stable under filtered colimits. Those size and closure properties do not replace factorization in the corollary. □

Commentaire sur Proposition 3. On peut être encore plus exigeant, en demandant dans M 3, M 4 également la stabilité par facteurs directs, et (quand seuls M 1, M2, M′, M″ sont satisfaits) en saturant C, TC, F, TF également pour cette stabilité supplémentaire. La proposition 2 assure encore que M 1 continue à être vérifié (et M 2, M 3, M 4 trivialement), on voit qu'il en est ainsi encore de M′, M″ à condition qu'on renforce l'axiome de saturation faible M 5 sur W par

stabilité de W par facteurs directs,

ce qui implique en effet que Cof_W, Fib_W sont stables par facteurs directs, ainsi que W^{univ} et W_{univ}.

Il ne semble pas que les axiomes M 0 à M 4, plus M′ et M″ suffisent à développer les suites [page 12]
exactes de suspension et de cosuspension. Il faut un petit chouia de plus :

Définition 2. J'appelle *pré-Q-catégorie de modèles à gauche,* la donnée de $\mathcal{M}$ et de W, p. 8
C, F, TC, $TF \subset \mathrm{Fl}(\mathcal{M})$, satisfaisant les axiomes M 0 à M 5, M′, M″, plus la forme renforcée de la première inclusion dans M′

$$\mathrm{M}'_0\ (\mathrm{g}) \qquad\qquad TC = C \cap W \qquad\qquad (\text{non seulement } TC \subset C \cap W).$$

De même, on définit la *pré-Q-catégorie de modèles à droite,* par la condition

$$\mathrm{M}'_0\ (\mathrm{d}) \qquad\qquad TF = F \cap W.$$

NB Quand les deux conditions sont satisfaites à la fois, alors la donnée de TC, TF résulte déjà de celle de W, C, F, et on a simplement une Q-catégorie de modèles "propre" (au sens de Quillen).

Commentary · Exposition [ms. 12]

The purpose of the one-sided equalities

The one-sided conditions are intended to recover exactness of homotopy fibres or cofibres while leaving the auxiliary choices flexible. They should not be read as a claim that every relative category has such a structure, or that a left structure and a right structure must use the same four classes. Grothendieck explicitly allows different choices. The assertion about a proper Quillen category when both equalities hold uses Quillen's original conventions; for a modern closed model category one also requires the retract conditions, or replaces the classes by their retract closures when the stated hypotheses allow it.

The historical motivation is coherent with the earlier reduction to categories of fibrant objects. Brown's formulation develops homotopy using weak equivalences, fibrations and path objects, without specifying a full model structure; see Brown (1973, §1, pp. 420–421). Grothendieck is pursuing a further independence statement: the resulting homotopy operations should be attached to W, with (C, TC, F, TF) used to prove that they exist and have exactness properties. Later in these pages, the same issue reappears for all diagram categories, where objectwise replacement alone does not automatically construct a coherent derived Kan extension.

The claims on manuscript p. 13 about exactness are explicitly provisional: the source says that they still require checking. They are therefore recorded as conjectural assertions in the audit. The completion proved in the commentary on manuscript p. 32 settles their conclusion under the printed hypotheses: either one-sided equality implies exact factorization of weak equivalences, after which the two designated trivial classes can be enlarged to $C \cap W$ and $F \cap W$. The resulting structure

is biexact with the same W, C, F, though it need not be closed. Thus one-sided structures retain flexibility in the designated trivial maps, but their existence already yields a possibly nonclosed Quillen structure. This is a later verification of the assertion, not a proof supplied on p. 13. The cross-reference to "proposition 3" on p. 13 points in fact to Proposition 4: the property cited there is the universal base-change property just proved, together with Corollary 1.

Scholie. Pour moi, l'introduction de C, TC, F, TF est purement auxiliaire – ce qui m'importe, ce sont les propriétés de W. Ainsi, l'existence de C, TC, F, TF satisfaisant aux axiomes faibles M 0 à M 4, M′, M″, du fait qu'elle donne les factorisations dont il est [page 13]
question dans [la] proposition 3, entraîne la propriété remarquable de W énoncée dans cette proposition, et dans le corollaire qui la précède. De même, ces propriétés de factorisation ([9]) assurent l'existence d'une bonne théorie des fibres et cofibres W-homotopiques sans besoin de référence dans cette théorie à C, TC, F, TF (dont l'introduction donne tout au plus des petits compléments …). Mais je ne vois pas comment, à partir des seules hypothèses de factorisation, prouver la propriété cruciale d'exactitude pour les carrés W-cartésiens, et W-cocartésiens, nécessaire pour pouvoir développer la suite *exacte* de cosuspension et de suspension. C'est pour avoir cette exactitude que l'introduction auxiliaire, et transitoire, de l'attirail (C, TC, F, TF) est utile, l'axiome supplémentaire à gauche $TC = C \cap W$ assurant (sauf erreur) l'exactitude des carrés W-cartésiens, et l'axiome à droite $TF = F \cap W$ celle des carrés W-cocartésiens. (Chose à vérifier avec plus de soin que je ne l'ai fait à présent.) Une fois ceci obtenu, et éventuellement itou pour les $(\mathcal{M}(I), W(I))$ pour toute catégorie-diagramme I, on peut totalement oublier ces ensembles auxiliaires – j'ai envie en tous cas de les oublier. [page 14]

Commentary · Context [ms. 14]

The auxiliary status of the Quillen classes

Grothendieck wants the eventual constructions to belong to the pair $(\mathcal{M}, W)$, even when their existence is established by choosing cofibrations and fibrations. His wish to forget those choices is therefore a mathematical requirement: two suitable presentations should give the same homotopy theory of diagrams, including its Kan extensions and their comparison maps. It does not assert that the choices are dispensable in a proof.

The letter to Thomason of 2 April 1991 places this passage in its immediate setting. Grothendieck begins with the accessibility theory he had been developing from SGA 4, then distinguishes the intrinsic localizer from the additional classes used to calculate with it. Concerning closed Quillen triples he writes, "J'avais cru pouvoir m'en passer, mais finalement n'y suis pas parvenu" (Grothendieck, 1991a, pp. 3–4). The contrast he draws there with Brown's one-sided methods explains why the present chapter keeps trying weaker combinations of axioms. The asymmetry is deliberate: the existence of homotopy fibres and that of homotopy cofibres need not initially be established by the same auxiliary structure.

There are two distinct tasks in such a programme. One must first construct the localized categories of diagrams, with sufficient control over their morphisms to form derived operations. One must then prove that the operations satisfy comparison laws as the indexing category varies. An equivalence between two ordinary homotopy categories settles neither task by itself. This is why the apparently elementary question whether a lifting problem can be solved naturally in a diagram will become decisive on manuscript page 41. A family of componentwise solutions need not be a natural transformation.

The later literature realizes these two tasks in several settings, with hypotheses that must be retained. Cisinski's construction of homotopy right Kan extensions starts from a closed Quillen model category with small limits; it does not require an injective model structure on every diagram category (Cisinski, 2003, Theorem 6.11). His subsequent theory of derivable categories provides a further framework for one-sided and exact-category examples (Cisinski, 2010, Introduction and §1). These results give a precise continuation of the programme, but they should not be substituted for a proof of the particular conjectural recognition criterion now being formulated. Here the outstanding issue is the smallness of the classes from which the factorization systems are to be built.

9. sous une forme légèrement renforcée il est vrai – il faut une factorisation *fonctorielle* pour f …

Mon espoir, c'est que pour une W donnée, même si on n'arrive pas à trouver une structure de triple de Quillen (W, C, F) associée (p. ex. parce qu'il n'y en aurait pas), on peut trouver à la fois des quintuplets (W, C, F, TC, TF) qui soient des pré-Quillen à gauche, et des quintuplets (d'*autres* quintuplets!) qui soient des pré-Quillen à droite.

Voici le genre d'énoncé en forme, pour le moment conjectural voire totalement heuristique, auquel je songe :

Théorème-scholie conjectural : *On suppose que $\mathcal{M}$ est stable par $\varinjlim$ "quelconques", et par $\varprojlim$ finies, et que W est stable par $\varinjlim$ filtrantes (en plus de la saturation faible).*

① *Alors* Cof_W *et* W^{univ} *ont les propriétés de stabilité* a) *et* c) *de la proposition* 2 (p. 4), *et aussi la propriété de stabilité* b) *par facteurs directs, pourvu que W lui-même l'a.* p. 9

② *Supposons* $\mathcal{M}$ accessible, *de sorte qu'on dispose du théorème* 1. *Conditions équivalentes sur W :* [page 15]

a) *Il existe une partie petite C_0 de* Cof_W, *et TC_0 de* W^{univ}, *telles que*

$$TF \overset{\text{déf}}{=} C_{0*} \subset W, \qquad (TC_0)_* \overset{\text{déf}}{=} F \subset \mathrm{Fib}_W.$$

a′) *Il existe un quadruplet (C, TC, F, TF) de parties de* $\mathrm{Fl}(\mathcal{M})$, *satisfaisant les conditions* M 1 *à* M 4, M′, M″ *de la page* 6 ([10]).

a″) *Comme* a′), *en supposant* M′ *sous forme renforcée avec* M'_0 (g), i.e. *on a une structure de pré-Q-catégorie de modèles à gauche ($TC = C \cap W$).*

b) *On a*

$$(\mathrm{Cof}_W)_* \subset W, \qquad (W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W$$

(donc $(\mathrm{Cof}_W)_* \subset \mathrm{Fib}_W \cap W$ *puisque* $(\mathrm{Cof}_W)_* \subset (W^{\mathrm{univ}})_*$ ([11])*).*

b′) *On a*

$$(\mathrm{Cof}_W)_* \subset W_{\mathrm{univ}}, \qquad (W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W.$$

③ *Pour qu'il existe un quadruplet qui, avec W, définisse une pré-Q-catégorie de modèles à droite ($TF = F \cap W$)* ([12]), *il faut et il suffit qu'on ait* b′) *ci-dessus, ainsi que*

$$(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} \quad \textit{est clos à droite.}$$

④ *Les hypothèses préliminaires sur $(\mathcal{M}, W)$, y inclus l'accessibilité, ainsi que les conditions équivalentes dans* ②, *sont stables par passage de $(\mathcal{M}, W)$ à $(\mathcal{M}(I), W(I))$. Mais qu'en est-il de la condition dans* ③ *? Est-elle conséquence des conditions dans* ② (i.e. *leurs est-elle équivalente) ?* [page 16]

Je vais esquisser la démonstration du théorème-scholie, pour cerner le travail technique qui reste à faire.

Commentary · Exposition [ms. 16]

The closure part of the conjectural theorem

The theorem-scholie combines a correct closure calculation with a much more substantial assertion that small generating data exist. It helps to finish the closure calculation before attempting the existence argument. Assume the colimit and weak-equivalence hypotheses stated on manuscript p. 14. Then W^{univ} and Cof_W contain isomorphisms and are stable under pushout and composition, by pasting pushout squares and using two-out-of-three where appropriate.

For transfinite composition, let $(A_\alpha)_{\alpha \leq \lambda}$ be continuous. Suppose first that every successor map is a universal weak equivalence. Push the chain out along an arbitrary $A_0 \to T$, obtaining

10. avec C, TC clos à gauche, F, TF clos à droite.
11. $W^{\mathrm{univ}} \subset \mathrm{Cof}_W$.
12. On suppose toujours $\mathcal{M}$ accessible dans 3° et 4°, avec en plus F, TF (et C, TC) closes à droite (resp. à gauche).

$T_\alpha = T \amalg_{A_0} A_\alpha$. Each successor is in W. Transfinite induction shows that $T \to T_\beta$ is in W: the successor step uses composition, while a limit step is the filtered colimit of the arrows $T \to T_\alpha$. Thus $A_0 \to A_\lambda$ lies in W^{univ}.

For Cof_W, start with a weak equivalence $T \to T'$ under A_0. The two pushed-out chains satisfy $T_0 \to T'_0 \in W$. The successor step preserves this relation because the corresponding base change of $A_\alpha \to A_{\alpha+1}$ is a W-cofibration; at a limit step use filtered-colimit closure of W. It follows that pushing out along $A_0 \to A_\lambda$ preserves weak equivalences. Repeating after arbitrary cobase change establishes the universal quantifier in the definition of Cof_W.

Retract closure is available here without a further assumption on W. If f is a retract of $g \in W$ in the arrow category, write the retract maps as $s : f \to g$ and $r : g \to f$, with $rs = 1_f$. Then f is the colimit of

$$g \xrightarrow{sr} g \xrightarrow{sr} g \xrightarrow{sr} \cdots .$$

Indeed a compatible cocone $h : g \to z$ satisfies $h(sr) = h$ and factors uniquely as $hs : f \to z$ followed by r. Since this is a filtered diagram of arrows in W, its colimit f belongs to W. Pullback and pushout preserve retract diagrams, so the intrinsic and universal classes inherit retract closure. This is the elementary mechanism behind Beke (2000, Proposition 1.19); the stronger accessibility hypothesis is not needed when filtered-colimit closure is already assumed.

These arguments establish item ①. They do not establish that either whole class is defined by a lifting property, nor do they produce a small generating family. The distinction becomes decisive in the next paragraph of the manuscript.

1°) Est de la vérification de routine.

2°) Voici les implication ± tautologiques entre les conditions envisagées :

$$(*) \qquad a'' \Longrightarrow a' \overset{?}{\Longrightarrow} a \Longrightarrow b \Longleftarrow b',$$

mais je vois que $a' \Longrightarrow a$ n'est nullement tautologique, et peut-être même faux après tout ! p. 10
([13]). Il faudrait supposer que dans `[le]` quadruplet (C, F, TC, TF), F et TF sont clos à droite, et plus précisément, que $F = (TC)_*$, $TF = C_*$, ce qui sera le cas p. ex. si on a une structure de Q-catégorie de modèles "close" ("closed model category"), au sens de Quillen. Les autres trois implications dans $(*)$ sont bel et bien tautologiques.

$a \Longrightarrow a'$. On peut dans a) supposer

$$TC_0 \ \subset \ C_0$$

(quitte à remplacer C_0 par $C_0 \cup TC_0$), puis, grâce à 1°) (W^{univ} et Cof_W sont clos à gauche), [page 17]
posant

$$\overline{TC_0} = TC, \qquad \overline{C_0} = C, \qquad \texttt{[plutôt } \widetilde{TC_0} = TC, \qquad \widetilde{C_0} = C, \texttt{]}$$

on aura $TC \subset W^{\mathrm{univ}}$, $C \subset \mathrm{Cof}_W$. Passant de TC_0 à TC, de C_0 à C, on a perdu seulement que ces parties de $\mathrm{Fl}(\mathcal{M})$ soient petites. Mais par le théorème 1, posant

$$F \ = \ (TC)_*, \qquad TF \ = \ C_*,$$

les couples de parties closes (à gauche – à droite)

$$(C,\, TF), \qquad (TC,\, F)$$

satisfont à la condition de factorisation de Quillen. On aura alors les propriétés M 1 à M 4, plus les inclusions $TC \ \subset \ C \cap W$ (car $TC \ \subset \ W^{\mathrm{univ}} \ \subset \ W$, et $TC \ \subset \ C$ par construction), et $C \subset \mathrm{Cof}_W$ de M′ et M″. Il reste à vérifier $TF \subset F \cap W$, $F \subset \mathrm{Fib}_W$, mais $F \ (= (TC)_*)$ $\subset \mathrm{Fib}_W$ par hypothèse, et $TF \ (= C_*) \ \subset W$ aussi ; d'autre part $TF \subset F$ résulte de $TC \subset C$.

13. C'est pourquoi je l'ai modifié, en renforçant a') par `[la condition de la note 10]`.

Commentary · Exposition [ms. 17]

From generators to the two factorizations

The implication $(a) \Rightarrow (a')$ can be proved completely without the unsupported assertion that Cof_W and W^{univ} themselves are left lifting closed. Replace C_0 by $C_0 \cup TC_0$; this preserves the required inclusions and makes $TC_0 \subseteq C_0$. Put

$$C = \mathrm{cof}(C_0), \qquad TC = \mathrm{cof}(TC_0), \qquad TF = C_0^{\square}, \qquad F = TC_0^{\square},$$

where cof means pushouts, transfinite composites and retracts. The small object theorem identifies these left classes with the corresponding double lifting closures and supplies both factorizations. The closure calculation in the preceding block gives

$$C \subseteq \mathrm{Cof}_W, \qquad TC \subseteq W^{\mathrm{univ}}, \qquad TC \subseteq C.$$

Condition (a) supplies $TF \subseteq W$ and $F \subseteq \mathrm{Fib}_W$; antitonicity gives $TF \subseteq F$. All of M 1–M 4, M′ and M″ follow.

This repairs the proof, not by assuming the desired global closure statement, but by applying the theorem to the actual small sets that condition (a) provides. The reverse implication remains a separate issue: a right lifting closed class need not be generated by a set on the left. The order-embedding example above explains why the footnote adding lifting closedness to (a') does not, by itself, supply that missing smallness. Thus $(a'') \Rightarrow (a')$, $(a) \Rightarrow (b)$ and $(b') \Rightarrow (b)$ are immediate, and $(a) \Rightarrow (a')$ is now proved; the remaining arrows in the proposed equivalence require additional arguments.

$a' \Longrightarrow a''$. On veut donc, en plus des conditions M 1 à M 4 et M′, M″, la condition

$$TC \;=\; C \cap W \;(= C \cap W^{\mathrm{univ}}).$$

L'idée, c'est de remplacer le couple [page 18]

$$C,\ TC \qquad (C \subset \mathrm{Cof}_W,\ TC \subset C \cap W),$$

donnant naissance à

$$F = (TC)_*, \qquad TF = C_*,$$

par

$$C,\ C \cap W\ (\supset TC),$$

ce qui ne change pas le couple (C, TF), mais bien le couple (TC, F), remplacé par p. 11

$$\underbrace{(TC)'}_{\supset TC} \;=\; \underbrace{C \cap W}_{=C \cap W^{\mathrm{univ}}}, \qquad F' \;=\; \underbrace{(TC')_*}_{\subset F}$$

(on a remplacé F par un F' plus petit) ([14]). Le seul problème, c'est si (TC', F') satisfait encore à la condition de factorisation de Quillen. Ce sont des parties closes (à gauche pour TC', à droite pour F') "duales" l'une de l'autre,

$$TC' = F'^{*}, \qquad F' = TC'_{*},$$

mais comme on ne sait pas si TC' est de la forme $\widetilde{TC'_0}$, avec TC'_0 petite, on n'est pas sûr que la conclusion du théorème 1 s'applique. Mais si on suppose dans a') que C est une partie *accessible* de $\mathrm{Fl}(\mathcal{M})$ (*i.e.*, étant déjà close à gauche, que $C = \widetilde{C_0}$, C_0 petit), alors je présume qu'on pourra prouver qu'il en est de même de $C \cap W$ (W elle-même étant accessible, grâce à la condition de stabilité par petites $\varinjlim$ filtrantes), donc le théorème 1 s'applique bel et bien à $TC' = C \cap W$. Mais si on garde a') telle quelle, alors il faudrait sans doute prouver que a') *implique* a') sous la forme plus forte, avec C *accessible.* Mais comme on a $a' \Longrightarrow a$, et qu'on [page 19]

14. NB TC' sera encore clos à gauche comme intersection de deux parties closes à gauche.

vient d'établir que $a \Longrightarrow a'$ sous cette forme plus forte, on gagne (modulo le fait conjectural admis sur les parties admissibles [plutôt accessibles] de $\mathrm{Fl}(\mathcal{M})$).

Commentary · Later developments [ms. 19]

The solution-set repair and Smith's theorem

Grothendieck is trying to enlarge TC to $C \cap W$ while keeping a factorization theorem. The successful modern recognition theorem places the smallness assumption on the weak equivalences, where it can be checked independently. Smith's theorem, published with proof by Beke (2000, Theorem 1.7), assumes a locally presentable category, a set I of arrows, two-out-of-three and retract closure for W, the inclusion $I^{\square} \subseteq W$, closure of $\mathrm{cof}(I) \cap W$ under pushouts and transfinite composition, and a solution-set condition for maps from each $i \in I$ into W in the arrow category. It then gives a cofibrantly generated model structure with cofibrations $\mathrm{cof}(I)$ and fibrations $(\mathrm{cof}(I) \cap W)^{\square}$. Accessibility and accessible embeddedness of the full weak-equivalence subcategory imply the required solution-set condition; this is Beke's Proposition 1.15.

Here is the exact consequence for these pages. Retain their hypotheses and condition (a), and assume in addition that the full subcategory of weak equivalences is accessible and accessibly embedded in $\mathcal{M}^{[1]}$. Use $I = C_0 \cup TC_0$ and the two factorizations constructed in the preceding block. Corollary 1 gives $\mathrm{Cof}_W \cap W = W^{\mathrm{univ}}$. Hence

$$C \cap W = C \cap W^{\mathrm{univ}}$$

is closed under pushouts, transfinite composites and retracts. Smith's hypotheses hold, so $C \cap W$ is generated by a set and the desired replacement of TC has factorizations. In fact the result is stronger than the proposed left pre-Q structure: it is a full combinatorial model structure. It is proper because $C \subseteq \mathrm{Cof}_W$ and

$$(C \cap W)^{\square} \subseteq TC_0^{\square} \subseteq \mathrm{Fib}_W.$$

The first inclusion uses $TC_0 \subseteq C \cap W$.

This application is a repair under an explicit additional hypothesis, not a proof of the original theorem-scholie. Closure under filtered colimits says that colimits of diagrams already in W stay in W; accessibility additionally supplies a set of sufficiently presentable arrows from which all of W is built. Nor is the manuscript's parenthetical definition $C = \widetilde{C}_0$ with C_0 small equivalent to accessibility of the full arrow subcategory. The example in Pos separates those notions even when C is left lifting closed.

Il reste donc à prouver

$$b \implies a, \qquad b \implies b',$$

et il suffit de prouver la première implication, car on sait que $a) \Longrightarrow a')$, et que $a')$ implique que

$$\mathrm{Fib}_W \cap W \;=\; W_{\mathrm{univ}}$$

(cor. 1, page 10), donc $(\mathrm{Cof}_W)_* \subset W$ et $(W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W$ (*i.e.* b)) impliquent, comme $(\mathrm{Cof}_W)_* \subset (W^{\mathrm{univ}})_*$ (car $W^{\mathrm{univ}} \subset \mathrm{Cof}_W$), $(\mathrm{Cof}_W)_* \subset W \cap \mathrm{Fib}_W = W_{\mathrm{univ}}$, ce qui est la partie à établir de b') (l'autre $(W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W$ étant tautologiquement contenue dans b).

Notons maintenant que b) n'est autre que la variante affaiblie de a), quand on omet de [page 20] spécifier que C_0, TC_0 doivent être petits. Donc le seul problème, pour $b \Longrightarrow a$, c'est de voir ceci :

Lemme conjectural ([15]).

① *Si on a une partie close à gauche* Φ *de* $\mathrm{Fl}(\mathcal{M})$*, telle que* $\Phi_* \subset \mathrm{Fib}_W$ *(resp.* $\Phi_* \subset W$*), alors il existe une partie* petite $\Phi_0 \subset \Phi$*, telle que* $\Phi_{0*} \subset \mathrm{Fib}_W$ *(resp.* $\Phi_0 \subset W$*).*

② *Si* C*,* C' *sont deux parties closes à gauche de* $\mathrm{Fl}(\mathcal{M})$*, si* C *et* C' *sont accessibles, il en est de même de* $C \cap C'$*.*

p. 12

15. Ce lemme a l'air un peu faux, mais ça doit pouvoir s'arranger …

Je crois que c'est bel et bien vrai sous les hypothèses faites sur $\mathcal{M}$, W – qui doivent impliquer que dans un sens convenable, W est une partie accessible de l'ensemble $\mathrm{Fl}(\mathcal{M})$ des flèches de la catégorie accessible $\mathcal{M}$. Il doit en résulter qu'une partie de $\mathcal{M}$ construite explicitement en termes de W, telle Fib_W, est elle-même accessible, et le lemme doit sortir de là.

Ainsi, 2° est prouvé, modulo ce lemme d'accessibilité, qu'il me faudra prouver ± en même temps que le théorème 1 (que je n'ai fait ici qu'énoncer).

[page 21]

Commentary · Later developments [ms. 20]

The intersection lemma has a later affirmative answer

The second part of the conjectural lemma has a precise modern resolution when its word "accessible" is read in the sense specified on manuscript p. 18, namely set-generated under left lifting closure. In a locally presentable category, if

$$C = \mathrm{cof}(I), \qquad C' = \mathrm{cof}(J)$$

for sets I, J, then $C \cap C'$ is again $\mathrm{cof}(K)$ for a set K. This follows from Makkai and Rosický (2014a, Theorem 3.2 and Remark 3.8): combinatorial cellular structures are stable under the relevant pseudopullbacks. Apply their result to the two identity functors from $(\mathcal{M}, C)$ and $(\mathcal{M}, C')$ into $\mathcal{M}$ with every arrow cellular. The resulting structure has exactly the intersection as its cellular class. This resolves the intersection assertion; it does not imply that the entire intrinsic class W^{univ} has such generators.

The first part of the lemma asks for a different kind of compactness: from $\Phi^{\square} \subseteq T$, where T is W or Fib_W, it seeks a set $\Phi_0 \subseteq \Phi$ with $\Phi_0^{\square} \subseteq T$. Neither the Galois connection nor the preceding intersection theorem provides this reduction. The final parenthesis in the edition has $\Phi_0 \subseteq W$; its intended expression is $\Phi_{0*} \subseteq W$, as the surrounding reduction from (b) to (a) requires. The printed slip is retained and recorded separately.

We found the applicable positive results in the small object theorem, Smith's recognition theorem, and the cellular-category theorem just cited. They do not prove this small-subfamily assertion under precisely the preliminary assumptions of the manuscript. We therefore leave that assertion unresolved in this audit rather than attach a claim of current openness to a loosely specified accessibility principle. In a small category the selection is immediate by taking $\Phi_0 = \Phi$; its entire content here is the passage from a proper class to a set. Modern accessible weak factorization systems also require care: accessibility refers to a factorization functor, and does not guarantee that its full left or right class is an accessible subcategory. The corrected statements and the distinction from set generation are recorded in Rosický (2021, §3, especially Remarks 3.2, 3.5 and Theorem 3.9).

Prouvons 3°. Supposons d'abord qu'il existe un quadruplet "clos" (C, TC, F, TF), s'insérant dans un "pré-quintuplet de Quillen clos" qui soit une Q-catégorie de modèles à droite, *i.e.*

$$TF \;=\; F \cap W \;=\; F \cap W_{\mathrm{univ}}.$$

Prouvons alors `[que]`

(∗) $\underbrace{(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}}}_{A_W}$ est clos à droite.

En effet, on a

$$TC \;\subset\; W^{\mathrm{univ}},$$

d'où

$$(W^{\mathrm{univ}})_* \;\subset\; (TC)_* \;=\; F,$$

donc

$$A = (W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} \;\subset\; F \cap W_{\mathrm{univ}} \overset{(\text{par hyp.})}{=} TF,$$

or TF est clos à droite et contenu dans W_{univ}, d'où

$$\overline{A} \ \subset \ TF \ \subset \ W_{\mathrm{univ}},$$

et comme $(W^{\mathrm{univ}})_*$ est clos à droite, on a aussi

$$\overline{A} \ \subset \ (W^{\mathrm{univ}})_*,$$

d'où $\overline{A} \subset W_{\mathrm{univ}} \cap (W^{\mathrm{univ}})_* = A$, donc A est clos à droite, q.e.d.

Prouvons la réciproque, *i.e.* supposons satisfaites les conditions de 2°, *plus* la condition $(*)$ ci-dessus. On doit construire le quadruplet.

[page 22]

Commentary · Exposition [ms. 21]

A closure obstruction before the existence problem

Grothendieck is trying to extract a property of the weak equivalences which is independent of the auxiliary Quillen structure. The class

$$A_W = (W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}}$$

is designed for this purpose: its first condition is a lifting condition, its second says that every pullback is a weak equivalence. There is a useful separation here between a necessary condition, which is established without an accessibility argument, and a construction of factorizations, which still needs one.

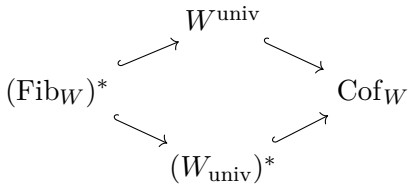
Suppose that a closed weak structure is right exact. Since $TC \subset W^{\mathrm{univ}}$, we have $(W^{\mathrm{univ}})_* \subset F$. Consequently

$$A_W = (W^{\mathrm{univ}})_* \cap TF.$$

Indeed, the forward inclusion uses $TF = F \cap W_{\mathrm{univ}}$, while the reverse inclusion uses $TF \subset W_{\mathrm{univ}}$. This writes A_W as an intersection of two right lifting classes. It is therefore right closed. This short proof is equivalent to the closure computation in the manuscript and shows exactly why no generation hypothesis enters the necessary condition.

The converse is more delicate. Set $L = W^{\mathrm{univ}}$, $F = L_*$, $T = F \cap W_{\mathrm{univ}}$ and $C = T^*$. If T is right closed, then $C_* = T$, and $L \subset C$. These are statements about orthogonality; they do not factor an arbitrary arrow. To obtain the proposed structure, one must additionally know that (L, L_*) and (T^*, T) admit factorizations and that $T^* \subset \mathrm{Cof}_W$. If also L is left closed, these conditions give the two weak factorization systems. Since $L \subset C \cap W$, $T \subset F \cap W$, and $F \subset \mathrm{Fib}_W$, they give a closed weak structure; the right exactness follows from $F \cap W = F \cap W_{\mathrm{univ}}$, using the universal-equivalence criterion already proved on manuscript pp. 10–11.

The sentence on the next page which attributes left lifting closure of Cof_W and W^{univ} to part 1 of the conjectural theorem passes over precisely this distinction. Part 1 establishes stability under certain constructions. Left lifting closure is a stronger assertion unless a generation theorem applies. The earlier block *From generators to the two factorizations* supplies the appropriate repair when generators have been specified. We read the diagrams on pp. 22–24 as the formal organization of a proposed construction, with the remaining factorization hypotheses still visible; they are not an additional proof of those hypotheses.

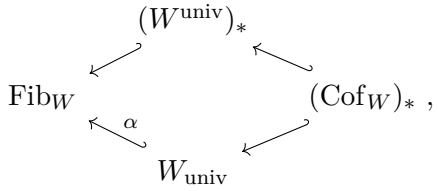


Notons d'abord, pour nous y reconnaître, que les relations b') de 2°), et les relations transposées (compte tenu que Cof_W et W^{univ} sont clos à gauche, par 1°), savoir

$$\left\{ \begin{array}{lcl l lcl} (\mathrm{Cof}_W)_* & \subset & W_{\mathrm{univ}} & , & (W^{\mathrm{univ}})_* & \subset & \mathrm{Fib}_W \\ (W_{\mathrm{univ}})^* & \subset & \mathrm{Cof}_W & , & (\mathrm{Fib}_W)^* & \subset & W^{\mathrm{univ}}, \end{array} \right.$$

donnant ([16]) les deux diagrammes carrés d'inclusions p. 13

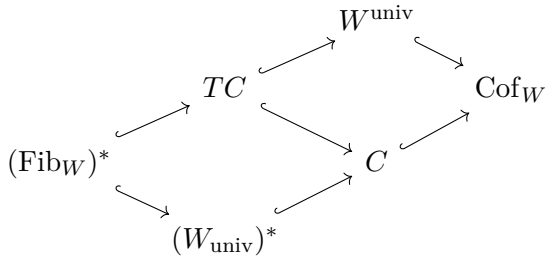
16. compte tenu de $W^{\mathrm{univ}} \subset \mathrm{Cof}_W$, $W_{\mathrm{univ}} \subset \mathrm{Fib}_W$ et des inclusions transposées.



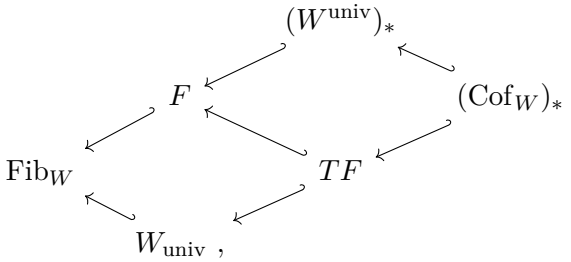
(I)

([17])

et



(II)



dont le premier est transposé (par $\Phi \longmapsto \Phi^*$) du second, et où les 8 ensembles de flèches envisagés, à l'exception de Fib_W et W_{univ} (reliés par α dans le carré II) sont clos (les quatre ensembles de I clos à gauche, et les deux ensembles de II non intéressés par α, clos à droite).

Les "pré-quintuplets de Quillen clos", associés à W, correspondent au choix de parties closes à gauche TC et C, s'insérant dans le diagramme (I) comme montré dans I′ ci-dessous, et donnent lieu par transposition à F et TF comme dans II′ ci-dessous, [page 23]

(I′)

(II′)

le "hic" étant donc de choisir TC et C assez grandes pour qu'on ait

$$\underbrace{(TC)_*}_{=F} \subset \mathrm{Fib}_W, \qquad \underbrace{C_*}_{=TF} \subset W_{\mathrm{univ}} \quad -$$

et les inclusions stipulées dans 2°, b') assurent qu'on peut bel et bien trouver TC et C, quitte à les prendre les plus grandes possibles, $TC = W^{\mathrm{univ}}$, $C = \mathrm{Cof}_W$ – auquel cas, d'ailleurs, on aura p. 14 [page 24]

$$TC \;=\; C \cap W^{\mathrm{univ}},$$

i.e. on a une pré-Q-catégorie de modèles à gauche. Mais il s'agit d'assurer maintenant, par contre, que

$$TF \;=\; F \cap W_{\mathrm{univ}},$$

17. **NB** On a ces carrés d'inclusions, chaque fois qu'on a un système de Quillen (W, C, F, TC, TF) *clos.*

ce qui implique, on vient de le voir, (en notant $(W^{\mathrm{univ}})_* \subset F$) que

$$(*) \qquad \overline{(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}}} \ \subset \ \overline{F \cap W_{\mathrm{univ}}} = \overline{TF} = TF \subset W_{\mathrm{univ}}.$$

Inversement, si $(*)$ est satisfait, prenons

$$F = (W^{\mathrm{univ}})_*$$

le plus petit possible, *i.e.* $C = W^{\mathrm{univ}}$ `[plutôt` $TC = W^{\mathrm{univ}}$`]` le plus grand possible. On doit donc prendre

$$TF \ = \ F \cap W_{\mathrm{univ}} \ = \ (W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}},$$

et cet ensemble est bien clos à droite par hypothèse.

Corollaire. *Supposons la condition* b′) *du théorème-scholie satisfaite. Les conditions suivantes* a), b) *sur W sont équivalentes (et impliquent la condition de* 3° *du théorème-scholie).*

[page 25]

ⓐ $(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} = (\mathrm{Cof}_W)_*$.

ⓑ $\widetilde{W^{\mathrm{univ}} \cup (W_{\mathrm{univ}})}^{\,*} = \mathrm{Cof}_W$, i.e. Cof_W *est la partie close à gauche engendrée par* W^{univ} *et* $(W_{\mathrm{univ}})^*$,

et ces conditions impliquent

ⓒ *qu'il existe une structure de* triple clos de Quillen (W, C, F) *incluant W (donc avec $TC = W \cap C$, $TF = W \cap F$) (lequel sera clos au sens de Quillen si et seulement si W* `[est]` *stable par facteurs directs – car C et F sont déjà stables spontanément).*

Il suffit en effet de prendre alors

$$TC \ = \ W^{\mathrm{univ}}, \qquad C \ = \ \mathrm{Cof}_W.$$

Mais je doute que l'existence d'un triple clos de Quillen (W, C, F) suffise à impliquer les conditions *a*), *b*) ci-dessus, ni même la condition plus faible

$$(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} \ = \ (\mathrm{Cof}_W)_*$$

qui signifie *exactement* que $C = \mathrm{Cof}_W$, $TC = W^{\mathrm{univ}}$, et leurs transposés $TF = (\mathrm{Cof}_W)_*$, $F = (W^{\mathrm{univ}})_*$ forment une catégorie de Quillen close.

p. 15
[page 26]

Conditions sur $(\mathcal{M}, W)$ avec

a) $\mathcal{M}$ stable par $\varprojlim$ finies et $\varinjlim$ (petites),

b) W stable par $\varinjlim$ filtrantes,

c) $\mathcal{M}$ accessible.

Commentary · Exposition [ms. 25]

The two closures in the maximal construction

The corollary seeks a particularly economical structure: take every universal weak cofibration as a trivial cofibration and every W-cofibration as a cofibration. Its strength comes from this maximal choice, and the two different closures in the formulas measure its cost.

For arbitrary classes L, R of arrows, the lifting calculus gives

$$\big(L \cup R^*\big)_* = L_* \cap (R^*)_* = L_* \cap \overline{R}.$$

Thus the right orthogonal of $W^{\mathrm{univ}} \cup (W_{\mathrm{univ}})^*$ is $(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}}$, with a bar on the second factor. It is not, without another hypothesis, $(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}}$. If Cof_W is left closed, applying the Galois correspondence proves the equivalence

$$(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} = (\mathrm{Cof}_W)_* \quad \Longleftrightarrow \quad \widetilde{W^{\mathrm{univ}} \cup (W_{\mathrm{univ}})^*} = \mathrm{Cof}_W.$$

The superscript star must belong to the second summand inside the tilde. The printed formula on manuscript p. 25 places it outside the visible tilde; the accompanying prose and the summary on p. 26 identify the intended expression. We preserve the edition's formula and record the discrepancy separately.

Under condition b' one has $(\mathrm{Cof}_W)_* \subset W_{\mathrm{univ}}$. Hence the stronger displayed equality implies

$$(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} = (\mathrm{Cof}_W)_*.$$

For the inclusion from right to left, use $W^{\mathrm{univ}} \subset \mathrm{Cof}_W$ and b'; for the reverse inclusion, enlarge W_{univ} to its right closure and apply the stronger equality. The latter equality is exactly the compatibility needed by the maximal two pairs, once their factorizations exist. It does not itself supply factorizations.

This explains the hierarchy I–IV on p. 26. At the level of formal implications, IV imposes a closure identity stronger than the identity in III, and a maximal structure in III is a special instance of a structure in II. The alleged equivalences inside I and the construction clauses inside II retain the accessibility and factorization problems from pp. 17–20. The hierarchy is a research programme with several proved implications, not four unconditional recognition theorems. In particular, the correct formula in II(c) is $C = (TF)^*$; the printed subscript star is a variance slip.

I
- ⓐ existence d'un système de Quillen faible (W, C, TC, F, TF) (clos si on y tient)
- ⇕
- ⓑ existence d'un système de Quillen faible exact à gauche ($TC = C \cap W$).
- ⇕
- ⓒ $\underbrace{(\mathrm{Cof}_W)_* \subset W,\ (W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W}_{(*)}$ $(\Longleftrightarrow \quad (\mathrm{Cof}_W)_* \quad \subset \quad W_{\mathrm{univ}},$ $(W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W)$.

$\Uparrow$

II $\begin{cases} \text{ⓐ} & \text{existence d'un système de Quillen faible exact à droite } (TF = F \cap W) \\ \Updownarrow & \\ \text{ⓓ} & \text{On a } (*), \text{ et de plus } (W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} \text{ clos à droite.} \\ \Updownarrow & \\ \text{ⓑ} & \text{existence d'un système de Quillen clos (closed model category), } TC = C \cap W,\ TF = F \cap W,\ F = (TC)_*,\ TF = C_*,\ TC = F^*,\ C = (TF)^*. \\ \Updownarrow & \\ \text{ⓒ} & \text{Posant } TC = W^{\mathrm{univ}},\ F = (TC)_*,\ TF = F \cap W_{\mathrm{univ}},\ C = (TF)_*, \text{ on trouve avec } W \text{ un système de Quillen clos.} \end{cases}$

$\Uparrow$

III $\begin{cases} C = \mathrm{Cof}_W \text{ et } TC = W^{\mathrm{univ}} \text{ font partie (avec } W) \text{ d'un système de Quillen clos (donc } F = (W^{\mathrm{univ}})_*,\ TF = (\mathrm{Cof}_W)_*,\ W = TF \circ TC). \\ \Updownarrow \\ \texttt{[On a]}\ (*), \text{ et de plus } (W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} = (\mathrm{Cof}_W)_*. \end{cases}$

IV $\begin{cases} \text{On a } (*) \text{ et } \mathrm{Cof}_W = \widetilde{(W_{\mathrm{univ}})^* \cup W^{\mathrm{univ}}}\ . \\ \Updownarrow \\ \text{On a } (*) \text{ et } (W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} = (\mathrm{Cof}_W)_*. \end{cases}$

Cas $\mathcal{M} = \mathrm{Cat}$, $W = \mathbf{W}_\infty$. On sait que II est satisfait, par Thomason. Donc on a p. 16

$$(\mathrm{Cof}_W)_* \subset W_{\mathrm{univ}}, \qquad (W^{\mathrm{univ}})_* \subset \mathrm{Fib}_W, \qquad (W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}} \text{ clos à droite.}$$

J'ai pu prouver directement les deux premières inclusions (*i.e.* I), mais pas que $(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}}$ soit clos à droite. (Je devrais au moins essayer!) ([18]). On n'a pas IV, *i.e.* on a

$$(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} \neq (\mathrm{Cof}_W)_*$$

car

$$(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} \not\subset W_{\mathrm{univ}}$$

(contient les $X \longrightarrow e$ avec X discrète), donc on a

$$(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} \supsetneq \underbrace{(W^{\mathrm{univ}})_* \cap W_{\mathrm{univ}}}_{\text{n'est } \textit{pas} \text{ l'orthogonal de } W^{\mathrm{univ}} \cup (W_{\mathrm{univ}})^*} .$$

[page 27]

Commentary · Development (commentators') [ms. 26]

Discrete categories detect the extra closure

Grothendieck's example deserves a proof because it distinguishes two conditions that otherwise look nearly identical. We take W in Cat to be the functors inducing weak homotopy equivalences of nerves. Thomason's theorem gives a proper model structure with this W; its existence does not imply the maximal closure condition IV (Thomason, 1980, Theorem 4.9 and Corollary 5.5).

A discrete obstruction to condition IV. [ours] For every nonempty discrete category D, its terminal map belongs to

$$(W^{\mathrm{univ}})_* \cap \overline{W_{\mathrm{univ}}} \cap \mathrm{Fib}_W.$$

If D has at least two objects, this map does not belong to W_{univ}.

Proof. We first examine a functor $i : A \to B$ having the left lifting property against every universally weakly equivalent functor. We claim that $\pi_0(i) : \pi_0 A \to \pi_0 B$ is injective. Suppose that two distinct components of A have images connected in B by a zigzag of length m. Choose a finite poset J whose Hasse diagram is an alternating linear zigzag with more than m edges. Its nerve is an interval subdivided into edges, so $J \to e$ is a weak equivalence. It is universally so: its pullback over any category E is the projection $J \times E \to E$, and the nerve preserves products; a product with this finite contractible simplicial set is a weak homotopy equivalence.

Send the first chosen component of A to one endpoint of J, the second to the other endpoint, and every other component to either endpoint. This defines a functor $a : A \to J$, constant on components. A lift against $J \to e$ would extend a to $B \to J$. The zigzag of length m in B would then connect the two endpoints of J by at most m edges. Every nonidentity arrow of the alternating poset joins adjacent vertices, so this is impossible. This proves the claim.

Now a functor $A \to D$ is just a function $\pi_0 A \to D$. If $i \in (W_{\mathrm{univ}})^*$, injectivity of $\pi_0(i)$ lets us extend this function to $\pi_0 B$: use its prescribed values on the image and one fixed object of D on all remaining components. Thus $D \to e$ has the right lifting property against $(W_{\mathrm{univ}})^*$, which is exactly membership in $\overline{W_{\mathrm{univ}}}$.

Every functor in W^{univ} is in W, so induces a bijection on components. The same extension argument, now with a unique possible value on every component, gives $D \to e \in (W^{\mathrm{univ}})_*$. Finally, any base change of $D \to e$ is a coproduct of copies of an identity map. Pulling a weak equivalence back along it gives the corresponding coproduct of that weak equivalence; the nerve and geometric realization verify that the result is again a weak equivalence. Therefore $D \to e \in \mathrm{Fib}_W$. If $|D| \geq 2$, the map fails already to induce a bijection on components, so is not in W, and a fortiori not in W_{univ}. □

This also explains the qualification required in the footnote: a nonempty discrete category supplies the displayed membership, but a counterexample requires at least two components. The empty category is not included in the lifting argument because extending a function to a newly

18. Il suffirait de savoir que $\overline{W_{\mathrm{univ}}} \cap \mathrm{Fib}_W = W_{\mathrm{univ}}$, ce qui impliquerait que III et IV sont équivalents ([19]).
19. Mais c'est faux, p. ex. si X `[est une]` catégorie discrète non vide, $X \longrightarrow e$ est dans $\overline{W_{\mathrm{univ}}} \cap \mathrm{Fib}_W$.

> appearing component would then be impossible. The proof expands the manuscript's example; we checked Thomason's construction and the cited modern treatments of lifting and localization, without finding this precise zigzag proof there. The marker records a proof supplied for this commentary, not a claim of priority.

3 Catégorie de Quillen (deuxième mouture)

On se donne toujours un couple

$$(\mathcal{M}, W), \qquad W \subset \mathrm{Fl}(\mathcal{M}), \qquad W \text{ faiblement saturé},$$

$\mathcal{M}$ satisfait M 0 (stabilité par $\varprojlim$ finies et $\varinjlim$ finies).
Définition 1 : Une *structure de Quillen faible* associée à la catégorie de modèles $(\mathcal{M}, W)$ est la donnée de quatre parties (C, TC, F, TF) de $\mathrm{Fl}(\mathcal{M})$, satisfaisant les conditions suivantes.

- **M 1** $C \longleftrightarrow TF$, $TC \longleftrightarrow F$ (*i.e.* $TF \subset C_*$, $F \subset (TC)_*$).
- **M 2** Propriété de factorisation de Quillen pour (C, TF) et (TC, F).
- **M 3** Stabilité de C par composition et par cochangement de base, de F par composition et changement de base – C et F contiennent les isomorphismes.
- **M 4** Stabilité similaire pour TC et TF.
- **M′** $TC \subset C \cap W$, $TF \subset F \cap W$.
- **M″** $C \subset \mathrm{Cof}_W$, $F \subset \mathrm{Fib}_W$.

On dit que la structure de Quillen est *exacte* si elle satisfait à l'axiome supplémentaire

M 2 bis $W = TF \circ TC$. p. 17

On dit qu'elle est *exacte à gauche* si elle satisfait l'axiome supplémentaire

M$'_0$ (g) $TC = C \cap W$ (au lieu de $TC \subset C \cap W$ seulement),

exacte à droite si elle satisfait

M$'_0$ (d) $TF = F \cap W$ (au lieu de $TF \subset F \cap W$ seulement) ([20]).

Remarque. [page 28]

a) Une structure de Quillen exacte à gauche ou exacte à droite est exacte.

b) Si on a une donnée (C, TC, F, TF) satisfaisant M 1, M 2, M$'$, M$''$, quand on sature C, TC à gauche et F, TF à droite, pour les stabilités précisées dans M 2, M 3, on trouve une structure de Quillen. (Tous les axiomes sont évidents, sauf M$'$, pour lequel je renvoie à p. 9, 10, notamment prop. 4.) Si on avait M 2 bis, cela sera encore vérifié (a fortiori) après saturation, *i.e.* on a une structure de Quillen exacte.

Commentary · Exposition [ms. 27]

Exactness belongs to the chosen classes

The second definition rearranges the earlier axioms around the task they have to perform. The inclusions $TC \subset C \cap W$ and $TF \subset F \cap W$ distinguish designated trivial maps from all weak equivalences among the designated cofibrations and fibrations. This distinction is essential before retract closure has been imposed. In modern terminology, the closed case consists of two nested weak factorization systems; Grothendieck's M$''$ adds properness relative to the specified weak equivalences.

There are three different assertions. Exactness says that every weak equivalence has a factorization using the two designated trivial classes. Left exactness identifies the designated trivial cofibrations with $C \cap W$; right exactness identifies the designated trivial fibrations with $F \cap W$. Either identification implies exactness. For example, if $w = pi$ with $i \in C$ and $p \in TF$, then $w, p \in W$ imply $i \in W$, and left exactness gives $i \in TC$. The dual argument uses the other factorization.

Neither this argument nor the two-out-of-three axiom proves that the original chosen class TF is retract closed. Footnote 20 tries to infer too much from retract closure of C, F, W. Its conclusion becomes correct after replacing the missing trivial class by its retract closure, but the chosen class need not already equal that closure. The next example makes the distinction concrete. For closed structures, by contrast, exactness alone forces both equalities by the retract argument developed later in the commentary on manuscript p. 57.

Définition 1 bis. La structure de Quillen faible est dite *structure de Quillen* (tout court) si elle est exacte à gauche et à droite, ou (comme on dit) "biexacte", alors (C, F) determine déjà (C, TC, F, TF). (Ça correspond exactement aux "model categories" de Quillen `[propres]`.) On dit que la structure de Quillen faible est *close* si on a

$$C \leftarrow\!+\!\rightarrow TF\ , \qquad TC \leftarrow\!+\!\rightarrow F\ ,$$

i.e. $TF = C_*$, $C = (TF)^*$ et $F = (TC)_*$, $TC = F^*$ ([21]). Une structure de Quillen faible à la fois biexacte (*i.e.* pas faible du tout!) et close est appelée structure de Quillen *parfaite*. (Ça correspond exactement à la "closed model category" `[propre]` de Quillen.)

Remarque. Pour qu'une structure de Quillen faible soit parfaite, il suffit qu'elle soit biexacte et qu'on ait [page 29]

$$C = (TF)^*, \qquad F = (TC)_*$$

(ce qui implique déjà que $TC = F^*$, $TF = C_*$, *i.e.* que TC est clos à gauche et TF clos à droite). C'est prouvé dans Quillen. Ça implique aussi que W est fortement saturé – c'est le pays de cocagne!

20. **NB** Si C, F, W `[sont]` stables par facteurs directs (donc aussi $C \cap W$ et $F \cap W$), alors l'exactitude à gauche $TC = C \cap W$ *équivaut* à l'exactitude à droite $TF = F \cap W$, et implique que C, TC, F, TF sont *clos* (à gauche pour C, TC, à droite pour F, TF).

21. Cela signifie aussi que C, TF, TC, F sont stables par facteurs directs. On dit que la structure de Quillen faible est *close à gauche* (resp. *à droite*) si C, TC (resp. F, TF) sont clos à gauche (resp. à droite).

Commentary · Development (commentators') [ms. 28]

A retract condition missing from footnote 20

Grothendieck wants the ordinary model-category identities to reappear as soon as retracts behave well. They do reappear after completing the designated classes, but not necessarily before. The following example isolates the missing step without involving any topological pathology.

Left exactness without right exactness. [ours] Assume the axiom of choice. In Set put

$$W = \mathrm{Fl}(\mathrm{Set}), \qquad C = TC = \{\text{injections}\}, \qquad F = \{\text{surjections}\},$$

and let TF consist of those surjections all of whose fibres are either singletons or infinite sets. These classes satisfy all the weak Quillen axioms on manuscript p. 27. The classes C, F, W are retract closed, and the structure is left exact, but it is not right exact.

Proof. Injections have the left lifting property against surjections: on the complement of the injected subset, choose a preimage in each relevant nonempty fibre. Both required lifting properties follow. For an arbitrary map $f : A \to B$, use

$$A \longrightarrow A \amalg (B \times \mathbb{N}) \xrightarrow{p} B, \qquad p|_A = f, \quad p(b, n) = b.$$

The first map is injective and every fibre of the second is infinite; when B is empty, necessarily A is empty and the assertion is vacuous. This one factorization serves both required pairs.

Injections contain the isomorphisms and are stable under composition and pushout. Surjections have the corresponding pullback and composition properties. For the special class TF, pullback preserves each fibre up to bijection. A fibre of a composite is a disjoint union of nonempty fibres of the first map indexed by a fibre of the second. If the indexing fibre is a singleton, the result is a permitted fibre of the first map; if it is infinite, the disjoint union is infinite. Thus TF also has the required stability. The inclusions $TC \subset C \cap W$ and $TF \subset F \cap W$ hold. Since all maps are weak equivalences, Cof_W and Fib_W are both the class of all maps, so M'' holds as well.

The usual elementwise arguments show that injections and surjections are retract closed in the arrow category, while W trivially is. We have $TC = C \cap W$. However, the map from a two-element set to a singleton belongs to $F \cap W$ and does not belong to TF. It is a retract of $\mathbb{N} \to \{*\}$, which does belong to TF. This proves both the failure of right exactness and the failure of retract closure of the designated class. □

The repaired assertion can be stated precisely. Suppose C, F, W are retract closed and $TC = C \cap W$. Then TC is retract closed. The factorization and lifting axioms give $TC = {}^{\perp}F$ and $F = TC^{\perp}$. If $p \in F \cap W$, factor $p = qi$ with $i \in C$ and $q \in TF$. Two-out-of-three gives $i \in TC$, and lifting i against p exhibits p as a retract of q. Conversely every retract of a map in TF lies in $F \cap W$. Hence

$$\mathrm{Retr}(TF) = F \cap W.$$

Replacing TF by this class preserves lifting, factorization and properness and produces a perfect structure. The standard retract argument also gives $C = {}^{\perp}(F \cap W)$ and $C^{\perp} = F \cap W$. The dual repair applies to a right exact structure. We checked the standard model-category retract arguments and Cisinski's treatments; the particular fibre-cardinality example is supplied here to settle this exact footnote, without a priority claim.

Scholie : Le couple $TC \longleftrightarrow F$, satisfaisant à la condition de factorisation de Quillen, et satisfaisant $TC \subset W$, $F \subset \mathrm{Fib}_W$, permet déjà de développer une théorie satisfaisante des fibres W-homotopiques dans $\mathcal{M}$ – mais sans propriété d'exactitude pour les carrés W-cartésiens. Dualement, la donnée de $C \longleftrightarrow TF$, avec factorisation, et $TF \subset W$, $C \subset \mathrm{Cofib}_W$, donne une bonne théorie des cofibres W-homotopiques, mais sans propriété d'exactitude pour les carrés W-cocartésiens. La structure de Quillen faible réunit ces deux données duales l'une de l'autre, avec en plus le lien supplémentaire entre ces deux donnés, par $TC \subset C$, $TF \subset F$ (stipulé dans M'). Cette donnée assure déjà que p. 18

$$\underbrace{\mathcal{M}_{\mathrm{cf}}}_{\substack{\text{sous-catégorie pleine de } \mathcal{M} \text{ formée des objets fibrants et cofibrants à la fois}}} \qquad W_{\mathrm{cf}}^{-1} \xrightarrow{\sim} \mathcal{M}W^{-1} = \mathrm{Ho}_W$$

est une équivalence, mais non pas que le foncteur localisation [page 30]

$$\mathcal{M}_{\mathrm{cf}} \longrightarrow \mathcal{M}_{\mathrm{cf}} W_{\mathrm{cf}}^{-1}$$

est un simple passage au quotient sur les flèches, *i.e.* que si X, Y sont dans $\mathcal{M}_{\mathrm{cf}}$, alors

$$(*) \qquad \mathrm{Hom}_{\mathcal{M}}(X,Y) \longrightarrow \underbrace{\mathrm{Hom}_W(X,Y)}_{\overset{\text{déf}}{=} \mathrm{Hom}_{\mathrm{Ho}_W}(X,Y)}$$

soit surjectif. Ceci est assuré par l'axiome d'exactitude M 2 bis,

$$W = TF \circ TC.$$

Avec ce seul axiome, on n'a pas de caractérisation sympathique de la relation d'équivalence dans $\mathrm{Hom}_{\mathcal{M}}(X,Y)$ définie par la flèche $(*)$ (pour X, Y dans $\mathcal{M}_{\mathrm{cf}}$).

Commentary · Exposition [ms. 29]

Replacement controls arrows as well as objects

The passage to fibrant-cofibrant objects is the first point where the lifting axioms recover information which would be lost by merely choosing a weakly equivalent object. Grothendieck's assertion of an equivalence of localizations is correct under the weak axioms. The mechanism is worth making explicit because exactness will be needed only for the next assertion, that ordinary arrows represent all localized arrows.

Choose $q_X : QX \to X$ in TF with QX cofibrant. Given $f : X \to Y$, lift against q_Y to obtain $Qf : QX \to QY$ with $q_Y Qf = f q_X$. This lift need not be unique as an arrow. It is unique in the localization of the cofibrant objects. Indeed, for two lifts $a, b : QX \to QY$, form $P = QY \times_Y QY$. Its projections belong to TF by pullback stability. Choose a cofibrant replacement $q_P : QP \to P$ and lift (a,b) through it. The diagonal $QY \to P$ likewise lifts through q_P because QY is cofibrant. Call this lift $d : QY \to QP$. The two composites

$$QY \xrightarrow{d} QP \xrightarrow{\mathrm{pr}_j\, q_P} QY$$

are identities. Each $\mathrm{pr}_j\, q_P$ belongs to TF, so $d \in W$. After localization both projections are therefore the inverse of d, and $a = b$ there. This uniqueness proves compatibility with identities and composition. Two-out-of-three shows that a weak equivalence f gives a weak equivalence Qf. Thus Q defines an inverse, after localization, to the inclusion of the cofibrant objects.

For the second step choose $r_X : X \to RX$ in TC, with RX fibrant, when X is cofibrant. Then RX remains cofibrant. An arrow $X \to Y$ extends to $RX \to RY$ by lifting r_X against $RY \to e$. To compare two extensions, form $P = RX \amalg_X RX$. The two inclusions $RX \to P$ are in TC. Choose $P \to RP$ in TC with RP fibrant. The fold $P \to RX$ extends to $d : RP \to RX$ because RX is fibrant. If $v_0, v_1 : RX \to RP$ are the two induced maps, then $dv_0 = dv_1 = 1$, and d, v_0, v_1 are weak equivalences. The two extensions consequently agree after localization, by first extending their

common pushout map $P \to RY$ to $RP \to RY$. This gives the inverse equivalence for the inclusion of fibrant-cofibrant objects into cofibrant objects.

No equality $TC = C \cap W$ or $TF = F \cap W$ entered these two arguments. What is indispensable is the ability to compare choices inside the relevant full subcategory. This is the same distinction already emphasized in the commentary on Chapter VI, manuscript p. 87. For the usual model-category statement, see Cisinski (2019a, Theorem 2.2.15 and Corollary 2.2.18); the argument above records the weaker hypotheses actually used here.

Si on a exactitude à gauche,

$$TC = C \cap W \qquad (\Longleftrightarrow\ TC = C \cap W^{\mathrm{univ}}),$$

alors cette relation d'équivalence est celle engendrée par la relation de *Q-homotopie à droite* ([22], [23]) (impliquée par la Q-homotopie à gauche), et la catégorie quotient ainsi définie

$$\pi_{\mathrm{d}}\mathcal{M}_{\mathrm{cf}} \;=\; \pi\mathcal{M}_{\mathrm{cf}} \;\simeq\; \mathrm{Ho}_W,$$

s'envoie dans $\pi_{\mathrm{d}}\mathcal{M}_{\mathrm{c}}$,

$$\pi\mathcal{M}_{\mathrm{cf}} \longrightarrow \pi_{\mathrm{d}}\mathcal{M}_{\mathrm{c}},$$

et ce foncteur peut être interprété (sauf erreur)

Commentary · Examples [ms. 30]

Two path conventions and a nontransitive homotopy

Footnote 22 requires a distinction which the text does not explicitly make. A diagonal factorization

$$Y \xrightarrow{s} PY \xrightarrow{p=(d_0,d_1)} Y \times Y$$

may be required to have $s \in TC$ and $p \in F$, or only $s \in W$ and $p \in F$. Call these, respectively, a *designated* path object and a *broad* path object. In standard model-category terminology the first is a very good path object and the second a good path object. The raw relation associated with a fixed path object declares $f, g : X \to Y$ related when $(f, g) = pH$ for some $H : X \to PY$. Taking the union of these relations over all broad path objects is another operation; it must not be silently identified with the relation from a designated one.

Every designated path object gives a reflexive and symmetric relation, for every source. Reflexivity uses sf. For symmetry, lift s against p, with top map s and bottom map τp, where τ interchanges the two factors of Y^2. The filler $r : PY \to PY$ satisfies $pr = \tau p$, and rH reverses a homotopy. Moreover, if $Y \xrightarrow{s'} P'Y \xrightarrow{p'} Y^2$ is another designated path object, the square with vertical maps s, p' and horizontal maps s', p has a filler $PY \to P'Y$ preserving the endpoints. Interchanging the objects gives the converse comparison. Thus *one fixed designated path object and all designated path objects define the same raw relation*, without fibrancy, cofibrancy or retract-closure assumptions. Transitivity is the additional issue.

A counterexample with every object fibrant and cofibrant. The following is a dual application of the graph example of Kurz and Rosický (2005, Definition 3.1, Observation 3.3 and Example 3.6). Let $\mathcal{G}$ be the category of reflexive directed multigraphs. An object consists of sets of vertices and edges, maps $s, t : E \rightrightarrows V$, and a distinguished loop $e : V \to E$ satisfying $se = te = 1_V$. Morphisms preserve these data. This is a functor category, hence has all small limits and colimits. Let

$$L = \mathrm{Mono}(\mathcal{G}), \qquad R = L^{\square}.$$

Here monomorphisms are injective on both vertices and edges. For precision, R is defined by the literal lifting property, not by an abbreviated assertion about whether two image vertices are adjacent: in a multigraph a lifting problem specifies the target edge as well as its endpoints.

22. Il semblerait que la relation de Q-homotopie à droite est une relation d'équivalence, dès que Y [est] dans $\mathcal{M}_{\mathrm{f}}$ et sans supposer la structure de Quillen faible exacte à droite ou à gauche.

23. **NB** D'après Baues, il semblerait que sur $\mathcal{M}_{\mathrm{cf}}$, cette relation d'homotopie à droite équivaut à la relation d'homotopie à gauche, et que celle-ci ne dépend pas du cylindre choisi …

The pair (L, R) is a weak factorization system. One generating map adds a vertex with its distinguished loop to the empty graph. The other adds a directed edge between the two vertices of a discrete two-vertex reflexive graph. In a pushout the two endpoints may coincide, so the latter generator also adds a nondistinguished loop. Every subgraph inclusion is a composite of pushouts of these maps: first adjoin its missing vertices, then its missing edges. Conversely such pushouts, their composites and their retracts are monomorphisms. The finite generating graphs are finitely presentable, so the small object theorem proved earlier gives exactly $(L, L^{\square})$.

Pass to $\mathcal{M} = \mathcal{G}^{\mathrm{op}}$ and put

$$W = C = \mathrm{Mor}(\mathcal{M}), \qquad TF = \mathrm{Iso}(\mathcal{M}), \qquad TC = R^{\mathrm{op}}, \qquad F = L^{\mathrm{op}}.$$

Both (C, TF) and (TC, F) are weak factorization systems. In particular their classes contain the isomorphisms and have the required composition, pushout or pullback stability, and even retract stability. The inclusions $TC \subset C \cap W$ and $TF \subset F \cap W$ hold. Since every arrow is weak, the intrinsic classes Cof_W and Fib_W also contain every arrow. Thus all the printed weak axioms, including M″, hold.

Every object is cofibrant because C consists of all arrows. Every object is fibrant because its map to the terminal object of $\mathcal{M}$ is opposite to an inclusion of the empty graph, hence belongs to L^{op}. These observations make the example independent of any failure to replace its source or target.

Let V denote the graph with one vertex and its single distinguished loop. Let D have two vertices $0, 1$ and exactly one directed edge for each ordered pair of vertices, with the two diagonal edges distinguished. The inclusion $j : V \amalg V \to D$ belongs to L. The unique map $q : D \to V$ belongs to R: a graph map from a subgraph to D extends by sending each additional vertex to 0, and then sending each edge to the unique edge with the prescribed endpoints. This extends every lifting problem against a monomorphism. The equality $qj = \nabla_V$ therefore becomes a designated path factorization in the opposite category,

$$Y \xrightarrow{q^{\mathrm{op}}} D \xrightarrow{j^{\mathrm{op}}} Y \times Y, \qquad Y = V \quad \text{viewed in } \mathcal{M}.$$

Now let X be the reflexive graph with vertices a, b, c, distinguished loops, and four further edges

$$a \rightleftarrows b \rightleftarrows c,$$

with no edge from a to c or from c to a, again viewed as an object of $\mathcal{M}$. The three vertex maps $V \to X$ in $\mathcal{G}$ are three arrows $f_a, f_b, f_c : X \to Y$ in $\mathcal{M}$. A right homotopy through the displayed path object is precisely a graph map $D \to X$ with the specified vertex images. Such maps exist for (a, b) and (b, c), whereas none exists for (a, c). Consequently

$$f_a \sim_r f_b, \qquad f_b \sim_r f_c, \qquad f_a \not\sim_r f_c.$$

The comparison argument above shows that allowing every designated path object does not change this calculation. Raw designated right homotopy is not transitive even though every object is fibrant and cofibrant and all four lifting classes are retract closed.

This weak structure is not exact. Indeed $TF \circ TC = TC$, and the opposite of a vertex inclusion $V \to X$ is not in TC: the vertex inclusion fails the right lifting property against the map adding a vertex. Thus $TC \neq W$. There is also a useful exact variant: replace C by TC and TF by F, retaining W, TC, F. This is a perfect model structure with all arrows weak. The same path calculation still fails transitivity for the same source, which is now noncofibrant. To see the latter directly, $X \to V$ in $\mathcal{G}$ does not lift the edge-adding generator with endpoints mapped to a, c. Hence even exactness does not make the raw relation from very good paths transitive for unrestricted sources.

The broad relation for a fibrant target. Under the printed weak axioms, the relation defined by existence of a homotopy through *some* broad path object is an equivalence relation whenever Y is fibrant, with arbitrary source X. Here is the direct argument. Reflexivity uses the constant section of any designated, hence broad, path object. Symmetry uses the same broad object with its endpoints interchanged. For transitivity choose broad path objects

$$Y \xrightarrow{s_P} P \xrightarrow{(d_0, d_1)} Y^2, \qquad Y \xrightarrow{s_Q} Q \xrightarrow{(e_0, e_1)} Y^2$$

and homotopies from f to g through P and from g to h through Q. Form

$$K = P \times_Y Q \quad \text{using } d_1 \text{ and } e_0, \qquad t = (s_P, s_Q) : Y \longrightarrow K.$$

Each endpoint map d_i, e_i belongs to F, since it is the composite of a path fibration with a projection $Y^2 \to Y$, and the latter is a pullback of $Y \to e$. Each endpoint is also in W by two-out-of-three applied to its composite with the constant section. The projection $K \to P$ is the pullback of $e_0 \in W$ along $d_1 \in F \subset \mathrm{Fib}_W$, so it is in W. Its composite with t is $s_P \in W$, and hence $t \in W$.

The map $K \to Y^3$ recording the two outer endpoints and their common middle endpoint is the pullback of

$$P \times Q \longrightarrow Y^2 \times Y^2$$

along $(y_0, y_1, y_2) \mapsto (y_0, y_1, y_1, y_2)$. Products and pullbacks of F-maps are in F, so this map is in F. The projection $Y^3 \to Y^2$ retaining the outer coordinates is again a pullback of $Y \to e$. Their composite $K \to Y^2$ is therefore in F. Thus $Y \xrightarrow{t} K \to Y^2$ is a broad path object. The two given homotopies induce $X \to K$, supplying the homotopy from f to h. No exactness or retract closure has entered.

The missing implication for designated paths is now visible: this argument proves $t \in W$, but does not prove $t \in TC$. The graph example shows that the omission cannot be repaired from the weak axioms alone. In that example the broad path $Y \xrightarrow{\Delta} Y^2 \xrightarrow{1} Y^2$ makes every pair related, whereas every designated path retains the nontransitive relation just calculated. Consequently footnote 22 has a positive answer for the existential broad convention and a negative answer for the designated convention used in the replacement constructions. Its status is a question of these precise conventions, not an unresolved general homotopy theorem.

et la localisée s'explicite par un calcul de fractions à droite.

Commentary · Development (commentators') [ms. 30]

Exactness and the congruence generated by both homotopies

Grothendieck has now isolated the hypothesis which allows a weak equivalence between good objects to be inverted by an ordinary arrow. His observation admits a precise completion even before one-sided exactness identifies a preferred homotopy relation.

A chosen cylinder of X is a factorization

$$X \amalg X \xrightarrow{(j_0, j_1)} IX \xrightarrow{q} X, \qquad (j_0, j_1) \in C, \quad q \in TF.$$

A chosen path object of Y is a factorization

$$Y \xrightarrow{s} PY \xrightarrow{(p_0, p_1)} Y \times Y, \qquad s \in TC, \quad (p_0, p_1) \in F.$$

Left and right Q-homotopies are maps $IX \to Y$ and $X \to PY$ with the prescribed endpoints. We allow all such factorizations in these definitions.

A quotient description under exactness alone. [ours] Assume the weak Quillen axioms and $W = TF \circ TC$. Let $\equiv$ be the smallest congruence on $\mathcal{M}_{\mathrm{cf}}$ containing both left and right Q-homotopy. Then

$$\mathcal{M}_{\mathrm{cf}}/\!\equiv \;\simeq\; \mathcal{M}[W^{-1}].$$

In particular every morphism between fibrant-cofibrant objects in the localization is represented by an ordinary morphism.

Proof. Both kinds of homotopy become equalities after localization: for a cylinder, $qj_0 = qj_1 = 1$ and $q \in W$; for a path object, $p_0 s = p_1 s = 1$ and $s \in W$. It therefore suffices to prove that the quotient inverts every weak equivalence between fibrant-cofibrant objects.

Let $w : X \to Y$ be such a weak equivalence. Exactness gives $w = pi$ with $i : X \to Z$ in TC and $p : Z \to Y$ in TF. The intermediate object Z is cofibrant because $TC \subset C$ and X is cofibrant; it is fibrant because $TF \subset F$ and Y is fibrant. Lifting i against $X \to e$ gives $r : Z \to X$ with $ri = 1_X$. Lifting $\varnothing \to Y$ against p gives $t : Y \to Z$ with $pt = 1_Y$.

To compare ir with 1_Z, choose a path object $Z \xrightarrow{s} PZ \xrightarrow{v} Z \times Z$. The square with left edge i, right edge v, top edge si and bottom edge $(ir, 1_Z)$ commutes. The lifting axiom $TC \perp F$ supplies a right homotopy from ir to 1_Z. To compare tp with 1_Z, choose a cylinder $Z \amalg Z \xrightarrow{j} IZ \xrightarrow{q} Z$. The square with left edge j, right edge p, top edge $(tp, 1_Z)$ and bottom edge pq commutes. The lifting axiom $C \perp TF$ supplies a left homotopy from tp to 1_Z.

Consequently i and p are invertible in the quotient, with inverses r and t, and w has inverse rt. The universal property of localization now identifies the quotient with $\mathcal{M}_{\mathrm{cf}}[W_{\mathrm{cf}}^{-1}]$. The replacement argument in the preceding block identifies that category with $\mathcal{M}[W^{-1}]$. □

The congruence formulation deliberately keeps the two homotopies together. Under left exactness a left homotopy implies right homotopy: for a cofibrant source, either cylinder endpoint is in $C \cap W = TC$, so the familiar endpoint lifting square against a path fibration produces the right homotopy. Dually, right exactness converts a right homotopy into a left homotopy. Thus the proposition also proves the manuscript's description by the relation *generated* by right homotopy under left exactness, and its dual. We have checked Cisinski's model-category and derivable-category treatments; their standard statements identify a single homotopy relation under their own hypotheses. The joint-congruence formulation is supplied here for the exact weak axioms on these pages, without claiming that it is new.

Dans le cas biexacte (*i.e.* celui des véritables structures de Quillen), les deux relations de Q-homotopie dans $\mathcal{M}_{\mathrm{cf}}$ (plus généralement dans $\mathrm{Hom}(X, Y)$, si X dans $\mathcal{M}_{\mathrm{c}}$ et Y dans $\mathcal{M}_{\mathrm{f}}$) coïncident, et deviennent même particulièrement simples. (Car si $f, g : X \rightrightarrows Y$, avec X cofibrant et Y fibrant, alors $f \sim g$ peut se tester sur *n'importe quel* "objet cylindre" pour X, ou sur *n'importe quel* "objet chemins" pour Y.) [page 32]

Commentary · Exposition [ms. 31]

Why the localization has a fully faithful adjoint

The proposed adjoint is a way to recognize fibrant replacement from a universal property in the homotopy quotient. Assume left exactness, and write $\pi_{\mathrm{d}}\mathcal{M}_{\mathrm{c}}$ for the category of cofibrant objects modulo the equivalence relation generated by right Q-homotopies. Right homotopy is compatible with both compositions: precomposition is immediate, while postcomposition follows by extending a map between the constant paths across $s : Y \to PY$ using $TC \perp F$. Thus taking its generated equivalence relation really defines a category.

Choose $r_X : X \to RX$ in TC with RX fibrant. For any fibrant-cofibrant Y, restriction along r_X gives a bijection

$$\mathrm{Hom}_{\pi_{\mathrm{d}}\mathcal{M}_{\mathrm{c}}}(RX, Y) \xrightarrow{\sim} \mathrm{Hom}_{\pi_{\mathrm{d}}\mathcal{M}_{\mathrm{c}}}(X, Y).$$

Surjectivity follows by lifting r_X against $Y \to e$. For injectivity, a right homotopy between ur_X and vr_X extends across r_X by lifting against the path fibration $PY \to Y^2$, giving a right homotopy between u and v. For a chain of homotopies, choose extensions of all intermediate maps and apply this argument successively. The same proof works for chains with either orientation.

The previous block identifies the homotopy quotient on fibrant-cofibrant objects with Ho_W. Moreover its inclusion in the larger quotient is fully faithful: any relation in the larger quotient gives equality after localization, and on fibrant-cofibrant objects such equality is already the generated right-homotopy relation. The displayed bijection therefore says exactly that the localization

$$L : \pi_{\mathrm{d}}\mathcal{M}_{\mathrm{c}} \longrightarrow \mathrm{Ho}_W$$

is left adjoint to the inclusion of the fibrant-cofibrant homotopy category. The unit is represented by r_X. This proves the suggested fully faithful right adjoint without any claim that a chosen lift is unique before homotopy.

It also proves the stated calculus of fractions. Write S for the images of the arrows of W in this quotient; identities and compositions belong to S. Precomposition by $s : X \to X'$ in S is bijective on maps into any fibrant-cofibrant object, since the displayed bijection identifies these Hom sets with those in the localization. Given $f : X \to Y$ and $s : X \to X'$ in S, choose the denominator $r_Y : Y \to RY$. That bijectivity supplies a map $g : X' \to RY$ with

$$gs = r_Y f,$$

which is the common-denominator condition. For cancellation, suppose $f, g : X \to Y$ and $s : X' \to X$ in S satisfy $fs = gs$. The same bijectivity, now with target RY, gives $r_Y f = r_Y g$. Thus the denominator r_Y also supplies the cancellation condition. Every localized arrow consequently has a representative $X \to RY \leftarrow Y$, with the right-hand arrow in S; this specifies the manuscript's left-fraction convention.

Applying the whole argument to the opposite category proves the right-exact statement and the fully faithful left adjoint on the quotient of fibrant objects. The editors' changes from π_{d} to π_{g} on this page are therefore mathematically required.

For the cofibrant sources and fibrant targets considered here, the biexact case gives a single homotopy relation, computable using any cylinder or path object (Cisinski, 2019a, Lemma 2.2.12). Footnote 22 omits the cofibrancy assumption on the source and leaves the path convention implicit. The block *Two path conventions and a nontransitive homotopy* resolves that distinction. For designated TC–F paths, raw right homotopy can fail transitivity even when every object is fibrant and cofibrant if the weak structure is not exact; it can also fail in a perfect structure for a noncofibrant source. Both failures come from the graph example of Kurz and Rosický (2005, Example 3.6). In contrast, the existential relation obtained by allowing all W–F path objects is an equivalence relation for a fibrant target and an arbitrary source, by direct concatenation. The generated relation used in the adjoint argument above is therefore a deliberate and sufficient formulation.

Dans le cas où la structure de Quillen faible est exacte à gauche, *i.e.* où la relation d'équivalence pertinente dans $\mathrm{Fl}\,\mathcal{M}_{\mathrm{cf}}$ est la Q-homotopie à droite, alors l'axiome d'exactitude est vérifié pour les carrés W-cartésiens, mais je doute qu'il en soit de même pour les carrés W-cocartésiens ([24]). (Si on ne fait une hypothèse supplémentaire, p. ex. l'exactitude à droite de la structure de Quillen.) Si on n'a que l'exactitude (mais ni à gauche ni à droite), il semble qu'on ne peut en conclure l'exactitude ni des carrés W-cartésiens, ni des carrés W-cocartésiens, donc pas celle des suites de cosuspension (loop sequences), ni des suites de suspension. On pourrait donc penser que la condition d'exactitude, à elle seule, ne sert pas à grand chose pour [page 33] le formalisme homotopique dans les catégories de fractions Ho_W etc. Mais on a pourtant ceci :

soit $\Psi = \begin{array}{ccc} & & 1 \\ 0 & \nearrow & \\ & \searrow & \\ & & 2 \end{array}$, et supposons que $(\mathcal{M}, W)$ *et* $(\mathcal{M}(\Psi), W(\Psi))$ [où pour toute petite catégorie I, $\mathcal{M}(I)$ désigne la catégorie des préfaisceaux sur I à valeurs dans $\mathcal{M}$, et $W(I)$ est la partie de $\mathrm{Fl}(\mathcal{M}(I))$ formée des morphismes de préfaisceaux p. 20 qui sont dans W "argument par argument"] admettent une structure de Quillen faible exacte. Alors dans $\mathcal{M}$ les carrés W-cartésiens sont W-exactes, donc on a dans $\mathcal{M}$ des suites exactes longues de cosuspension (exact loop sequences) ([25]). (L'hypothèse sur $(\mathcal{M}(\Psi), W(\Psi))$ sert uniquement à assurer que toute flèche de $\mathrm{Ho}_{W(\Psi)} = \mathcal{M}(\Psi)W(\Psi)^{-1}$ est isomorphe à une flèche provenant d'une flèche de $\mathcal{M}(\Psi)$ lui-même. Mais c'est là une propriété apparemment très délicate, et je ne connais d'autre façon de l'obtenir que via l'existence d'une structure de Quillen faible exacte.) Dualement, si $(\mathcal{M}, W)$ et $(\mathcal{M}(\Phi), W(\Phi))$ admettent des structures de Quillen faibles exactes, alors les carrés W-cocartésiens dans $\mathcal{M}$ sont W-exacts, et on trouve (si $\mathcal{M}$ est ponctué) des suites exactes longues de suspension.

24. Il semble pourtant que c'est le cas, d'après Baues, cf. annotation marginale correspondante page 30.
25. il semble que je me suis canulé ici, et je doute que le résultat évoqué soit exact.

Commentary · Development (commentators') [ms. 32]

Exactness permits completion of the trivial classes

Grothendieck's hesitation about exactness can be resolved by changing the designated trivial classes while keeping the weak equivalences, cofibrations and fibrations. This is a different operation from asserting that the original designated classes were already complete. It is therefore compatible with the counterexample to footnote 20.

Completion under exactness. [ours] Suppose (C, TC, F, TF) is an exact weak Quillen structure. Then

$$\big(C,\ C\cap W,\ F,\ F\cap W\big)$$

is a biexact Quillen structure, with the same C, F, W. No retract-closure hypothesis on these classes is needed for this assertion. If all four original lifting classes were closed, the completion makes no change.

Proof. The only new lifting problems involve $C\cap W$ against F, and C against $F\cap W$. Let $j\in C\cap W$. Exactness gives $j=qi$ with $i\in TC$ and $q\in TF$. Since $j\in C$ and $q\in TF$, the lifting axiom exhibits j as a retract of i in the arrow category. Lifting properties are preserved by retracts, so j has the left lifting property against every map in F. Dually, if $p\in F\cap W$, factor $p=qi$ with $i\in TC$ and $q\in TF$. Lifting i against p exhibits p as a retract of q, so it has the right lifting property against C.

The original factorizations still serve, because $TC\subset C\cap W$ and $TF\subset F\cap W$. The classes C and F have not changed. The classes $C\cap W$ and $F\cap W$ have the required pushout or pullback stability by M″ and the universal-equivalence criterion of manuscript pp. 10–11; composition and identities follow from two-out-of-three. Thus every axiom holds, and both exactness equalities hold by definition. When TC and TF are retract closed, the two retract arguments also show $C\cap W\subset TC$ and $F\cap W\subset TF$, giving equality with the original classes. □

This completion is a possibly nonclosed model structure in Quillen's original terminology. It suffices for the ordinary homotopy theory of cofibrant and fibrant objects: the standard endpoint arguments now use $C\cap W\perp F$ and $C\perp F\cap W$. In particular both homotopies classify the localized maps from a cofibrant object to a fibrant object, and any good chosen cylinder or path object from the original weak structure remains available. The existence of different designated classes therefore does not obstruct the usual homotopy calculation once exactness holds. This also explains the applicability of the nonclosed Quillen case in Cisinski (2010, Example 5.2).

We checked the quoted Quillen and derivable-category frameworks and did not locate this completion stated using the exact four-class axioms of the manuscript. The proof is a direct application of the standard retract argument; its purpose is to settle the hypotheses on these pages, not to claim a new model-category theorem.

[page 34]

Ceci montre que si, pour une catégorie de modèles $(\mathcal{M}, W)$ donnée, on s'intéresse à "faire de l'algèbre homotopique" pour tous les couples $(\mathcal{M}(I), W(I))$ à la fois, avec I dans Cat, il suffit (si on veut avoir une bonne théorie des fibres et cofibres W-homotopiques dans ces catégories, y inclus la propriété de W-exactitude pour les carrés W-cartésiens et pour les carrés W-cocartésiens) de disposer pour chaque $(\mathcal{M}(I), W(I))$ d'une structure de Quillen faible exacte sans plus.

Commentary · Exposition [ms. 33]

Exactness of squares after completing the classes

Grothendieck introduces $\mathcal{M}(\Psi)$ to recover relations among maps while representatives remain available. Exactness in that diagram category indeed says that every localized arrow is isomorphic, in the arrow category, to an actual natural transformation: replace its source and target by fibrant-cofibrant objects and apply the quotient description above. His footnote correctly warns that this representability argument has not, by itself, established compatibility with the chosen homotopy pullback.

There is a more direct repair. The completion just proved turns an exact weak structure on $\mathcal{M}$ into a possibly nonclosed proper Quillen structure with the same W, C, F. Both homotopy-cartesian and homotopy-cocartesian exactness follow from that structure. For this conclusion the additional exact structure on $\mathcal{M}(\Psi)$ is unnecessary. Thus the asserted conclusion on p. 33 is valid, while the proposed route through arrow representability leaves a step unproved.

Here is the local lifting calculation behind the cartesian assertion. After taking the usual fibrant representatives, write the homotopy pullback as the ordinary pullback $P = E \times_S Y$, where $p : E \to S$ is a fibration and E, Y, S are fibrant. Let T be cofibrant. Suppose maps $a : T \to E$ and $b : T \to Y$ have homotopic composites to S. Represent the homotopy by $H : IT \to S$, with endpoints pa and qb. The endpoint inclusion $j_0 : T \to IT$ is in $C \cap W$: it is a cofibration because T is cofibrant, and a weak equivalence because the cylinder projection is one. The completed lifting property against p gives a lift $\widetilde{H} : IT \to E$. Its other endpoint $a' = \widetilde{H} j_1$ is homotopic to a and satisfies $pa' = qb$. The pair (a', b) therefore gives a map $T \to P$. This proves the required surjectivity onto pairs of homotopy classes with equal composites. The dual argument gives cocartesian exactness and the corresponding suspension sequences in the pointed case.

The geometry of the calculation is visible in the cospan $* \to S^1 \leftarrow *$. Its homotopy pullback is ΩS^1, not the one-point strict pullback. Lifting a based loop to $\mathbb{R}$ with initial point 0 assigns its endpoint in $\mathbb{Z}$; two loops are homotopic relative endpoints precisely when those integers agree. Hence $\pi_0 \Omega S^1 = \mathbb{Z}$. The path between the two composites is part of the homotopy-pullback data. The lifting argument preserves that datum while making the square strictly commute. This is the compatibility that mere representability of an arrow does not explain.

Ceci nous montre donc l'intérêt de développer des critères, pour une $(\mathcal{M}, W)$, assurant qu'il en est bien ainsi. À ce sujet, je note que je ne sais comment vérifier l'exactitude d'une structure de Quillen *que si* je dispose de l'exactitude à gauche, ou à droite. C'est dire que je dois dégager en fait des conditions sur $(\mathcal{M}, W)$ qui assurent (disons) que les $(\mathcal{M}(I), W(I))$ admettent des structures de Quillen faibles exactes à gauche.

Les structures de Quillen faibles pour les $(\mathcal{M}(I), W(I))$ seront déduites d'une structure de Quillen faible pour $(\mathcal{M}, W)$, de la façon suivante : elles seront toutes *"closes à droite", i.e.* [page 35]

$$F(I) \;=\; (TC(I))_*, \qquad TF(I) \;=\; (C(I))_*, \tag{1}$$

en particulier (pour $I = e$)

$$F \;=\; (TC)_*, \qquad TF \;=\; C_*,$$

ce qui implique déjà (puisque $C \subset \mathrm{Cof}_W$, $TC \subset W^{\mathrm{univ}}$)

$$(\mathrm{Cof}_W)_* \;\subset\; W, \qquad (W^{\mathrm{univ}})_* \;\subset\; \mathrm{Fib}_W \tag{2}$$

(d'où $(\mathrm{Cof}_W)_* \subset W_{\mathrm{univ}}$). En vertu de (1), pour définir les structures de Quillen faibles pour les $(\mathcal{M}(I), W(I))$, il suffit de définir $C(I)$, $TC(I)$, et même, comme on veut l'exactitude à gauche, *i.e.*

$$TC(I) \;=\; C(I) \cap W(I) \tag{3}$$

(en particulier

$$TC \;=\; C \cap W \quad), \tag{4}$$

p. 21

il reste à définir C. On définira $C(I)$ "argument par argument", *i.e.* pour $f \in \mathrm{Fl}(\mathcal{M}(I))$

$$f \in C(I) \qquad \Longleftrightarrow \qquad \alpha_s^*(f) \in C \;\text{ pour tout } s \in \mathrm{Ob}\, I, \tag{5}$$

où

$$\alpha_s : e \longrightarrow I \qquad \texttt{[est]} \text{ défini par } \alpha_s(e) = s.$$

Il en résulte d'ailleurs aussitôt, par (3),

$$f \in TC(I) \qquad \Longleftrightarrow \qquad \alpha_s^*(f) \in TC \;\text{ pour tout } s \in \mathrm{Ob}\, I. \tag{6}$$

On suppose donc que $(\mathcal{M}, W)$ admet une structure de Quillen faible exacte à gauche et close à droite (C, TC, F, TF), définie en termes de

[page 36]

$$C \;\subset\; \mathrm{Fl}(\mathcal{M}),$$

par

$$TC \;=\; C \cap W, \qquad F \;=\; (TC)_*, \qquad TF = C_*.$$

Pour que cela donne bel et bien une structure de Quillen faible (forcément exacte à gauche et close à droite), il faut simplement vérifier les conditions suivantes.

Commentary · Exposition [ms. 35]

The injective choice of diagram structure

Grothendieck now makes a choice which determines the variance of the whole construction. Cofibrations and weak equivalences will be tested at each object of the indexing category. Fibrations will be characterized by lifting against these objectwise classes. In modern terminology this is the injective choice. The asymmetry is productive: every restriction of diagrams preserves the classes specified objectwise, so its right adjoint becomes a candidate for a right Quillen functor.

Keep the variance explicit: $\mathcal{M}(I) = \mathrm{Fun}(I^{\mathrm{op}}, \mathcal{M})$. If $C(I)$ is the objectwise class associated with C, then

$$TC(I) = C(I) \cap W(I) = (C \cap W)(I)$$

is an identity of classes, not an existence theorem. Once $F(I) = TC(I)_*$ and $TF(I) = C(I)_*$ are defined, lifting is automatic and the right classes have their required composition and pullback stability. Objectwise pushouts show the stability of $C(I)$; the corresponding statement for $TC(I)$ uses the universal weak-equivalence property already obtained in the base category.

The remaining two tasks have different characters. The inclusions $TF(I) \subset W(I)$ and $F(I) \subset \mathrm{Fib}_{W(I)}$ can be checked by evaluation and its adjoints; pp. 37–39 give that argument. Factorization in the diagram category requires a construction of coherent fillers and cannot be inferred merely by factoring every component. Even functorial componentwise factorizations do not make both lifting classes objectwise. The walking-arrow example below shows the distinction in the smallest nontrivial indexing category.

ⓘ Factorisation pour $(C, TF = C_*)$ et $(TC = C \cap W, F = (TC)_*)$ – on reviendra sur ce point.

ⓘⓘ Stabilité de C par composition et cochangement de base, et C contient les isomorphismes (d'où résultera la stabilité similaire de $TC = C \cap W$, compte tenu que $C \subset \mathrm{Cof}_W$) (NB Les stabilités idoines pour F, TF sont triviales par définition $F = (TC)_*$, $TF = C_*$.)

ⓘⓘⓘ $C \subset \mathrm{Cof}_W$, $\underbrace{C_*}_{=TF} \subset W$, $(C \cap W)_* \subset \mathrm{Fib}_W$.

Pour vérifier, de même, que $(C(I), TC(I), F(I), TF(I))$ soit une structure de Quillen faible pour $W(I)$, il faut vérifier les conditions similaires à ⓘⓘⓘ . Or (*ii*) pour $C(I)$ résulte aussitôt de la condition (*ii*) pour C. Il reste à examiner (*iii*) et (*i*).

Les inclusions de (*iii*).

L'inclusion p. 22 [page 37]

$$C \;\subset\; \mathrm{Cof}_W$$

implique que toute $f \in C(I)$ est dans Cof_W argument par argument. Cela implique que f est dans $\mathrm{Cof}_{W(I)}$, comme on voit aussitôt sur la définition – je l'explicite en le

Lemme 1 : *Soit $f : X_\bullet \longrightarrow Y_\bullet$ une flèche de $\mathcal{M}(I)$. Pour que f soit dans* $\mathrm{Cof}_{W(I)}$ (resp. *dans* $\mathrm{Fib}_{W(I)}$), *il* suffit *que pour tout s dans* $\mathrm{Ob}\, I$, $\alpha_s^*(f)$ *soit dans* Cof_W (resp. *dans* Fib_W). *Itou (pour mémoire) pour une condition pour que $f \in W(I)$ – là il faut et il suffit que $\alpha_s^*(f) \in W \;\forall\, s \in \mathrm{Ob}\, I$.*

Nous allons appliquer ce même lemme pour établir les inclusions

$$C(I)_* \;\subset\; W(I), \qquad (C(I) \cap W(I))_* \;\subset\; \mathrm{Fib}_{W(I)}.$$

Donc il suffit de voir que

$$\begin{aligned} \alpha_s^*(C(I)_*) \;&\subset\; C_* && (\subset\; W) \\ \alpha_s^*(\underbrace{(C(I) \cap W(I))}_{(C \cap W)(I)}{}_*) \;&\subset\; (C \cap W)_* && (\subset\; \mathrm{Fib}_W), \end{aligned}$$

et plus généralement

$$\alpha_s^*(\Phi(I)_*) \ \subset \ \Phi_* \tag{7}$$

pour toute (?) partie Φ de $\mathrm{Fl}(\mathcal{M})$, définissant donc $\Phi(I) \subset \mathrm{Fl}(\mathcal{M}(I))$ terme à terme.

En explicitant la chose, on trouve la condition [page 38]

$$\alpha_{s\,!}(\Phi) \subset \Phi(I) \qquad \text{pour tout } s \in \mathrm{Ob}\, I,$$

pour que ça marche, *i.e.* on veut que

$$i \in \Phi \qquad \Longrightarrow \qquad \alpha_{s\,!}(i) \in \Phi(I), \quad \textit{i.e.} \ \ \alpha_t^*(\alpha_{s\,!}(i)) \in \Phi \ \ \forall\, t \in \mathrm{Ob}\, I.$$

Or le foncteur $\alpha_t^*\alpha_{s\,!}$ s'explicite comme

$$A \longmapsto \underbrace{\mathrm{Hom}_I(t,s) \times A}_{\substack{\text{somme de } \mathrm{Hom}_I(t,s) \\ \text{copies de } A \text{ dans } \mathcal{M}}},$$

donc il faut supposer Φ *stable par sommes directes* (du type envisagé $\mathrm{Hom}_I(t,s) \times A$). C'est bien le cas pour $\Phi = C$ et $\Phi = C \cap W$ et pour des sommes directes *finies,* grâce à (*ii*). On trouve donc le

p. 23

Lemme 2.

a) *Soit I dans* Cat *telle que les sommes directes de type* $\mathrm{Hom}_I(t,s)$ *existent dans* $\mathcal{M}$. *(P. ex. on suppose que I est* finie, *plus généralement que les* $\mathrm{Hom}_I(t,s)$ *sont des ensembles finis ; ou que les "petites" sommes directes existent dans* $\mathcal{M}$.*) Soit* Φ *une partie de* $\mathrm{Fl}(\mathcal{M})$, *stable par ce type de sommes directes, et soit* $\Phi(I) \subset \mathrm{Fl}(\mathcal{M}(I))$ *la partie correspondante. Alors pour tout* $s \in \mathrm{Ob}\, I$, *on a*

[page 39]

$$\alpha_s^*(\Phi(I)_*) \ \subset \ \Phi_*.$$

b) *Supposons que les* $\mathrm{Hom}_I(t,s)$ *soient finis (p. ex. I finie). Alors l'hypothèse de* a) *s'applique pour* $\Phi = C$ *et pour* $\Phi = C \cap W$, *donc la condition* (iii) *p.* 36 *est satisfaite pour la structure* $(W(I), C(I), TC(I), F(I), TF(I))$ *dans* $\mathcal{M}(I)$. *Même conclusion sans hypothèse de finitude sur les* $\mathrm{Hom}_I(t,s)$, *quand on suppose* $\mathcal{M}$ *stable par "petites" sommes directes, et C et W stables également par de telles sommes directes.*

Commentary · Exposition [ms. 38]

Evaluation transports the lifting problem

The copower formula is the essential calculation in the two lemmas. Let s be an object of I. The left adjoint to evaluation at s is

$$(\alpha_{s!}A)_t = \coprod_{\mathrm{Hom}_I(t,s)} A.$$

For an arrow $t' \to t$, precomposition sends $\mathrm{Hom}_I(t,s)$ to $\mathrm{Hom}_I(t',s)$ and defines the presheaf restriction map. A natural transformation $\alpha_{s!}A \to X$ is uniquely determined by the map from the summand indexed by 1_s to X_s; all other summands are obtained by restriction. This proves the adjunction and fixes the direction of the Hom set.

Suppose Φ is stable under the copowers appearing in this formula. Then $\alpha_{s!}(i) \in \Phi(I)$ for every $i \in \Phi$. For $p \in \Phi(I)_*$, a lifting square from i to p_s transposes to a square from $\alpha_{s!}i$ to p. Its diagonal transposes back to the required lift. Hence

$$\alpha_s^*(\Phi(I)_*) \subset \Phi_*.$$

The statement on p. 37 for an arbitrary class, accompanied by a question mark, therefore needs exactly the additional closure used in Lemma 2. We are not assuming that evaluation itself preserves right orthogonals without an adjoint test.

Finite copowers require no new hypothesis for C or TC. For maps $i : A \to B$ and $j : A' \to B'$, the coproduct map factors as

$$A \amalg A' \longrightarrow B \amalg A' \longrightarrow B \amalg B',$$

where each factor is a pushout of one of the original maps. The empty copower is an identity on the initial object. Induction proves the finite statement. For arbitrary copowers one must either assume their stability or obtain it from transfinite composition by adjoining the summands in a well-order. The required colimits must exist.

Finally, finite limits and colimits of presheaves are computed objectwise. A double pushout diagram testing a $W(I)$-cofibration evaluates to the corresponding test in $\mathcal{M}$, and an objectwise weak equivalence remains one after all these tests. This proves Lemma 1 and its dual. Combining it with the lifting argument proves all the inclusions on p. 36 under the finite-Hom hypothesis, while deliberately leaving factorization for the next stage.

NB Vu le scholie plus haut, il est parfaitement raisonnable de se borner au besoin aux catégories I *finies* – vu que la catégorie de ces I est stable par les produits $I \longmapsto I \times \Psi$, $I \longmapsto I \times \Phi$.

Il reste, pour être heureux, à vérifier la condition de factorisation ⓘ pour (C, TF), (TC, F), mais aussi et surtout pour les $(C(I), TF(I), TC(I), F(I))$. C'est dire que de partir même d'une structure de Quillen close (pays de cocagne) ne nous avance guère à lui tout seul, faute de [page 40] savoir que l'axiome de factorisation se conserve, en passant de $(\mathcal{M}, W, \ldots)$ à $(\mathcal{M}(I), W(I), \ldots)$.

Commentary · Examples [ms. 39]

A complete calculation for the walking arrow

The formulas become especially transparent when $I = [1]$, with its arrow $0 \to 1$. A presheaf is a map $X_1 \to X_0$. Let Φ contain identities and be stable under finite coproducts, and put $R = \Phi_*$. Write $x : X_1 \to X_0$ and $y : Y_1 \to Y_0$ for the structural maps. For a natural transformation $p : X \to Y$, consider the matching map

$$m_p : X_1 \longrightarrow Y_1 \times_{Y_0} X_0.$$

Then p has the right lifting property against every objectwise Φ-map if and only if

$$p_0 : X_0 \to Y_0 \ \in R, \qquad m_p \in R.$$

To prove sufficiency, take a square from an objectwise Φ-map $A \to B$ to p. First lift its component at 0 against p_0, obtaining $B_0 \to X_0$. The component at 1, together with this already chosen map composed with $B_1 \to B_0$, gives a lifting square against m_p. A lift provides $B_1 \to X_1$ and enforces precisely the naturality relation. Thus the two component lifts fit together.

For necessity, evaluation at 0 and its left adjoint show $p_0 \in R$. To test m_p against $i : A \to B$ in Φ, write a square as maps $a : A \to X_1$, $b_1 : B \to Y_1$, and $b_0 : B \to X_0$ with

$$p_1 a = b_1 i, \qquad xa = b_0 i, \qquad p_0 b_0 = y b_1.$$

Use the map of arrow diagrams

$$(A \xrightarrow{i} B) \longrightarrow (B \xrightarrow{1} B),$$

whose components are i at 1 and 1_B at 0. This is objectwise in Φ. A lift of its induced square against p is exactly a solution to the original square against m_p. This proves necessity.

Apply the calculation in sets with Φ the injections and R the surjections, assuming choice. Let $E_1 = \{a\}$, $E_0 = \{0, 1\}$, and let $E_1 \to E_0$ send a to 0. The transformation from E to the terminal arrow diagram is surjective at both objects. Its matching map is the non-surjective map $\{a\} \to \{0, 1\}$, so it is not in $\Phi(I)_*$. Explicitly, a proposed lift choosing the element 1 at vertex 0 cannot be extended to vertex 1. This is a failure of naturality, despite the existence of lifts at each object separately.

For the injective model structure, taking $\Phi = C$ gives the characterization of trivial fibrations, and taking $\Phi = TC$ gives the characterization of fibrations. It follows in particular that an injectively fibrant arrow has fibrant target and a fibration as its structural arrow. The general admissible-edge result later in the manuscript is an extension of this relative lifting calculation, rather than a consequence of pointwise fibrancy alone.

C'est ici que le théorème de factorisation du no. 1 doit s'avérer providentiel. Mais pour pouvoir l'appliquer aux couples $(C(I), C(I)_*)$, $(TC(I), TC(I)_*)$, il faut (en plus de l'accessibilité de $\mathcal{M}$, ce qui est une condition fort anodine) des conditions de stabilité très fortes pour $C(I)$, $TC(I)$ ([26]). À vrai dire, il reste la stabilité de C et de $C \cap W$ par limites inductives ordinales (ce qui impliquera la même stabilité pour les $C(I)$, $(C \cap W)(I) = C(I) \cap W(I)$).

À dire vrai, je vois peu de chances de trouver une structure de Quillen faible (C, TC, F, TF) associé à W, et satisfaisant toutes les conditions dites, y compris celle de stabilité de C et de $C \cap W$ par $\varinjlim$ ordinales, sans supposer que W elle-même ne soit déjà stable par (petites) limites inductives filtrantes.

[page 41]

On peut songer à utiliser une factorisation *fonctorielle* des flèches dans $\mathcal{M}$ en

$$\begin{aligned} f = pi \quad \text{avec} \quad & i \in TC, \quad p \in F \\ \text{ou} \quad & i \in C, \quad\ \ p \in TF, \end{aligned}$$

Commentary · Later developments [ms. 40]

The factorization problem remains a coherence problem

The final paragraph should be read as a choice of a sufficient strategy, not as a necessity theorem about weak equivalences. Transfinite closure of cofibrations and trivial cofibrations is part of the small-object method; closure of every weak equivalence under every filtered colimit is a convenient, stronger condition from which Grothendieck hopes to obtain it. Nothing on this page proves that such closure of W is necessary for diagram model structures.

The later injective existence theorem in the combinatorial setting answers the construction problem with explicit generation hypotheses; its precise application belongs to the discussion of manuscript pp. 42–44. There is also a different route through weaker diagram-compatible structures: Cisinski (2010, Theorem 6.22) proves stability under presheaf categories for homotopically complete model categories in his sense; the theorem also covers homotopically complete and cocomplete weak model categories. These are two ways to obtain the coherence which the walking-arrow calculation detects. Neither licenses treating the pointwise right class as the required right lifting class.

p. 24

pour déduire une factorisation similaire pour les flèches f de $\mathcal{M}(I)$, en

$$\begin{aligned} f = pi \quad \text{avec} \quad & i \in TC(I), \quad p \in F(I) \\ \text{ou} \quad & i \in C(I), \quad\ \ p \in TF(I), \end{aligned}$$

où $C(I)$, $TC(I)$, $F(I)$, $TF(I)$ sont ici définis via C, TC, F, TF "argument par argument". Mais l'ennui, c'est que en procédant de cette façon naïve, on n'aura plus nécessairement $C(I) \longleftrightarrow TF(I)$, $TC(I) \longleftrightarrow F(I)$. Il faut considérablement rapetisser $TF(I)$ et $F(I)$, pour avoir une propriété RLP par rapport à $C(I)$ resp. $TC(I)$.

Donc je ne vois guère d'autre moyen de s'en tirer, dans ce contexte général, qu'en supposant la stabilité de W par $\varinjlim$ filtrantes (ce qui n'est après tout pas très méchant).

[page 42]

Commentary · Exposition [ms. 41]

Natural factorizations and natural fillers

26. Plus les *petits* systèmes de générateurs pour C, TC.

Grothendieck has reached the obstruction which makes a theory of diagrams more than a repetition of the theory of objects. A functorial factorization in $\mathcal{M}$ does produce a factorization of every natural transformation. Its middle objects and their transition maps fit together because the original factorization is functorial on the arrow category. But a choice of a filler for each component of a lifting problem need not commute with the transition maps. The missing datum is a compatible family of fillers, and the factorization functor supplies no such family.

The walking-arrow calculation in the commentary at manuscript pp. 38–39 makes this failure completely explicit. For diagrams $X_1 \to X_0$ and $Y_1 \to Y_0$, right lifting against all objectwise maps in a left class L requires both

$$X_0 \longrightarrow Y_0 \in R, \qquad X_1 \longrightarrow Y_1 \times_{Y_0} X_0 \in R, \qquad R = L_*.$$

The second condition remembers the compatibility of the lift with the arrow. Requiring only $X_1 \to Y_1 \in R$ forgets it. This is the first matching-object condition of the later Reedy formalism; the general condition appears in Hovey (1999a, Definition 5.2.2 and Theorem 5.2.5).

There are consequently two different ways to organize the model structure of a diagram category. In the injective structure the cofibrations and weak equivalences are objectwise, and fibrations are defined by a global right lifting property. In the projective structure the fibrations and weak equivalences are objectwise, and the cofibrations carry the compatibility condition. The manuscript is pursuing the injective structure. Its decision to keep $C(I)$ and $TC(I)$ objectwise therefore forces the replacement of the naive classes of fibrations by the smaller orthogonal classes $(TC(I))_*$ and $C(I)_*$.

This choice has a purpose beyond obtaining factorizations. Restriction along any functor preserves the two objectwise left classes. Its right adjoint will therefore preserve the two right classes, which is exactly the input needed to construct homotopy right Kan extensions. Thus the apparent asymmetry of the construction already prepares the three variances of the next section.

Bon gré, mal gré, on revient à la situation envisagée dans le paragraphe 2. On va réénoncer l'essentiel de ce qui a été pressenti alors :

Théorème 2 (encore un peu conjectural). *Soit $(\mathcal{M}, W)$ une catégorie de modèles, avec W (comme toujours) faiblement saturée, mais de plus on suppose $\mathcal{M}$ stable par petites $\varinjlim$ et par $\varprojlim$ finies, et W stable par $\varinjlim$ filtrantes, enfin $\mathcal{M}$ accessible. Considérons les conditions suivantes :*

a) *Il existe une structure de Quillen faible pour W, exacte à gauche, close à droite, (C, TC, F, TF).*

a′) *Comme* a)*, mais avec de plus C, TC clos à gauche (*i.e. *on a une structure de Quillen faible close), et C, TC de la forme $\widetilde{C_0}$, $\widetilde{TC_0}$, où C_0 et TC_0 sont petits.*

a″) *Il existe $C_0 \subset \mathrm{Cof}_W$, $TC_0 \subset W^{\mathrm{univ}}$, parties petites, telles que $C_{0*} \subset W$, $(TC_0)_* \subset \mathrm{Fib}_W$.*

b) *On a*

$$(\mathrm{Cof}_W)_* \ \subset \ W_{\mathrm{univ}}, \qquad (W^{\mathrm{univ}})_* \ \subset \ \mathrm{Fib}_W$$

(d'où résulte, Cof_W et W^{univ} étant clos à gauche, que

$$(W_{\mathrm{univ}})^* \subset \mathrm{Cof}_W, \qquad (\mathrm{Fib}_W)^* \subset W^{\mathrm{univ}} \qquad).$$

[page 43]

Ces conditions impliquent que pour toute I dans Cat*, il existe une structure de Quillen faible exacte à gauche et close pour $W(I)$ dans $\mathcal{M}(I)$. Une telle structure se définit, en termes d'une structure similaire C, $TC = C \cap W$, $F = (TC)_*$, $TF = C_*$ pour W, par*

$$C(I) \ = \ \Big\{ f \in \mathrm{Fl}(\mathcal{M}(I)) \ \Big| \ \alpha_s^*(f) \in C \ \ \forall\, s \in \mathrm{Ob}I \Big\},$$

puis

$$\begin{aligned} TC(I) \ &= \ C(I) \cap W(I) \ = \ \Big\{ f \in \mathrm{Fl}(\mathcal{M}(I)) \ \Big| \ \alpha_s^*(f) \in TC \ \ \forall\, s \in \mathrm{Ob}I \Big\} \\ F(I) \ &= \ (TC(I))_* \\ TF(I) \ &= \ C(I)_* \,. \end{aligned}$$

p. 25

Corollaire-Scholie. *Ces conditions impliquent que pour tout I dans* Cat, $(\mathcal{M}(I), W(I))$ *donne lieu à une bonne théorie des fibres et cofibres $W(I)$-homotopiques, avec carrés $W(I)$-cartésiens $W(I)$-exacts, et carrés $W(I)$-cocartésiens $W(I)$-exacts – donc avec des suites* exactes *longues de cosuspension et de suspension, dans le cas où $\mathcal{M}$, donc aussi $\mathcal{M}(I)$, est une catégorie avec objet neutre.*

[page 44]

Commentary · Later developments [ms. 43]

The injective existence theorem and its precise hypothesis

Grothendieck wants the factorization theorem to work uniformly after adding any small indexing category. One part of this proposal is now a standard existence theorem: a combinatorial model category has injective and projective model structures on each small diagram category. In the terminology of the present pages, a closed structure exact on the left is already an ordinary closed model structure, and condition a' supplies the two sets of generators. Since an accessible cocomplete category is locally presentable, a' places us in the combinatorial situation.

For the injective construction, the set of generators on the diagram category is the substantive point. One cannot simply use the free diagrams on the generators at each object: those give the projective left class. A theorem of Makkai and Rosický (2014a, Corollary 3.4, author preprint of 21 November 2013) instead says that the pointwise left class associated with a set-generated, retract-closed cellular structure on a locally presentable category is again set-generated. Apply it separately to C and TC. The two resulting small-object factorizations have left classes $C(I)$ and $TC(I)$ and right classes $C(I)_*$ and $(TC(I))_*$.

Here is why the compatibility of these two factorizations survives. Evaluation takes either right class into its corresponding right class in $\mathcal{M}$: its left adjoint is the copower by the representable presheaf, and copowers preserve C and TC. Consequently $C(I)_* \subset W(I)$, while an element of $(TC(I))_*$ which belongs to $W(I)$ is objectwise in TF. To obtain the reverse lifting assertion without confusing componentwise and natural fillers, factor such a map f using $(C(I), C(I)_*)$, say $f = pi$. The maps p and f are weak equivalences, so $i \in C(I) \cap W(I) = TC(I)$. The lifting property of f against i exhibits f as a retract of p. Hence $f \in C(I)_*$. This proves the second trivial-class equality, and the model axioms follow.

Properness also passes to these structures. Pushouts and pullbacks are objectwise; injective cofibrations are objectwise cofibrations, and injective fibrations are objectwise fibrations by the preceding evaluation argument. The base properness axioms therefore apply at every object. These conclusions are recorded in Barwick (2007, Theorems 1.17 and 1.19, Propositions 1.21–1.22); the numbering here is that of the 2007 preprint.

This settles the diagram construction under a'. It does not establish every proposed recognition implication involving a, a'' or b. Closure under filtered colimits alone is not the solution-set condition in a model-structure recognition theorem. The standard Smith theorem requires an accessible, accessibly embedded class of weak equivalences in the arrow category, as well as a specified set of generating cofibrations; see Barwick (2007, Proposition 1.7). No assertion that the whole conjectural theorem has been proved is justified by citing the injective existence theorem. Conversely, once a combinatorial model structure is given, its diagram structures do not require preservation of *every* filtered colimit by the weak equivalences. That stronger hypothesis belongs to Grothendieck's proposed route to recognition.

Je m'occuperai de la démonstration du théorème précédent, ainsi que du théorème de factorisation du paragraphe 1, quand j'aurai mes notes sur les catégories et foncteurs accessibles et filtrations cardinales. En attendant, j'ai envie déjà d'expliciter un peu plus le formalisme auquel on parvient moyennant les hypothèses faites ci-dessus. (Je suis à peu près sûr tout au moins que la condition a'') suffit à impliquer toutes les autres. Et c'est bien sous la forme a'') que ces conditions vont se vérifier en pratique, je présume, notamment dans le cas où $\mathcal{M} =$ Cat.)

Commentary · Exposition [ms. 44]

The variance is fixed by presheaves

Grothendieck now turns the diagram model structures into operations. Throughout these pages

$$\mathcal{M}(I) = \mathrm{Fun}(I^{\mathrm{op}}, \mathcal{M}), \qquad u : I' \longrightarrow I.$$

This convention determines the comma categories in both pointwise Kan formulas. If $X' : (I')^{\mathrm{op}} \to \mathcal{M}$, then

$$(u_! X')(i) = \operatorname*{colim}_{(i \downarrow u)^{\mathrm{op}}} X'(i'),$$
$$(u_* X')(i) = \lim_{(u \downarrow i)^{\mathrm{op}}} X'(i').$$

The manuscript writes $i\backslash I'$ and I'/i, with the contravariant convention understood. Making the opposites explicit explains the otherwise surprising occurrence of an *initial* object in footnote 27: it becomes terminal in the indexing category of the colimit. It also prevents interchanging the two comma categories when passing to modern covariant notation.

The lifting argument behind Proposition 2 is a precise form of the principle that adjunction transfers extension problems. Suppose $L : \mathcal{A} \rightleftarrows \mathcal{B} : R$ and let $i : A \to A'$ and $p : B \to B'$. By the adjunction, the two horizontal maps in a square from Li to p correspond to the two horizontal maps in a square from i to Rp. Naturality of the adjunction bijection identifies the commutativity conditions. A diagonal $LA' \to B$ corresponds to a diagonal $A' \to RB$, and each of the two triangle identities required of a filler is carried to the corresponding identity. The sets of fillers are therefore naturally bijective. In particular

$$Li \perp p \quad \Longleftrightarrow \quad i \perp Rp.$$

Applying this first to $u^* \dashv u_*$ proves the preservation of F and TF by u_*. Applying it to $u_! \dashv u^*$ proves the two equivalences in (3). This is the same elementary mechanism as Hovey (1999a, Lemma 1.3.4).

For a useful special case, suppose every component of $i \downarrow u$ has an initial object e_α. The left Kan formula reduces to

$$(u_! X')(i) \cong \coprod_{\alpha} X'(e_\alpha).$$

A left orthogonal class is closed under coproducts: a square out of a coproduct is a family of squares, and a family of fillers assembles to a filler. Thus $u_!$ preserves C and TC under this hypothesis, and u^* preserves F and TF. No claim about preservation of general colimits by the weak equivalences is involved. The comma-category hypothesis has replaced that issue by a coproduct calculation.

4 Les variances u^*, u_*, $u_!$ pour $(\mathcal{M}(I), W(I))$ (I variable)

Je suppose les conditions du paragraphe précédent vérifiées pour $(\mathcal{M}, W)$ (cf. théorème p. 42), et choisis une structure de Quillen faible close et exacte à gauche (C, TC, F, TF) pour W, d'où pour tout I dans Cat

[page 45]

une structure de Quillen faible close et exacte à gauche $(C(I), TC(I), F(I), TF(I))$ pour $W(I)$, dans $\mathcal{M}(I)$, décrite page 43. Soit maintenant

$$u \ : \ I' \longrightarrow I$$

une flèche dans Cat, d'où une flèche

$$u^* \ : \ (\mathcal{M}(I), W(I)) \ \longrightarrow \ (\mathcal{M}(I'), W(I')).$$

On sait, vu que $\mathcal{M}$ est stable par $\varinjlim$ quelconques et aussi (étant de plus accessible) par $\varprojlim$ quelconques, que u^* admet des foncteurs adjoints à gauche et à droite,

$$u_!, \ u_* \ : \ \mathcal{M}(I') \ \longrightarrow \ \mathcal{M}(I),$$

p. 26

et je me propose ici de résumer les propriétés les plus immédiates de u^* et de $u_!$, u_* par rapport aux structures de Quillen faibles envisagées.

Proposition 1 : *Avec les notations précédentes, on a les relations :*

$$u^*(C(I)) \subset C(I'), \qquad u^*(TC(I)) \subset TC(I'). \tag{1}$$

$$u_*(F(I')) \subset F(I), \qquad u_*(TF(I')) \subset TF(I). \tag{2}$$

$$\begin{aligned} u^*(F(I)) \subset F(I') &\iff u_!(TC(I')) \subset TC(I) \\ u^*(TF(I)) \subset TF(I') &\iff u_!(C(I')) \subset C(I). \end{aligned} \tag{3}$$

D'autre part, je ne sais rien dire de positif pour les inclusions

$$\begin{aligned} u_*(C(I')) \ &\subset \ C(I), \ \ u_*(TC(I')) \ \subset \ TC(I) \\ u_!(F(I')) \ &\subset \ F(I), \ \ u_!(TF(I')) \ \subset \ TF(I). \end{aligned}$$

Si ce n'est que pour un u tant soit peu général (u pas un isomorphisme, disons), u_* n'a aucune envie

[page 46]

d'être compatible avec les structures C, TC (propriété d'exactitude homotopique à droite, moralement, vu que u_* est exact à gauche et en général pas du tout à droite), ni $u_!$ avec les structures F, TF (commentaire dual à donner, $u_!$ est exacte à *droite*, et n'a pas envie d'être "homotopiquement exact à gauche").

Démonstration de (1), (2), (3). Les relations (1) sont évidentes par définition. Les relations (2), (3) le sont à peine moins, vu la propriété soritale générale suivante, dont la place serait au paragraphe 1 :

Proposition 2. *Soit*

$$C' \underset{u^*}{\overset{u_!}{\rightleftarrows}} C$$

un couple de foncteurs adjoints $(u_!, u^*)$*, et soit* $\Phi' \subset \mathrm{Fl}(C')$*,* $\Psi \subset \mathrm{Fl}(C)$*. Alors*

$$(u_!(\Phi') \longleftrightarrow \Psi) \qquad \Longleftrightarrow \qquad (\Phi' \longleftrightarrow u^*(\Psi)).$$

Corollaire. (C'est le même énoncé, avec seulement des notations changées.) *Supposons que* $u^* : C \longrightarrow C'$ *admette un adjoint à* droite u_* *(pas forcément un adjoint à gauche)*

$$C' \underset{u_*}{\overset{u^*}{\rightleftarrows}} C,$$

soit $\Phi \subset \mathrm{Fl}(C)$*,* $\Psi' \subset \mathrm{Fl}(C')$*, alors* p. 27

$$(u^*(\Phi) \longleftrightarrow \Psi') \qquad \Longleftrightarrow \qquad (\Phi \longleftrightarrow u_*(\Psi')).$$

C'est la proposition 2 pour $C'_0 \underset{u_0^*}{\overset{u_{0!}}{\rightleftarrows}} C_0$, avec $C'_0 = C$, $C_0 = C'$, $(u_{0!} : C \longrightarrow C') = u^*$, et $(u_0^* : C' \longrightarrow C) = u_*$.

[page 47]

Pour les inclusions (2), on utilise le corollaire de la proposition 2 pour les couples $\Phi = TC(I)$, $\Psi' = F(I')$, resp. $\Phi = C(I)$, $\Psi' = F(I')$ `[plutôt` $\Psi' = TF(I')$`]`, et on applique (1) qui donne $u^*(\Phi) \longleftrightarrow \Psi'$, d'où $\Phi \longleftrightarrow u_*(\Psi')$, ce qui n'est autre que (2). Pour les équivalences (3), on utilise la proposition 2, en faisant $\Psi = F(I)$, $\Phi' = TC(I')$ resp. $\Psi = TF(I)$, $\Phi' = C(I')$.

Corollaire 1 (de la proposition 1) : *Supposons $u : I' \longrightarrow I$ telle que pour tout $i \in \mathrm{Ob}I$, la catégorie $i\backslash I'$ soit discrète* ([27]) *(p. ex. I' discrète). Alors on a*

$$\begin{cases} u_!(C(I')) \subset C(I), \;\; u_!(TC(I')) \subset TC(I) \\ u^*(F(I)) \subset F(I'), \;\; u^*(TF(I)) \subset TF(I'). \end{cases}$$

En effet, les relations de la deuxième ligne équivalent (à cause de (3)) à celles de la première. Il faut prouver que si f dans $\mathrm{Fl}\mathcal{M}(I')$ est dans $C(I')$ resp. $TC(I')$, $u_!(f)$ est dans $C(I)$ resp. $TC(I)$, ce qui signifie aussi que $\alpha_s^*(u_!(f))$ est dans C resp. TC, pour tout $s \in \mathrm{Ob}I$. Or le foncteur

$$\alpha_s^* u_! \; : \; \mathcal{M}(I') \longrightarrow \mathcal{M}$$

s'explicite par la formule bien connue

$$\alpha_s^*(u_!(X')) \overset{\text{déf}}{=} u_!(X')(s) \simeq \varinjlim_{i' \in s\backslash I'} X'(i').$$

Comme

[page 48]

$s\backslash I'$ est discrète, on a donc l'isomorphisme fonctoriel en X' dans $\mathcal{M}(I')$

$$\alpha_s^*(u_!(X')) \simeq \coprod_{(s', x : s \longrightarrow u(s')) \text{ dans } \mathrm{Ob}(s\backslash I')} X'(s'),$$

donc si $f : X' \longrightarrow Y'$, $\alpha_s^*(u_!(f))$ s'explicite comme une somme directe dans $\underline{\mathrm{Fl}}(\mathcal{M})$ de flèches de la forme

$$f_{s'} \; : \; X'(s') \longrightarrow Y'(s'),$$

lesquelles sont dans C resp. TC puisque f est dans $C(I')$ resp. $TC(I')$. Comme C, TC sont p. 28
stables par sommes directes quelconques (C, TC étant clos à gauche), on gagne.

Corollaire 2. *Soit I dans* Cat, *et $f \in \mathrm{Fl}(\mathcal{M}(I))$. Pour que f soit dans $F(I)$* (resp. *dans $TF(I)$), il* faut *que $\forall\, s \in \mathrm{Ob}I$, $f_s : X(s) \longrightarrow Y(s)$ le soit.* (Mais cette condition n'a pas du tout l'air d'être suffisante !) *En particulier, soit $X \in \mathrm{Ob}\mathcal{M}(I)$, alors $X \in \mathrm{Ob}\mathcal{M}(I)_f \Longrightarrow X(s) \in \mathrm{Ob}\mathcal{M}_f \;\; \forall\, s \in \mathrm{Ob}I$.*

Commentary · Examples [ms. 48]

Ordinary limits and the two homotopical exactness properties

Grothendieck's hesitation on pp. 49–50 identifies a necessary distinction. A right Kan extension can preserve fibrations and trivial fibrations without preserving weak equivalences between arbitrary diagrams. Its derived functor is computed on fibrant diagrams, and it is this functor which preserves homotopy limits. The distinction already matters for a finite poset.

Work in simplicial sets, and let K be the nerve of the groupoid with two objects and exactly one morphism between every ordered pair. The simplicial set K is Kan and contractible. Consider the cospan

$$* \xrightarrow{0} K \xleftarrow{1} *,$$

where the two maps select distinct vertices. Its strict pullback is empty. Collapsing K to a point gives an objectwise weak equivalence from this cospan to the constant one-point cospan, whose strict pullback is a point. Hence the ordinary limit functor does not preserve objectwise weak equivalences, even though every value of both diagrams is fibrant. The square formed by this weak equivalence over the identity of the terminal diagram is homotopy cartesian; its image under the strict limit is not, since it would require the map from the empty space to the point to be a weak equivalence.

27. Plus généralement, il suffit que toute composante connexe Z_α de $i\backslash I'$ ait un objet initial e_α, de sorte que $\varinjlim_{i\backslash I'} X'(i') \simeq \coprod_{\alpha \in \pi_0(i\backslash I')} X'(e_\alpha)$. C'est le cas notamment si $I' \longrightarrow I$ est un isomorphisme local, p. ex. une immersion ouverte.

Fibrancy of values has not imposed the matching condition. The homotopy pullback of the first cospan is the space of paths from 0 to 1 in K, which is contractible, as it must be.

There is an equally concrete colimit example. Form the simplicial span

$$\Delta^1 \longleftarrow \partial\Delta^1 \longrightarrow \Delta^1$$

using the two boundary inclusions. Its pushout is a simplicial circle. Collapsing both intervals gives an objectwise weak equivalence to $* \leftarrow \partial\Delta^1 \rightarrow *$, whose strict pushout is a point. The first span consists of cofibrations and calculates the homotopy pushout; the second does not. Thus objectwise cofibrancy of all simplicial sets does not make every span a cofibrant diagram for computing colimits.

Even after deriving the right Kan extension, its preservation of homotopy pushouts is a different assertion and is generally false. Take u from the discrete two-object category to the terminal category and work with pointed spaces. Then $\mathbf{R}u_*$ is the product. In the category of pairs, the coproduct of $(S^1, *)$ and $(*, S^1)$ is (S^1, S^1). Applying the product gives the torus $S^1 \times S^1$, whereas taking the coproduct after applying the product gives $S^1 \vee S^1$. The comparison induces

$$\mathbb{Z} * \mathbb{Z} \longrightarrow \mathbb{Z} \times \mathbb{Z}$$

on fundamental groups and is not an isomorphism. Since a pointed homotopy coproduct is a homotopy pushout over the zero object, this supplies the finite-poset example requested in the manuscript.

Restriction has a different behavior. Once the diagram localizations form a derivator, restrictions between shifted derivators preserve homotopy Kan extensions in the independent diagram variable, and hence both cartesian and cocartesian squares; this is Groth (2013, Proposition 2.5). The two claims about restriction are therefore compatible. The asymmetry belongs to a general left or right Kan extension, and disappears in stable situations for *finite* homotopy limits and colimits, where the two notions coincide.

On applique le corollaire 1 à $\alpha_s : e \longrightarrow I$.

Scholie. La proposition 1 (relation (1)) montre que le foncteur u^* transforme carrés W-cocartésiens en itou, suites exactes longues de suspension en itou – c'est "l'exactitude à droite homotopique" de u^*. On s'attend à ce qu'il en soit de même pour les carrés cartésiens et les suites exactes

[page 49]

longues de cosuspension, mais pour le prouver il faudra un travail, qu'on fera dans la suite.

Les relations (2) montrent que le foncteur u_* transforme carrés W-cartésiens en itou, donc suites exactes longues de cosuspension en itou. Je ne m'attends *pas* à ce qu'il en soit de même en général pour les carrés W-cocartésiens – *i.e.* que u_* soit "homotopiquement exact à droite", et non seulement à gauche. Mais il faudrait au moins que je fasse des exemples (avec I', I des catégories finies ordonnées).

Quant à $u_!$, la proposition ne dit rien de bien palpable à son sujet. Néanmoins on s'attend à ce que $u_!$ transforme carrés W-cocartésiens en itou – c'est la moindre des choses ! Ou peut-être je fais erreur, en confondant les foncteurs u_*, $u_!$ envisagés ici, avec les foncteurs similaires

$$\mathrm{HO}_W(I') \underset{u_*^W}{\overset{u_!^W}{\rightrightarrows}} \mathrm{HO}_W(I),$$

adjoints à gauche resp. à droite de

$$\mathrm{HO}_W(I') \xleftarrow{u_W^*} \mathrm{HO}_W(I),$$

induit par

$$u^* \ : \ (\mathcal{M}(I), W(I)) \ \longrightarrow \ (\mathcal{M}(I'), W(I')).$$

Mais en général u_*, $u_!$ ne sont pas compatibles

[page 50]

avec les localiseurs $W(I')$, $W(I)$, donc ils ne doivent pas être confondus avec les foncteurs $u_!^W$, u_*^W. Donc j'ai été peut-être hâtif, dans ce que j'ai dit au sujet de u_* et de $u_!$. Je serai obligé d'étudier la situation de très près, quand j'essayerai de construire les foncteurs u_*^W et $u_!^W$. Pour le moment, je n'ai encore aucune assurance que les conditions envisagées pour $(\mathcal{M}, W)$ suffisent à assurer l'existence de u_*^W, $u_!^W$ – pas même pour I, I' des ensembles ordonnés finis !

Corollaire 1. *Soit $X \in \mathcal{M}(I)_{\mathrm{f}}$, alors pour toute $\alpha : s \longrightarrow t$ dans I qui est* [un] monomorphisme, *$X(\alpha) : X(t) \longrightarrow X(s)$ est dans F.*

(On applique [le] corollaire 1 (p. 47) à $\tilde{\alpha} : \mathbf{\Delta}_1 \longrightarrow I$.) p. 29

Proposition 3. ([28]) *Soit X dans $\mathcal{M}(\mathbf{\Delta}_1)$, $X = (X_0 \xleftarrow{\alpha} X_1)$. Alors X est dans $\mathcal{M}(\mathbf{\Delta}_1)_{\mathrm{f}}$ si et seulement si X_0, X_1* [sont] *dans $\mathcal{M}_{\mathrm{f}}$ et $\alpha \in F$.*

Corollaire 2. *Soit $I' \overset{u}{\hookrightarrow} I$* [une] immersion ouverte. *Alors pour $X \in \mathrm{Ob}\,\mathcal{M}(I)_{\mathrm{f}}$, $\varprojlim_I X(i) \longrightarrow \varprojlim_{I'} X(i)$ est dans F.*

5 Catégories de modèles quillénisables

Je reviens au cas général d'une catégorie de modèles $(\mathcal{M}, W)$.

Commentary · Exposition [ms. 50]

The two finite lifting arguments

Grothendieck isolates consequences of diagram fibrancy which can be proved before any large existence theorem. The walking-arrow criterion of Proposition 3 is the special case $Y = *$ of the matching-map calculation discussed above: $X = (X_1 \to X_0)$ is injectively fibrant precisely when X_0 is fibrant and $X_1 \to X_0$ is a fibration. The fibrancy of X_1 then follows by composition. This proves the proposition without an appeal to the later lemma cited in footnote 28.

The monomorphism hypothesis in Corollary 1 has an exact combinatorial role. Let $\alpha : s \to t$ be monic and let $a : [1] \to I$ classify it. For any object i, the category $i \downarrow a$ has objects given by maps $i \to s$ or $i \to t$. A map of the first kind is joined to its composite with α; a map of the second kind has at most one such predecessor because α is monic. Thus every component is either a singleton or a single arrow, and has an initial object. Footnote 27 shows that a^* preserves injective fibrancy. Applying Proposition 3 to a^*X gives $X(t) \to X(s) \in F$. No assumption that I is itself a poset is needed.

For the restriction of limits, let $j : J \hookrightarrow I$ be a sieve, the presheaf convention for the manuscript's open immersion, and let X be injectively fibrant. We prove directly that

$$\lim_I X \longrightarrow \lim_J j^* X$$

has the right lifting property against TC. Take a square against $a : A \to B \in TC$. The upper map is a cone from A to X over I, while the lower map is a cone from B over J extending it. Since j is a sieve, left extension $j_!$ is extension by the initial object outside J. The two cones combine to a map into X from

$$T = (\mathrm{const}_I\, A) \amalg_{j_! \,\mathrm{const}_J\, A} j_! \,\mathrm{const}_J\, B.$$

The canonical map $T \to \mathrm{const}_I\, B$ is the identity at objects of J and is a elsewhere. It belongs to $TC(I)$. The fibrancy of X supplies a lift $\mathrm{const}_I\, B \to X$, which is exactly the missing cone. This proves the corollary whenever the displayed limits and the required finite colimits exist. The construction exhibits the compatibility information in the lifting problem instead of suppressing it in a pointwise calculation.

Définition 1. On dit que $(\mathcal{M}, W)$ est *quillénisable* s'il existe une structure de Quillen faible *exacte* (C, TC, F, TF) pour $\mathcal{M}$.

C'est là une condition autoduale, mais que je ne sais vérifier en pratique que moyennant l'exactitude soit à gauche, soit à droite – donc par une condition plus forte qui détruit la

28. Comparer avec le lemme p. 63 et sa démonstration (plus exactement, le corollaire du lemme).

symétrie. C'est pour la sauvegarder dans la mesure du possible que j'introduis la définition précédente, ainsi que la

Définition 2. Soit, en plus de $(\mathcal{M}, W)$, Diag $\subset$ Cat une sous-catégorie pleine de Cat. On dit que W est *quillénisable sur* Diag, si pour tout I dans Diag, $(\mathcal{M}(I), W(I))$ est quillénisable. [page 51]

En pratique, j'utiliserai cette définition dans le cas où Diag = Cat, ou alors, qu'il satisfasse au moins les propriétés de stabilité utiles pour le domaine d'un dérivateur : stable par $\varprojlim$ finies, par sommes finies – eventuellement par $\varinjlim$ finies, etc ([29]).

Commentary · Exposition [ms. 51]

What quillenizability promises

Grothendieck wants a condition on the relative category $(\mathcal{M}, W)$, independent of the auxiliary choices of cofibrations and fibrations. Quillenizability says that some exact weak structure exists. Quillenizability on a domain of diagrams repeats this existence statement for every I in the domain. It does not itself choose compatible structures. The exact-completion argument in the commentary to pp. 32–34 does allow one to enlarge the two trivial classes to $C \cap W$ and $F \cap W$, recovering the original, possibly nonclosed Quillen axioms without changing C, F or W. Thus exactness has real force even before closure is imposed. The adjective "weak" must nevertheless retain the definition from p. 27. It is not a synonym for the later notions of a semi-model category or of a weak model category.

There are three separate questions. First, can one form the localization $\mathcal{M}(I)[W(I)^{-1}]$? Second, does it carry the fibre and cofibre operations constructed by replacement? Third, do restriction and Kan extension relate these categories with the exactness and pointwise formulas required of a derivator? Existence of localizations answers the first question, an exact weak structure addresses the second, and the uniform constructions aim at the third. Treating these three tasks separately explains why the author returns to examples from ordinary homological algebra rather than simply assuming arbitrary colimits from the outset.

His quotation marks around "triangulée" are also essential. In a pointed unstable theory there are suspension and loop functors, and long exact sequences obtained from fibres or cofibres. The suspension need not be an equivalence, the homotopy category need not be additive, and these data are not a triangulated category in Verdier's sense. Stable derivators do yield canonical triangulations, with exact restriction and Kan extension functors; the stability hypothesis is the additional mathematical content in Groth (2013, Theorem 4.16). For complexes, shifting is invertible on the unbounded derived category, whereas nonnegative chain complexes provide a pointed but generally unstable example. This is precisely the distinction the next example needs.

Commentary · Exposition [ms. 51]

Quillenisability and the strength of its qualifiers

Grothendieck is looking for hypotheses on a category with weak equivalences which survive passage to diagrams. The point is not merely to construct another presentation of its homotopy category. A derivator must retain enough of the original category to restrict a diagram, replace it, and eventually take its homotopy limit. His succession of adjectives records different parts of this programme; reading them all as the modern expression "model category" would erase the question he is asking.

Throughout these pages we use his variance:

$$\mathcal{M}(I) = \mathrm{Fun}(I^{\mathrm{op}}, \mathcal{M}), \qquad W(I) = \{f \mid f_i \in W \text{ for every } i\}.$$

Thus the ordered category $0 \to 1$ indexes an arrow $X_1 \to X_0$ in $\mathcal{M}$. A terminal object of I computes the ordinary limit of such a diagram. This explains several formulas which would have the opposite orientation with covariant diagrams.

The glossary supplied with the chapter makes the terminology precise. A weak Quillen structure has the two factorizations (C, TF) and (TC, F), their lifting properties, and $TC \subset C \cap W$, $TF \subset F \cap W$. The axiom called exactness is

$$W = TF \circ TC.$$

29. Je supposerai que Diag contient tout au moins les catégories provenant d'ensembles ordonnés finis.

Exactness on the left is the stronger-looking equality $TC = C \cap W$; exactness on the right is $TF = F \cap W$. Closedness says that the four classes are determined by their respective lifting properties. The additional axiom $\mathbf{M}''$ concerns preservation of weak equivalences under base change along fibrations and cobase change along cofibrations. In a usual model structure these are the properness requirements. Finally, **M**0 asks only for finite limits and finite colimits. Small completeness must therefore be supplied when an infinite Kan extension is used.

There is a useful simplification precisely when *closedness and exactness are both present*, as they will be in §6. It is the retract argument, not an extra smallness theorem. Suppose $f \in C \cap W$. Exactness supplies $f = pi$ with $i \in TC$ and $p \in TF$. The left lifting property of f against p makes f a retract of i in the arrow category. A class defined by a left lifting property is closed under retracts, so $f \in TC$. For $f \in F \cap W$, use the same factorization and lift i against f; this exhibits f as a retract of p, and hence puts it in TF. Consequently

$$TC = C \cap W, \qquad TF = F \cap W$$

under the closed exact hypotheses. This application of the familiar retract argument is particularly consequential here: see Hovey (1999a, Lemma 1.1.9). The proof uses neither arbitrary products nor a prior assertion that W is closed under retracts.

Quillenisability by itself, in Definition 1, does not include closedness. We therefore do not substitute the stronger hypothesis into §5. Once a uniform closed exact quillenisability has been assumed in §6, however, the preceding equalities are available in every diagram category. They will allow the apparently separate questions about finite posets, products, towers and group actions to be treated by one argument. Keeping this distinction visible preserves both the breadth of the definition and the actual force of the theorem's hypotheses.

Exemple 1 : Celui des paragraphes 3, 4, où on a dégagé des conditions sur $(\mathcal{M}, W)$, avec $\mathcal{M}$ une "grosse" catégorie et $\mathcal{M}$ accessible, pour que W soit quillénisable sur Cat tout entier. C'est le cas qui me paraît à présent le plus intéressant.

Exemple 2 : Soient $\mathcal{A}$ une catégorie abélienne, et $\mathcal{M} = K^\bullet(A)$ la catégorie des complexes de cochaînes à valeurs dans $\mathcal{A}$, $W = W_\mathcal{A}$ l'ensemble des quasi-isomorphismes, donc

$$\mathcal{M}W^{-1} \;=\; K^\bullet(\mathcal{A})W_\mathcal{A}^{-1} \;\simeq\; D^\bullet(\mathcal{A}), \qquad \text{catégorie dérivée de } \mathcal{A}.$$

On définit aussi $\mathcal{M}^+$, $\mathcal{M}^-$, $\mathcal{M}^\mathrm{b}$, avec les localiseurs induits $W_\mathcal{A}^+$, $W_\mathcal{A}^-$, $W_\mathcal{A}^\mathrm{b}$, et les catégories de fractions $D^+(\mathcal{A})$, $D^-(\mathcal{A})$, $D^\mathrm{b}(\mathcal{A})$. Ou encore, pour I dans Cat, [page 52]

$$\mathcal{M}(I) \;=\; K^\bullet(\mathcal{A}(I))$$

$$W(I) \;=\; \underbrace{W_{\mathcal{A}(I)}}_{\text{quasi-isomorphismes}} \;\subset\; \mathrm{Fl}(K^\bullet(\mathcal{A}(I))), \qquad \text{p. 30}$$

et de même pour $\mathcal{M}^\alpha(I)$, $W^\alpha(I)$ ($\alpha \in \{+, -, \mathrm{b}\}$), du moins *si I est finie.* Il y a aussi les sous-catégories $K^{\geq 0}(\mathcal{A})$ et $K^{\leq 0}(\mathcal{A})$ des complexes de cochaînes resp. de chaînes au sens strict (avec $K^i = 0$ si $i \geq 0$, resp. si $i \leq 0$ `[plutôt si` $i < 0$`, resp. si` $i > 0$`]`). On aura pour I quelconque

$$\begin{cases} K^{\geq 0}(\mathcal{A})(I) \;\simeq\; K^{\geq 0}(\mathcal{A}(I)) \\ W_\mathcal{A}^{\geq 0}(I) \;=\; W_{\mathcal{A}(I)}^{\geq 0}, \end{cases}$$

et de même pour $K^{\leq 0}$, $W^{\leq 0}$.

D'après Quillen page 1.2, $(K^+(\mathcal{A}), W_\mathcal{A}^+)$ est quillénisable si $\mathcal{A}$ a assez d'injectifs, $(K^-(\mathcal{A}), W_\mathcal{A}^-)$ l'est si $\mathcal{A}$ a assez de projectifs. Il ne dit rien pour $(K^\bullet(\mathcal{A}), W_\mathcal{A})$ sans plus – pourtant on fait de l'algèbre cohomologique avec $D^\bullet(\mathcal{A})$ sans plus, et même sans faire d'hypothèse d'existence d'injectifs ou de projectifs. J'ai un peu oublié ce que Verdier a fait à ce sujet – je devrais quand même regarder sa thèse (!), ou bien l'exposé de Hartshorne.

Commentary · Examples [ms. 52]

Two meanings of a bounded diagram of complexes

Grothendieck's qualification "du moins si I est finie" protects an important distinction. We use $\mathrm{Ch}(\mathcal{A})$ for his $K^\bullet(\mathcal{A})$, which here denotes complexes and chain maps, before quotienting by chain homotopy. For unbounded complexes there is a genuine identification

$$\mathrm{Fun}(I^{\mathrm{op}}, \mathrm{Ch}(\mathcal{A})) \cong \mathrm{Ch}(\mathrm{Fun}(I^{\mathrm{op}}, \mathcal{A})).$$

Both sides specify objects X_i^n, differentials, and structure maps satisfying the same commutation relations. Quasi-isomorphisms are objectwise because kernels, cokernels, and hence cohomology in an abelian functor category are computed objectwise. The same argument works for a fixed half-line of degrees, such as $n \geq 0$.

For Ch^+ there are two possible bounds. An object of $\mathrm{Fun}(I^{\mathrm{op}}, \mathrm{Ch}^+(\mathcal{A}))$ has a lower bound depending on i. An object of $\mathrm{Ch}^+(\mathcal{A}(I))$ has one lower bound valid for every i. A finite object set allows us to take the minimum of the finitely many lower bounds, so the two categories agree. An infinite object set need not. For $I = \mathbb{N}$ discrete and a nonzero abelian group A, the family $A[n]$, $n \geq 0$, has one nonzero term in degree $-n$ and gives an immediate counterexample. There are analogous upper-bound and two-sided-bound distinctions.

This also explains footnote 31. In $\mathrm{Ch}^+(\mathbf{Ab})$ take the filtered system

$$X_m = \bigoplus_{0 \leq n \leq m} \mathbb{Z}[n], \qquad X_m \longrightarrow X_{m+1}$$

with the evident inclusions and zero differentials. Its colimit in unbounded complexes has a copy of $\mathbb{Z}$ in every nonpositive degree. It does not belong to Ch^+. Thus the assertion "$K^\bullet(\mathcal{A})$ etc. have the same properties" cannot include bounded-below or bounded-above complexes without a common bound; the manuscript itself flags this point.

More seriously, the difference can destroy an adjoint. Suppose the right adjoint to the constant-diagram functor

$$D^+(\mathbf{Ab}) \longrightarrow \prod_{n \geq 0} D^+(\mathbf{Ab})$$

existed at the family $(\mathbb{Z}[n])_{n \geq 0}$, and call its value P. Applying the adjunction to $\mathbb{Z}[k]$ gives

$$\begin{aligned} H^{-k}(P) &\cong \mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}[k], P) \\ &\cong \prod_{n \geq 0} \mathrm{Hom}_{D(\mathbf{Ab})}(\mathbb{Z}[k], \mathbb{Z}[n]) \\ &\cong \mathbb{Z} \qquad (k \geq 0). \end{aligned}$$

The last equality uses the projectivity of $\mathbb{Z}$: only the factor $n = k$ is nonzero. No bounded-below complex can have these cohomology groups. Therefore this right adjoint does not exist. For a discrete indexing category, the localization of the objectwise bounded complexes is indeed the product of the bounded derived categories: choose a bounded-below injective resolution separately in each component and represent morphisms by chain maps between these resolutions.

Accordingly, the familiar $\mathbf{R}u_* : D^+(\mathcal{A}(I')) \to D^+(\mathcal{A}(I))$ refers to a *uniformly* bounded-below input. It must not be used without comment for the generally larger localization of $\mathrm{Fun}((I')^{\mathrm{op}}, \mathrm{Ch}^+(\mathcal{A}))$. This failure concerns the requested adjoint, not a proof that the latter relative category has no possible weak quillenization. The commentary on Chapter VI, manuscript p. 131, already records a uniform-bound obstruction; here the obstruction is located directly in the proposed domain of a derived Kan extension.

[page 53]

Toujours est-il qu'on a là des exemples de type tout différent de ceux envisagés dans 1°. Ainsi, il n'y a pas à supposer que $\mathcal{M}$ soit stable par petites $\varinjlim$ – $\mathcal{M}$ peut même être une petite catégorie, elle l'est si et seulement si $\mathcal{A}$ elle même l'est. Si $\mathcal{A}$ est stable par (petites) $\varinjlim$ filtrantes, et est accessible (p. ex. a une petite famille génératrice, et les $\varinjlim$ filtrantes sont exactes), alors $K^\bullet(\mathcal{A})$ etc. ([30]) ont les mêmes propriétés, et $(K^+(\mathcal{A}), W_{\mathcal{A}}^+)$ est quillénisable sur

30. !!

Cat tout entier ([31]). (C'est le cas où on sait que $\mathcal{A}$ a assez d'injectifs, et l'algèbre cohomologique se fait surtout à coups de résolutions injectives …) Dans ce cas on sait que les

$$u_* \ : \ D^+(I', \mathcal{A}) \longrightarrow D^+(I, \mathcal{A})$$

existent comme adjoints à droite des

$$u^* \ : \ D^+(I, \mathcal{A}) \longrightarrow D^+(I', \mathcal{A}),$$

mais je ne suis plus trop sûr si on sait définir u_* aussi sur $D(I', \mathcal{A})$ tout entier, et je doute que $u_!$ existe sans hypothèse sur u (genre : dimension cohomologique finie). Sans doute on doit toujours avoir

$$u_! \ : \ D^-(I', \mathcal{A}) \longrightarrow D^-(I, \mathcal{A}),$$

adjoint à gauche de

$$u^* \ : \ D^-(I, \mathcal{A}) \longrightarrow D^-(I', \mathcal{A}). \qquad \text{[page 54]}$$

Commentary · Examples [ms. 53]

A bound on each component is not a bound on the diagram

Grothendieck turns to complexes because they offer a familiar theory of derived coefficients without the large-colimit hypotheses of the preceding sections. His notation $K^\bullet(\mathcal{A})$ denotes complexes and chain maps here. To avoid conflict with the now customary use of $K(\mathcal{A})$ for the chain-homotopy category, we write $\mathrm{Ch}(\mathcal{A})$ for that category of complexes. Localization at quasi-isomorphisms gives the derived category in either convention.

For unbounded complexes the exchange of the two diagram directions is literal:

$$\mathrm{Fun}(I^{\mathrm{op}}, \mathrm{Ch}(\mathcal{A})) \simeq \mathrm{Ch}(\mathrm{Fun}(I^{\mathrm{op}}, \mathcal{A})).$$

Both sides are the same collection of objects, differentials, transition maps and commutativities. Quasi-isomorphisms agree because kernels, cokernels and cohomology in the functor category are computed at each object. The fixed truncation conditions $X^n = 0$ for $n < 0$, or for $n > 0$, also commute with arbitrary diagram categories. The editor's correction to the reversed inequalities on manuscript p. 52 is essential.

The movable bound in Ch^+ behaves differently. A functor into $\mathrm{Ch}^+(\mathcal{A})$ gives a lower bound b_i for each component. An object of $\mathrm{Ch}^+(\mathcal{A}(I))$ requires one bound valid for all components. These conditions agree for a finite set of objects, since one can take $\min_i b_i$, but need not agree otherwise. The same distinction applies to upper bounds and to bounded complexes. This is why the words "si I est finie" belong to the argument, rather than merely to its notation.

Here is the obstruction in its simplest form. Let k be a field and put $X_n = k[n]$, with our cochain convention $X[n]^j = X^{j+n}$. Thus X_n has a single nonzero term in degree $-n$. Each X_n is bounded below. The degreewise product

$$\prod_{n \geq 0} k[n]$$

has nonzero cohomology in every degree $0, -1, -2, \ldots$ and is not bounded below. This is not merely a defect of that chosen complex. If a product P of the family existed in $D^+(k)$, the defining universal property, tested on $k[m]$, would give

$$H^{-m}(P) = \mathrm{Hom}_{D(k)}(k[m], P) \cong \prod_{n \geq 0} \mathrm{Hom}_{D(k)}(k[m], k[n]) \cong k$$

for every $m \geq 0$. No object of $D^+(k)$ has this property. Thus the projection from an infinite discrete category does not have a right adjoint on the theory of *objectwise* bounded-below diagrams with values in $D^+(k)$.

The filtered-colimit warning in footnote 31 has an equally concrete witness. Let $P_r = \bigoplus_{0 \leq n \leq r} k[n]$ and include P_r into P_{r+1}. Each P_r is bounded, whereas their degreewise filtered

31. attention, $K^+(\mathcal{A})$ n'est *pas* stable par $\varinjlim$ filtrantes infinies – donc on ne peut appliquer le tapis des paragraphes 2, 3 directement à K^+.

colimit has nonzero terms arbitrarily far to the left. Hence Ch^{+}, and likewise Ch^{b}, is not closed under arbitrary filtered colimits in Ch. The dual example uses $k[-n]$ to treat Ch^{-}. The unbounded category and the two fixed half-line categories do not have this problem.

Enough injectives do give the familiar bounded-below resolutions, and enough projectives give bounded-above resolutions. What the argument on these pages does not establish is quillenisability on every infinite diagram shape for the category allowing a different bound at every object. The accessibility theorem quoted from the preceding sections cannot be applied directly to that category. We record this as a missing justification, not as a counterexample to quillenisability itself: the product calculation concerns a Kan extension, which a finite-limit model structure is not obliged to possess. Passing to unbounded complexes is the clean way to obtain the unrestricted diagram theory.

p. 31

Mais je ne sais plus trop s'il faut s'attendre à pouvoir définir $u_!$ sur $D(I', \mathcal{A})$ tout entier, en dehors d'hypothèses genre dimension cohomologique finie. La triste vérité, c'est que j'ai ± oublié la théorie des foncteurs dérivés ! (Il faudrait que je demande encore à Jean Malgoire de m'envoyer des textes canoniques.)

Commentary · Later developments [ms. 54]

Unbounded resolutions remove the dimensional restriction

Grothendieck's uncertainty about unbounded derived functors has a precise modern answer for Grothendieck abelian categories. An unbounded complex needs a resolution which is injective as a complex, in the homotopical sense, rather than merely injective in each degree. A complex J is K-injective when $\mathrm{Hom}^{\bullet}(A, J)$ is acyclic for every acyclic complex A. This condition makes homotopy classes of maps into J invariant under quasi-isomorphisms in the source.

Spaltenstein (1988, Theorems C and D) constructed unbounded resolutions for modules and for sheaves of modules. For an arbitrary Grothendieck abelian category, the general existence result is stated and proved in The Stacks Project Authors (2026h, Theorem 19.12.6, tag 079P). One may also equip $\mathrm{Ch}(\mathcal{A})$ with the proper injective model structure whose weak equivalences are quasi-isomorphisms and whose cofibrations are monomorphisms; see Cisinski and Déglise (2009, Theorem 1.2), where the existence theorem is attributed to Beke.

For a small category I, the abelian category $\mathcal{A}(I)$ is again Grothendieck. Exactness of filtered colimits is objectwise. A generating family is obtained by applying the left adjoints to evaluation to a generating family of $\mathcal{A}$; these left adjoints are coproducts indexed by hom-sets. Applying the injective and projective diagram constructions to unbounded complexes consequently gives

$$\mathbf{L}u_! \dashv u^* \dashv \mathbf{R}u_* \quad \text{on} \quad D(\mathcal{A}(I')) \text{ and } D(\mathcal{A}(I))$$

for every functor of small indexing categories. Here "projective diagram structure" refers to the diagram model structure and does not assert that $\mathcal{A}$ has enough projective objects. No finite cohomological dimension of u is required for existence on the unbounded categories.

Finite dimensionality becomes relevant when one asks these functors to preserve a chosen bounded subcategory. This can be seen without any sophisticated example. Let G be cyclic of prime order p, let $k = \mathbb{F}_p$, and consider constant coefficients k over BG. Write $\epsilon = g - 1$ in $k[G] \cong k[\epsilon]/(\epsilon^p)$. The periodic free resolution of the trivial module has differentials alternating multiplication by ϵ and ϵ^{p-1}:

$$\cdots \xrightarrow{\epsilon} k[G] \xrightarrow{\epsilon^{p-1}} k[G] \xrightarrow{\epsilon} k[G] \longrightarrow k \longrightarrow 0.$$

It is exact because the kernel of multiplication by ϵ is the image of multiplication by ϵ^{p-1}, and conversely. After tensoring with k, or applying $\mathrm{Hom}_{k[G]}(-, k)$, every differential is zero. Thus

$$H^{-n}(\mathbf{L}\operatorname{colim}_{BG} k) \cong k, \qquad H^{n}(\mathbf{R}\lim_{BG} k) \cong k \quad (n \geq 0).$$

The left derived colimit of this degree-zero input is not bounded below, and the right derived limit is not bounded above. Both nevertheless exist as unbounded complexes. The source's worries about existence and about boundedness therefore have different resolutions. For an arbitrary abelian category, existence of the Verdier localization alone still does not supply either unbounded resolutions or all these Kan extensions.

Commentary · Later developments [ms. 54]

From a presentation to a homotopy theory of diagrams

The uncertainty about derived direct images brings Grothendieck back to the reason for keeping all indexing categories at once. A construction on one localized category can conceal the choices needed to make it functorial. Passing first to diagrams and then localizing preserves the information on which the construction depends. In particular, a coherent square is an object of the localization of the category of squares; it is not merely a commutative square in the ordinary homotopy category.

Renaudin makes the comparison with Quillen presentations precise for combinatorial model categories. In the published version, the bicategorical localization of left proper combinatorial model categories at Quillen equivalences maps locally equivalently to the 2-category of derivators with adjunctions as morphisms; restricting to derivators of small presentation gives a biequivalence (Renaudin, 2009, Theorems 3.3.2 and 3.4.4). The choice of morphisms is part of this statement. It is not an assertion that every prederivator, or every transformation of prederivators, comes from an arbitrary relative category in this way.

The analogous construction for an infinity-category $\mathcal{C}$ has the particularly transparent form

$$I \longmapsto \mathrm{Ho}\,\mathrm{Fun}(NI^{\mathrm{op}}, \mathcal{C}).$$

Here N is the nerve, and the opposite records the presheaf convention of this chapter. Limits and colimits in $\mathcal{C}$ give the homotopy Kan extensions of this system. Riehl and Verity express the relevant comparison law as a Beck–Chevalley theorem for comma squares, and explain the resulting derivator of a complete and cocomplete quasi-category (Riehl and Verity, 2017, Proposition 5.3.9 and Remark 5.3.10).

This description also clarifies the role of the classes C and F in the preceding calculations. They supply replacements that compute these intrinsic operations. The right replacement for a presheaf is generally more than a list of fibrant values: the transition maps carry compatibility conditions. Grothendieck's arrow example on manuscript page 50 already exhibits this fact. On the other hand, forgetting to derive an ordinary Kan extension destroys precisely the homotopy invariance that the intrinsic description requires. The withdrawal on manuscript pages 49–50 corrects the construction while preserving its objective.

Scholie. Si $(\mathcal{M}, W)$ est quillénisable sur Diag $\subset$ Cat (et même sans qu'il soit quillénisable), il définit un prédérivateur $\mathbf{D}_{\mathcal{M},W}$ sur Diag. On posera parfois

$$\mathrm{HO}_{\mathcal{M},W}(I) \text{ ou } \mathrm{HO}_W(I) = \mathbf{D}_{\mathcal{M},W}(I).$$

L'hypothèse quillénisable implique, sur chacune de ces catégories homotopiques, la structure (relativement faible) "triangulée", provenant des suites *exactes* de suspension et de cosuspension ([32]). (Le caractère quillénisable assure l'exactitude de ces suites …) Les foncteurs $u^* : \mathrm{HO}_W(I) \longrightarrow \mathrm{HO}_W(I')$ sont "homotopiquement exacts" dans le sens des ces structures "triangulées" (non commutatives), *i.e.* transforment suites exactes de suspension resp. de cosuspension en itou. [page 55]

Commentary · Context [ms. 54]

An answer already present in Joyal's letter

The questions about complexes and uniform diagram structures have a particularly close antecedent in the correspondence surrounding *Pursuing Stacks*. In the letter begun on 11 April 1984, Joyal describes Heller's two model structures on simplicial presheaves and explicitly connects them with derived right and left Kan extensions for an arbitrary functor of indexing categories. In the continuation dated 15 April, Theorem 2 states the injective model structure on unbounded complexes in an arbitrary Grothendieck abelian category, with monomorphisms as cofibrations and homology isomorphisms as weak equivalences (Joyal, 1984, pp. 3 and 10).

This locates the present hesitation accurately. The manuscript records a return to an earlier set of questions, not the historical first appearance of the unrestricted complex example. The later

32. Dans le cas où $\mathcal{M}$ est ponctuée par `[un]` objet neutre. Sinon, il y a la structure associée aux carrés cartésiens et cocartésiens. Il serait assez intéressant d'axiomatiser une telle espèce de structure.

proofs by Beke and the constructions of K-injective resolutions make those statements accessible in systematic published forms. The letter is also unusually direct evidence for the role of Heller in the diagram-category approach; it supports that precise connection without requiring us to infer a chronology from similarities between later axiomatizations.

Commentary · Later developments [ms. 54]

Unbounded resolutions answer the derived-image question

Grothendieck's hesitation about unbounded derived images concerns the existence of resolutions on which an ordinary functor can safely be evaluated. A complex of injective objects is not automatically suitable when it is unbounded: what is needed is a condition on the whole complex. A complex J is K-injective when $\mathrm{Hom}^\bullet(A, J)$ is acyclic for every acyclic complex A. Equivalently, maps into J in the homotopy category already compute maps into its image in the derived category.

Spaltenstein's work was already available when these manuscript pages were written. His Theorem C treats unbounded complexes of modules, Theorem D treats sheaves of modules, and Theorem 4.5 gives the latter existence construction; these results should not be retrospectively attributed to the present text (Spaltenstein, 1988). For an arbitrary Grothendieck abelian category the general result is associated with Serpé (2003). A detailed modern statement, including a functorial monomorphic quasi-isomorphism into a termwise injective K-injective complex, is Theorem 19.12.6, Tag 079P, of the Stacks Project (The Stacks Project Authors, 2026g).

The application to right Kan extensions is short once this existence theorem has been supplied. Let $u : I' \to I$ be a functor of small categories and let $\mathcal{A}$ be Grothendieck abelian. The category $\mathcal{A}(I')$ is again Grothendieck: exactness of filtered colimits is checked componentwise, and free diagrams on a set of generators give a set of generators. Restriction u^* is exact, and its ordinary right adjoint u_* exists. If J is K-injective in $\mathrm{Ch}(\mathcal{A}(I'))$, then for any acyclic A in $\mathrm{Ch}(\mathcal{A}(I))$ the ordinary adjunction gives

$$\mathrm{Hom}^\bullet(A, u_*J) \cong \mathrm{Hom}^\bullet(u^*A, J).$$

The right-hand side is acyclic because u^*A is acyclic. Thus u_*J is K-injective. Replacing X' by such a J defines $\mathbf{R}u_*X' = u_*J$ on the entire unbounded derived category, and the same Hom identity proves $u^* \dashv \mathbf{R}u_*$ there.

The corresponding unbounded left Kan extensions also exist for Grothendieck coefficients. The precise model-theoretic input is Beke (2000, Proposition 3.13): unbounded complexes have a cofibrantly generated model structure with monomorphisms as cofibrations and quasi-isomorphisms as weak equivalences. The underlying category is locally presentable, so this is a combinatorial model; its projective diagram structures and the Brown argument supply all left Kan extensions. Neither construction requires a finite cohomological dimension for the indexing functor. Such dimension restrictions instead govern preservation of bounded ranges. Since restriction is exact for the standard degreewise t-structures, its right adjoint preserves lower bounds and its left adjoint preserves upper bounds. Thus the usual statements on globally bounded-below and globally bounded-above diagrams remain meaningful, while a bounded object can acquire cohomology in arbitrarily many degrees on the other side.

For this reason the letter $u_!$ here must be read as the left adjoint to restriction of diagrams. It is not a direct image with proper supports on a space. Those functors have their own geometric hypotheses; importing them would introduce difficulties unrelated to the question asked on pp. 53–54. The example of a finite group below will display the genuine boundedness issue without any such ambiguity.

Quels sont les axiomes des dérivateurs qui sont vérifiés sous la seule hypothèse quillénisable ? **Der** 1 `[voir chapitre I, p. 43]` l'est sans hypothèse aucune sur la catégorie de modèles $(\mathcal{M}, W)$:

$$\mathrm{HO}_W(\coprod_\alpha I_\alpha) \;\simeq\; \prod_\alpha \mathrm{HO}_W(I_\alpha)$$

pour une famille *finie* d'objets I_α dans Diag. L'axiome de localisation **Der** 2 `[voir chapitre I, p. 43]` l'est sous l'hypothèse que W soit *fortement saturé,* et quillénisable. On utilise le fait que toute flèche de $\mathrm{HO}_W(I)$ provient, à isomorphisme près, d'une flèche dans $\mathcal{M}(I)$. (C'était

là un des points qui restait en suspens dans VI, dans la théorie de HOT_W, $W \subset \mathrm{Fl}(\mathrm{Cat})$ un localiseur fondamental …)

Commentary · Exposition [ms. 55]

The two elementary derivator axioms

Grothendieck is now testing how much of the derivator is already present before constructing homotopy Kan extensions. The two assertions about finite coproducts of shapes and detection of isomorphisms have different proofs, and the latter uses a homotopical input which cannot be replaced by saturation alone.

For a finite family of shapes there is an isomorphism of relative categories

$$\mathcal{M}\Big(\coprod_{r=1}^{n} I_r\Big) \cong \prod_{r=1}^{n} \mathcal{M}(I_r)$$

with componentwise weak equivalences. Localization commutes with this finite product. One way to see the point is to separate each arrow $(f_1, \dots, f_n)$ into the n coordinate arrows, inserting identities in the other positions. Coordinate arrows commute, and this commutation remains true after inverting weak equivalences. Finite zigzags in the individual coordinates can therefore be padded with identities and assembled into a finite zigzag in the product. The same operation on the elementary relations between zigzags gives full faithfulness as well as essential surjectivity. The empty family gives the terminal category. Infinite products require an additional argument: one cannot pad zigzags of unbounded length to a single finite length. This is why the statement on the page is deliberately finite.

For detection of isomorphisms, use the representation property of the exact weak structure proved in the commentary to pp. 29–34: every arrow ξ in $\mathcal{M}(I)[W(I)^{-1}]$ is isomorphic in the arrow category to the localization of an actual map $f : X \to Y$. If every evaluation of ξ is invertible, the same is true of every f_i in $\mathcal{M}[W^{-1}]$. Strong saturation of W then gives $f_i \in W$ for all i, hence $f \in W(I)$, and ξ is invertible. The role of representability is to put all components into one honest natural transformation before applying saturation. The commentary on Chapter VI, manuscript p. 130, already explains why saturation by itself is insufficient.

These arguments establish the two stated axioms with their stated qualifications. They do not produce the pointwise Kan-extension formula. In the modern model-category treatment, that remaining structure is available: Groth (2013, Proposition 1.30) proves the strong derivator theorem in the combinatorial case, and his Theorem 1.32 records Cisinski's theorem for model categories in general. The word "model" in that latter statement has the ordinary model-category meaning. The exact-completion lemma above first recovers Quillen's original axioms from the weak structure; closedness, size conventions and the required small limits and colimits must still be tracked when invoking a modern formulation.

L'axiome **Der** 3, nouvelle mouture `[voir chapitre I, pp. 111-112]`, implique un localiseur fondamental $\mathbf{W} \subset \mathrm{Fl}(\mathrm{Cat})$ (pas forcément $\mathbf{W}_\infty$) ([33]). La forme la plus forte serait celle-ci : si

$$u \ : \ I' \longrightarrow I$$

est dans $\mathbf{W}$, on veut que le foncteur u^* induise une *équivalence* [page 56]

$$u^*_{\mathrm{lc}} \ : \ \mathrm{HO}^{\mathrm{lc}}_W(I) \xrightarrow{\sim} \mathrm{HO}^{\mathrm{lc}}_W(I').$$

Mais je doute qu'on soit armé pour vérifier un axiome aussi fort, sans avoir au moins une théorie des opérations $u_!$ ou u_*. On pourrait à tout hasard poser cet axiome en prenant $\mathbf{W} = \mathbf{W}_\alpha \overset{\text{déf}}{=}$ le plus petit localiseur fondamental satisfaisant W (1 à 7) (le plus grand de ces localiseurs étant $\mathbf{W}_\infty$). Pour l'instant, la façon de vérifier cet axiome (en termes de la donnée $(\mathcal{M}, W)$) est pour moi un mystère ± total. (Mais je sais le vérifier pour HOT_W, quand $W \subset \mathrm{Fl}(\mathrm{Cat})$ satisfait W (1, 2, 3, 4, 5, …).) p. 32

33. Il est naturel ici de supposer que $\mathbf{W}$ satisfait à tous les "bons axiomes" sur les localiseurs fondamentaux W (1, 2, 3, 4, 5, 6, 7) `[voir chapitre XII]`.

Commentary · Exposition [ms. 55]

Localization axioms, stability, and locally constant coefficients

Grothendieck now asks which parts of the derivator formalism are already forced by a good calculus of weak equivalences. Two separate gains should be distinguished. Localizing categories of diagrams preserves their coherent origin; obtaining homotopy Kan extensions requires additional functors between these localized categories. The prederivator exists before the second gain has been made.

Finite disjoint unions are formal. A diagram on $I_1 \amalg \cdots \amalg I_r$ is a tuple of diagrams, and weak equivalences are componentwise. Localization commutes with this finite product: finite zigzags may be padded by identities, and the relations may be checked in one coordinate at a time. This explains the absence of a quillenisability hypothesis in the stated finite version of **Der**1. The same argument is not an argument for arbitrary products of unrelated relative categories, since there may be no uniform finite zigzag length. No such infinite assertion is needed here.

For **Der**2, the point is to represent a localized arrow by a genuine arrow after replacing its endpoints. Let f be an arrow of $\mathrm{HO}_W(I)$ whose evaluations are all invertible. Under the stated homotopy calculus, choose a representative $a : A \to B$ in $\mathcal{M}(I)$, with the endpoint identifications weak equivalences. Every a_i is invertible after localization in $\mathcal{M}$. Strong saturation of W implies $a_i \in W$, so $a \in W(I)$ and f is invertible. The source is correctly using both ingredients: componentwise detection in the original relative category and representability of arrows in the localized diagram category. Strong saturation alone would not supply the latter.

The word "triangulée" has a deliberately broader meaning in this passage than the Verdier definition. In a pointed homotopy theory one has cofiber sequences, fiber sequences, suspension and loop objects. Suspension need not be invertible, and there is no reason for the homotopy category to be additive. Pointed spaces give the basic example. An actual triangulated category emerges in the stable case, where suspension and loop are inverse equivalences and cocartesian squares agree with cartesian squares. For strong stable derivators, the canonical triangulations and exactness of the induced functors are established in Groth (2013, Theorem 4.16 and Proposition 4.18). This is a later completion of the stable part of the programme, not an assumption hidden in the quoted scholium.

The locally constant condition on p. 56 is likewise a condition on a coherent diagram. Its transition arrows become isomorphisms after localization, but the object still belongs to $\mathrm{HO}_W(I)$, not merely to $\mathrm{Fun}(I^{\mathrm{op}}, \mathrm{HO}_W(e))$. The higher coherence carries information. For ordinary model categories, the precise later answer is Cisinski (2009, Theorem 1.3): a functor inducing a weak equivalence of nerves induces an equivalence between the corresponding categories of locally constant diagrams. One can interpret this as dependence only on the infinity-groupoid obtained by inverting all arrows of the indexing category. It does not assert the result for every relative category merely satisfying the definition of quillenisability in §5; the necessary homotopy theory must still be available.

The axiom numbers are historical. The present **Der**3 concerns a localizer and locally constant objects, whereas **Der**4 and **Der**5 below concern existence and pointwise computation of right images. Modern texts commonly number the existence and pointwise axioms as Der3 and Der4, with strength as an additional Der5. A reference to a modern numbered axiom must therefore be translated by its content.

Commentary · Later developments [ms. 56]

Locally constant diagrams depend on the homotopy type

Grothendieck wants a homotopy-invariance theorem for coefficients, stronger than invariance of a single homotopy limit. A locally constant diagram sends every arrow of the indexing category to a weak equivalence. Its transition maps consequently remember transport along paths, together with the higher compatibility data carried by the original diagram before localization. This is why the whole homotopy type of the indexing category, rather than only its set of connected components, enters.

For an ordinary model category $\mathcal{V}$, Cisinski (2009, Theorem 1.3) proves the precise statement anticipated here: if $N(u)$ is a weak homotopy equivalence, restriction induces an equivalence between the homotopy categories of locally constant $\mathcal{V}$-valued diagrams. Corollary 1.28 gives the converse when all coefficient model categories are allowed; simplicial sets already suffice. Apply the theorem to the opposite indexing categories to match the presheaf convention of these pages. This is an

established answer for the usual localizer of nerve weak equivalences, not a conjecture awaiting the construction of $u_!$ or u_*.

In the language of higher categories, the reason is that a locally constant diagram factors through the groupoid completion of the index. That completion is the homotopy type represented by its nerve. An equivalence of those homotopy types induces an equivalence of their categories of functors into any fixed homotopy theory. The model-category theorem makes this explanation precise while retaining strict diagrams and their objectwise weak equivalences.

Two qualifications keep this comparison faithful to the text. The source's "Der 3, nouvelle mouture" is an axiom about local systems and a chosen fundamental localizer; it is not the modern axiom usually numbered (Der3), which asserts existence of homotopy Kan extensions. Also, a fixed coefficient theory may detect fewer distinctions between shapes than all coefficient theories together. Cisinski's converse uses the latter quantifier. We refer to the commentary on Chapter VI, manuscript pp. 161–165, for the detailed comparison of those two forms of detection, rather than repeating it here.

Je vais m'en occuper, une fois que j'aurai une maîtrise raisonnable sur le formalisme de u_*, $u_!$ relatif aux $u : I' \longrightarrow I$ dans Diag. L'hypothèse quillénisable seule semble trop grossière pour assurer l'existence de $u_!$ ou de $u_\star$ dans des cas intéressants.

[page 57]

6 Catégorie de modèles quillénisables, et foncteurs $u_!$, u_*

Définition 1 :

ⓐ On dit que $(\mathcal{M}, W)$ est *quillénisable uniformément à gauche* sur Diag, si on peut trouver une structure de Quillen faible (C, TC, F, TF) pour $\mathcal{M}$ qui soit *close,* et qui de plus ait la propriété suivante : pour I dans Cat, soient $C(I)$, $TC(I) \subset \mathrm{Fl}(\mathcal{M}(I))$ définis par

$$(u : X \longrightarrow Y) \in C(I) \text{ (resp. } TC(I)) \text{ si et seulement si } \forall\, s \in \mathrm{Ob}\, I,$$
$$u_s : X_s \longrightarrow Y_s \text{ est dans } C(I) \text{ (resp. } TC(I)).$$

Soit de plus

$$F(I) \;=\; TC(I)_*, \qquad TF(I) \;=\; C(I)_*.$$

La condition envisagée, c'est que pour tout I *dans* Diag, $(C(I), TC(I), F(I), TF(I))$ est une structure de Quillen faible *close exacte* pour $W(I)$ ([34]).

ⓑ On dit que $(\mathcal{M}, W)$ est *quillénisable sur Diag uniformément et exactement* `[à]` *gauche*, si on a de plus $TC = C \cap W$, *i.e.* si (C, TC, F, TF) est exacte à gauche, donc défini par C seul, via

$$TC = C \cap W, \qquad F = (TC)_*, \qquad TF = C_* \qquad ([35])$$

On a vu au paragraphe 3 que si $\mathcal{M}$ est stable par petites $\varinjlim$ et accessible, et W stable par petites $\varinjlim$ filtrantes, enfin si W admet une structure de Quillen faible (C, TC, F, TF) qui soit close et exacte à gauche – alors les conditions de la définition 1 sont satisfaites. p. 33 [page 58]

Commentary · Exposition [ms. 57]

Why uniform left structures produce right images

Grothendieck's word "uniform" puts the same replacement mechanism on every diagram category. With cofibrations and trivial cofibrations defined objectwise, restriction preserves both classes for the elementary reason that it merely selects components. This makes restriction the left-hand member

34. (C, TC, F, TF) est appelé alors une *quillénisation uniforme à gauche* de $(\mathcal{M}, W)$ sur Diag.

35. On dit que $(C, \ldots)$, ou simplement C, définit une *quillénisation uniforme et exacte à gauche* de $(\mathcal{M}, W)$ sur Diag.

of the relevant Quillen adjunction, even though its geometric name is "inverse image". Its right adjoint is therefore the functor on which fibrant replacement should be performed.

Write $u : I' \to I$ and assume that the ordinary right Kan extension exists. The lifting adjunction immediately gives

$$u_* F(I') \subset F(I), \qquad u_* TF(I') \subset TF(I).$$

For example, lifting a map of $\mathcal{M}(I)$ in $C(I)$ against $u_* p$ is equivalent to lifting its restriction, which lies in $C(I')$, against $p \in TF(I')$. The argument for F uses TC instead. Since u_* preserves the terminal object, it also preserves fibrant objects. These are the facts summarized before the theorem-scholie; they do not yet appeal to a formula for a homotopy limit.

The pointwise formula determines which ordinary limits must exist:

$$(u_* X')(s) = \varprojlim_{(i',\, u(i') \to s) \in I'/s} X'(i').$$

Here the displayed limit is the limit of the contravariant diagram on I'/s. A finite category has finitely many morphisms as well as finitely many objects, so these are finite limits when I and I' are finite. The phrase "$\varinjlim$ finies" on p. 59 is a source slip: the relevant half of **M**0 is finite *limits*. For an infinite comma category, neither **M**0 nor the word quillenisable creates the missing limit.

There are two ways to continue. The manuscript isolates preservation of weak equivalences between fibrant diagrams as a new condition called admissibility, then proves it by finite gluing. This is a sound and instructive construction of finite homotopy limits. The closed exact hypotheses also permit the general Brown argument given below, in the block "The Brown argument makes admissibility automatic". It shows that admissibility is automatic whenever the ordinary right Kan extension exists. Consequently the remaining substantive issue is existence of appropriate diagram structures and ordinary limits, rather than an independent homotopy-invariance property of their right adjoints.

For comparison, a combinatorial model category has both the injective and projective model structures on every small diagram category. The injective structure is the modern counterpart of the objectwise-cofibration construction used here, and the projective structure of its dual. The existence statement and its derivator application are respectively Theorem 1.28 and Proposition 1.30 of Groth (2013). The original finite-limit formulation is still useful when arbitrary small limits do not exist, as in bounded complexes; it then yields only the Kan extensions for which the underlying limit problem can be solved.

D'autre part, notons que la proposition 1 page 45 et ses corollaires, y inclus la proposition 3 (page 50) et ses corollaires, sont valables dès lors que les quillénisations des $(\mathcal{M}(I), W(I))$ envisagés sont définies "uniformément à gauche" par une quillénisation uniforme à gauche (pas nécessairement exacte à gauche) de $(\mathcal{M}, W)$ sur Diag.

Commentary · Exposition [ms. 58]

Closure and exactness already imply both trivial-class equalities

Grothendieck introduces uniform quillenization to remove the dependence of the cofibration classes on the shape. The exact definition on p. 57 has a useful consequence which shortens the later discussion. In each diagram category it asks for a structure which is both *closed* and *exact*. Together these hypotheses force the two equalities which define biexactness.

Indeed, suppose $i \in C \cap W$. Exactness factors this very map as

$$i = pj, \qquad j \in TC, \quad p \in TF.$$

Since $i \in C$ and $p \in TF$, the square with top map j and bottom map the identity has a lift. The usual retract argument makes i a retract of j in the arrow category. Closedness of TC gives $i \in TC$. Thus $C \cap W = TC$. Dually, factoring $p \in F \cap W$ as qj with $j \in TC$, $q \in TF$ makes p a retract of q, so $F \cap W = TF$. These are applications of the ordinary retract argument, as in Hovey (1999a, Lemma 1.1.9); no transfinite construction is involved.

Consequently a closed exact weak structure is perfect in the manuscript's terminology. In particular, if the domain contains the terminal category, as stipulated on p. 51, Definition 1(a) already implies the additional equality in Definition 1(b). The advertised distinction between

uniform quillenizability and uniform *exact* left quillenizability is therefore redundant under the printed hypotheses. This is a logical consequence of those hypotheses, not a proposed emendation of the French text. If "exact" were removed from Definition 1(a), there would be a different and genuinely weaker notion, but that is not the definition supplied here.

The formula in Definition 1(a) has a separate typographical error: a component $u_s : X_s \to Y_s$ belongs to C or TC, not to $C(I)$ or $TC(I)$. The latter classes contain natural transformations, so the printed condition is not well-typed. The correction ledger records the error as a slip of the edition and preserves the printed text. After reading the component condition correctly, the uniform structures are precisely injective model structures with the same underlying cofibration classes, subject here also to the properness axiom M″ and to the available finite or small limits.

La quillénisation uniforme gauche nous servira à établir l'existence des images directes homotopiques u_*, pour certains u. La quillénisation uniforme droite, dualement, aura comme conséquence principale l'existence des $u_!$ homotopiques pour certains $u : I' \longrightarrow I$ dans Diag.

Je vais résumer ce que j'ai pu établir jusqu'à présent dans ce sens, dans le

Commentary · Later developments [ms. 59]

The Brown argument makes admissibility automatic

The purpose of admissibility is to ensure that a limit of a suitably fibrant diagram depends only on its homotopy class. Under the closed exact hypotheses actually imposed in Definition 1, this is already a consequence of the lifting and factorization axioms. We give the argument explicitly, since it both strengthens the theorem-scholie and settles the later questions without assuming the existence of limits which the source has not provided.

First recall the consequence of closedness and exactness proved above: $F \cap W = TF$. Let $T : \mathcal{C} \to \mathcal{E}$ be a functor, where $\mathcal{C}$ has the source's closed exact structure and $\mathcal{E}$ has a class V containing the identity maps and satisfying two-out-of-three. Assume that T carries trivial fibrations

between fibrant objects into V. If $f : X \to Y$ is a weak equivalence between fibrant objects, factor its graph as

$$X \xrightarrow{i} Z \xrightarrow{p} X \times Y, \qquad i \in TC, \quad p \in F, \quad pi = (1_X, f).$$

Put $p_X = \mathrm{pr}_X\, p$ and $p_Y = \mathrm{pr}_Y\, p$. The two projections are fibrations because X and Y are fibrant. Consequently Z is fibrant and $p_X, p_Y \in F$. The identities $p_X i = 1_X$ and $p_Y i = f$, together with $i, f \in W$, imply $p_X, p_Y \in W$. Both maps therefore lie in TF. Their images under T belong to V. Since $T(p_X)T(i) = 1$, two-out-of-three first gives $T(i) \in V$ and then gives

$$T(f) = T(p_Y)T(i) \in V.$$

This is the dual form of Ken Brown's lemma (Hovey, 1999a, Lemma 1.1.12). We have displayed its proof to identify the exact hypotheses used: finite products, factorization, composition and pullback stability of F, two-out-of-three, and the equality $TF = F \cap W$. There is no appeal to smallness, accessibility, or filtered colimits.

Apply this to $T = u_*$. Uniformity makes u^* preserve $C(I)$, so the lifting adjunction makes u_* preserve $TF(I')$. It also preserves fibrant objects. The lemma gives precisely

$$f \in W(I'), \quad X', Y' \in \mathcal{M}(I')_{\mathrm{f}} \quad \Longrightarrow \quad u_* f \in W(I).$$

Thus every functor u for which the ordinary right Kan extension exists is admissible under the stated uniform closed exact assumptions. The finite-poset theorem remains correct, but its restriction on shapes is unnecessary for this particular homotopy-invariance assertion.

The conclusion should not be enlarged in a different direction. It does not manufacture an ordinary right adjoint in a category lacking the required limits. Nor does it, by itself, prove the pointwise homotopy formula: that formula additionally needs fibrant restriction to the comma categories, as discussed at p. 72. These are genuine existence and compatibility questions. The question of preserving weak equivalences *after the relevant fibrant replacements exist* is answered by the short argument above. We attribute it to the established Brown lemma, rather than present the application as a new result.

Commentary · Later developments [ms. 60]

Every available right Kan extension is admissible

Grothendieck's admissibility condition asks for the exact homotopical property needed to derive u_*. Under the uniform hypotheses actually printed on p. 57, it holds for every functor for which the ordinary right Kan extension exists. There is no restriction to finite posets. The reason is the dual of Ken Brown's lemma, whose standard statement is Hovey (1999a, Lemma 1.1.12).

We give the short proof in the present notation. By the preceding retract argument, each uniform structure is perfect. Proposition 1 says that u_* preserves F and TF; as a right adjoint it preserves the terminal object, and hence fibrant objects. Let $f : X \to Y$ be a weak equivalence between fibrant diagrams. Factor its graph as

$$X \xrightarrow{j} Z \xrightarrow{q} X \times Y, \qquad j \in TC, \quad q \in F.$$

The composites $q_X : Z \to X$ and $q_Y : Z \to Y$ are fibrations because X and Y are fibrant. Their identities $q_X j = 1_X$ and $q_Y j = f$, together with $j, f \in W$, show that both belong to W. Biexactness gives $q_X, q_Y \in TF$. Their images under u_* therefore lie in W. The equality $(u_* q_X)(u_* j) = 1$ and two-out-of-three show $u_* j \in W$; hence $u_* f = (u_* q_Y)(u_* j) \in W$. This is precisely admissibility.

Choosing a fibrant replacement $X \to RX$ now defines

$$\mathbf{R}u_*[X] = [u_* RX].$$

Brown's lemma ensures independence of the replacement in the localized category. The adjunction with the derived left functor of u^* is the usual derived Quillen adjunction; since restriction already preserves all objectwise weak equivalences, that left derived functor is u^* itself. Thus $u^* \dashv \mathbf{R}u_*$. The dual argument with uniformly right-defined structures gives $\mathbf{L}u_! \dashv u^*$. This is exactly the construction developed in Hovey (1999a, Definition 1.3.6 and Lemma 1.3.10).

The pointwise criterion in part (a) remains useful for calculations. In the right Kan formula, the projection $I'/s \to I'$ is a discrete fibration. When the requisite fibre coproducts exist, in

particular for finite indexing categories, the left Kan extension of presheaves along such a projection is computed by those coproducts: each relevant comma component has an initial object obtained by lifting the arrow to the fibre. It therefore preserves TC, so restriction preserves fibrant diagrams. The admissibility of the slice then makes the pointwise limit preserve weak equivalences. If I is a poset, the slice projection identifies its domain with a sieve, as the author says. Under the full uniform hypotheses, the global Brown argument has already established both sides of the proposed converse, without requiring these auxiliary coproducts.

This proof uses finite products and factorizations in the diagram categories, plus the existence of the indicated right adjoint. The parenthesis on p. 59 should invoke finite *limits*; it prints finite colimits. Both are included in M 0, so this slip does not invalidate the finite-index assertion. Up to manuscript p. 60 the theorem is only stated; the proof above supplies its admissibility conclusion independently of the continuation.

Commentary · Exposition [ms. 60]

The noetherian sober poset condition is finite

Grothendieck tries to enlarge the finite-poset case by replacing finite induction with topological noetherian induction. For the usual Alexandrov topology attached to a poset, however, the two hypotheses he writes down already force finiteness. The observation concerns this topology, in which arbitrary intersections of open sets are open; it would not be true for arbitrary noetherian sober spaces.

To make the order convention immaterial, let P be the specialization poset and take its Alexandrov opens to be the upper sets. Closed sets are lower sets. An irreducible nonempty closed set is then exactly a directed lower set. For one direction, if D is directed and meets two upper open sets, a common upper bound in D lies in their intersection. Conversely, if a lower set D is irreducible and $x, y \in D$, the open sets $\uparrow x$ and $\uparrow y$ both meet D, so their intersection meets D; that is a common upper bound in D. Sobriety says that each such directed lower set is $\downarrow z$ for a unique z.

It follows that P has no strictly increasing infinite sequence. Otherwise, from $x_0 < x_1 < \cdots$ form the directed lower set $D = \bigcup_n \downarrow x_n$. If $D = \downarrow z$, then $z \leq x_N$ for some N, whereas $x_{N+1} \leq z$, a contradiction. This is the sobriety criterion of Picado and Pultr (2012, Chapter II, Proposition 6.4.4).

Every nonempty subset of P consequently has a maximal element: starting from an element with no maximal element above it would produce such an increasing sequence. A maximal element m of a subset S is isolated in S, since $(\uparrow m) \cap S = \{m\}$. The Alexandrov space is therefore scattered, meaning that every nonempty subspace has an isolated point.

Now use noetherianity only once. Among the finite open subsets choose a maximal one, U; it exists because a strictly increasing sequence of finite open subsets is forbidden. If the complement $P \setminus U$ were nonempty, scatteredness would give an isolated point x in that subspace. There would be an open V of P with $V \cap (P \setminus U) = \{x\}$. Then $U \cup V = U \cup \{x\}$ would be a strictly larger finite open set, contradicting maximality. Hence $P = U$ is finite.

Applied to I^{op}, the proof shows that the class on p. 60 consists exactly of finite posets. Both chain conditions are used: the order condition controls sobriety, and topological noetherianity controls opens. The sequence arguments use classical choice.

Overview · XIII-a

Chapter XIII, first part: building the machinery that can later be forgotten.

These sixty manuscript pages turn from the intrinsic calculus of a localizer to the auxiliary structures that make it calculable. Grothendieck calls a pair $(\mathcal{M}, W)$ a category of models when W contains the isomorphisms and satisfies two-out-of-three. This is much less than what "model category" ordinarily means today. He seeks classes of cofibrations and fibrations that provide replacements, homotopy fibres and cofibres, and eventually the two derived Kan extensions. Their purpose is to establish properties of the localized diagram categories

$$\mathrm{HO}_W(I) = \mathcal{M}^{I^{\mathrm{op}}}[W(I)^{-1}],$$

where $W(I)$ is defined objectwise. Once these constructions and their universal properties have been established, the auxiliary classes should cease to be part of the intrinsic answer (Grothendieck, 1990–1991e, manuscript pp. 12–14).

The chapter opens with the algebra of lifting properties. In current notation, Grothendieck's Φ_* is $\Phi^{\square}$, his Ψ^* is ${}^{\square}\Psi$, and his "couple de Quillen" is a weak factorization system. It is not what is now called a Quillen adjunction. The Galois connection explains why left classes are stable under pushouts, retracts, and continuous transfinite compositions, and why right classes have the dual properties. The small-object theorem then supplies factorizations from a set of generating arrows in a locally presentable category. Our commentary proves the construction with its cardinal bound and separates the cellular class from its retract closure. This distinction matters because factorization can exist before the two classes are closed under retracts.

The intrinsic classes Cof_W and Fib_W express preservation of weak equivalences under cobase change and base change. They are not defined by a lifting property. Their relation to the universally trivial arrows is established using the factorization hypotheses, not just two-out-of-three. The base-change argument on manuscript pages 10–11 is particularly economical: factor the change of base, apply the fibration condition along its weak-equivalence part, and use two-out-of-three. The commentary expands this proof and gives a three-element-poset example showing why the factorization assumption cannot simply be omitted.

The conjectural theorem of manuscript pages 14–26 asks whether the intrinsic classes contain small collections of tests sufficient to build the desired structures. Here three different forms of smallness enter: closure under filtered colimits, accessibility of a full subcategory of the arrow category, and generation of a lifting class by a set. They do not mean the same thing. In particular, even an accessible left lifting class can fail to be generated by a set in the ordinary small-object sense; the order-embedding example is worked out in the commentary. Conversely, one specific conjecture in these pages has a precise later answer: intersections of two set-generated left classes in a locally presentable category are again set-generated, by the limit theorem for combinatorial cellular categories (Makkai and Rosický, 2014a, Theorem 3.2 and Remark 3.8).

Smith's recognition theorem gives a useful repair of the larger programme. One fixes a set of generating cofibrations, assumes that its right orthogonal consists of weak equivalences, requires the trivial cofibrations to be stable under pushouts and transfinite composition, and imposes a solution-set condition on W. Under these hypotheses one obtains an ordinary cofibrantly generated model structure (Beke, 2000, Theorem 1.7). With the intrinsic inclusions envisaged here, the resulting structure is proper. This is a theorem with explicit extra hypotheses, not a proof that the manuscript's filtered-colimit assumption alone yields every assertion in its conjectural equivalence. The audit records the individual implications and their dependencies rather than assigning one status to the whole discussion.

The second formulation, beginning on manuscript page 27, isolates a different issue. A weak Quillen structure is called exact when $W = TF \circ TC$; it is left exact when $TC = C \cap W$

and right exact when $TF = F \cap W$. These distinctions are meaningful for classes that have not been closed under retracts. The marginal claim that retract closure of C, F, W alone makes the two one-sided exactness conditions equivalent is false. Our example in sets takes $C = TC$ to be the monomorphisms, F the surjections, W all maps, and TF the surjections whose fibres are singletons or infinite. It satisfies the weak axioms and left exactness, but excludes the map from a two-element set to a singleton from TF. The missing retract condition is visible directly.

Exactness nevertheless permits a useful completion without any retract closure assumption. If $j \in C \cap W$, factor $j = qi$ with $i \in TC$ and $q \in TF$. The lifting axiom makes j a retract of i, so j has the left lifting property against every fibration. The dual argument applies to $F \cap W$. Replacing the two designated trivial classes by $C \cap W$ and $F \cap W$ therefore gives a biexact Quillen structure with the same C, F, W. Properness supplies the required stability under base and cobase change. This is a completion of the designated classes; the counterexample shows why it cannot be replaced by an assertion that they were equal already. When all four original classes are closed, the completion makes no change, and a *closed exact* weak structure is already perfect. We use this observation again at the end of these pages to remove an unnecessary admissibility restriction on right Quillen functors.

The discussion of homotopy on manuscript pages 29–34 concerns the actual morphisms in the localization. Replacing objects by objects that are both cofibrant and fibrant is not yet the same as proving that all localized morphisms are represented by single arrows. Exactness supplies such representatives. We first prove a description by the congruence generated jointly by left and right homotopies. The completion then identifies each of the usual homotopies with equality after localization for a cofibrant source and a fibrant target. It also resolves the doubts on manuscript pages 32–34: homotopy-cartesian and homotopy-cocartesian squares are exact under the weak exact axioms themselves. An endpoint-lifting argument makes the first assertion explicit; the extra hypothesis about the diagram category used in the source's proposed proof is unnecessary for this conclusion. Pointedness gives the suspension and loop sequences. Stability is the additional condition needed for a triangulated structure. The separate suggestion about raw right homotopy depends on the path-object convention. A graph example, adapted from Kurz and Rosický (2005, Example 3.6), shows that paths supplied by the designated factorization system need not give a transitive relation without exactness, even on fibrant-cofibrant objects. Allowing some weak-equivalence–fibration path object gives an equivalence relation for a fibrant target by the concatenation argument proved in the commentary.

The passage to presheaves supplies the chapter's central technical test. Objectwise cofibrations lead to an injective diagram structure. Its fibrations are defined by lifting against all objectwise trivial cofibrations, and need not be merely objectwise fibrations. The calculation

$$(\alpha_{s!}A)(t) = \coprod_{\mathrm{Hom}_I(t,s)} A$$

explains the coproduct hypothesis in the evaluation lemma. The subsequent failure of componentwise factorization to solve natural lifting problems is exhibited by explicit examples. Modern existence results for injective structures apply in the combinatorial setting, while the cellular-category theorem also accounts for the set-generation of the pointwise left classes (Makkai and Rosický, 2014a, Corollary 3.4).

The variances then become transparent. Restriction preserves the objectwise cofibrations and trivial cofibrations, so its right adjoint is right Quillen. Its left adjoint is not automatically left Quillen for these same injective structures. Above all, an ordinary Kan extension and its derived functor are different constructions. Grothendieck explicitly withdraws the premature identification on manuscript pages 49–50. The commentary supplies counterexamples and the appropriate derived statements. Under the uniform closed exact hypotheses finally adopted on

manuscript page 57, every existing ordinary right Kan extension preserves weak equivalences between injectively fibrant diagrams by Brown's lemma. Consequently the final admissibility conclusion holds for every such indexing functor, beyond the finite posets singled out in the text.

Complexes give a complementary warning about size. For an infinite indexing category, a diagram of individually bounded-below complexes need not have a common lower bound. It therefore need not be a bounded-below complex in the abelian category of diagrams. A family with nonzero cohomology in successively lower degrees makes the resulting failure of a product in $D^{+}(\mathbf{Ab})$ explicit. Unbounded derived operations in Grothendieck abelian categories are instead available through suitable resolutions and model structures; the boundedness issue concerns the chosen subcategory and cannot be removed by renaming it.

The later derivator constructions realize the intended independence from presentation. Cisinski supplies homotopy right Kan extensions for general closed model categories with small limits (Cisinski, 2003, Theorem 6.11); Renaudin compares the localized 2-category of suitable combinatorial presentations with derivators of small presentation (Renaudin, 2009, Theorems 3.3.2 and 3.4.4); and the infinity-categorical treatment recovers the same pointwise comparison laws from Kan extensions in the underlying infinity-category (Riehl and Verity, 2017, Proposition 5.3.9 and Remark 5.3.10). These results give precise answers in their respective settings. The final order-topological extension also becomes precise: a noetherian sober Alexandrov T_0 space is finite, so under the ordinary poset topology the apparently broader class of shapes on manuscript page 60 adds no new cases. For the weakest recognition assertions of the manuscript, what was established here is kept apart from what was not located in the checked literature. An unlocated proof is not certified as an open problem.

p. 34

c) *En particulier, si I', I sont des ensembles ordonnés finis, alors tout $u : I' \longrightarrow I$ est admissible. Il en est de même, plus généralement, si I, I' sont des ensembles ordonnés et I'° est un espace noethérien sobre.*

2) *Supposons $u : I' \longrightarrow I$ admissible. Considérons*

$$u_*^W \ : \ \underbrace{\mathcal{M}(I')_{\mathrm{f}} W(I')_{\mathrm{f}}^{-1}}_{\simeq \mathrm{HO}_W(I')} \ \longrightarrow \ \underbrace{\mathcal{M}(I)_{\mathrm{f}} W(I)_{\mathrm{f}}^{-1}}_{\mathrm{HO}_W(I)},$$

induit par u_*. Ce foncteur est adjoint à droite de $u_W^* : \mathrm{HO}_W(I) \longrightarrow \mathrm{HO}_W(I')$.
De plus, l'homomorphisme canonique (pour $s \in \mathrm{Ob}I$, $X' \in \mathrm{Ob}\mathrm{HO}_W(I')$) [page 61]

$$u_*^W(X')(s) \ \simeq \ p_{s*}(X'|I'/s) \ \overset{\text{déf}}{=} \ \underset{\longleftarrow I'/s}{\mathrm{holim}}_W(X'|I'/s)$$

(où $p_s : I'/s \longrightarrow e$) est un isomorphisme, si on suppose que les I'/s sont admissibles (on dira alors que u est strictement *admissible).*

Corollaire. *Sur le domaine formé des ensembles ordonnés finis, le prédérivateur* HO_W *satisfait (en plus des axiomes* **Der** 1, **Der** 2*) aux axiomes* **Der** 4 *et* **Der** 5 *(existence des images directes u_*, adjoints à droite des foncteurs u^*, et calcul standard des fibres d'une image directe).*

Démonstration du théorème-scholie.

1°) *a*) est immédiat. Pour *b*), on procède par récurrence sur le cardinal n de l'ensemble ordonné fini I, les cas $n \in \{0, 1\}$ étant triviaux. Supposons donc $n \geq 2$, et le théorème prouvé pour les $n' < n$. Je distingue deux cas : si I admet un plus grand élément a, alors, désignant par $\alpha : e \longrightarrow I$ le foncteur de valeur a, par $p : I \longrightarrow e$ la projection, on sait que l'on a

$$p_* \ \simeq \ \alpha^*, \qquad i.e. \ \varprojlim_I X_i \simeq X_a,$$

d'où le fait que sur $\mathcal{M}(I)$ tout entier (pas seulement sur $\mathcal{M}(I)_{\mathrm{f}}$), p_* est compatible aux localiseurs $W(I)$, W. [page 62]

Commentary · Exposition [ms. 61]

Finite limits assembled from a two-piece cover

Grothendieck's finite-poset induction makes the geometry of a homotopy limit visible. Instead of treating a large compatibility diagram at once, he cuts the indexing poset into two lower sets and glues the two resulting limits over their overlap. This argument remains useful even though the Brown lemma gives a shorter proof of admissibility under the stronger standing hypotheses.

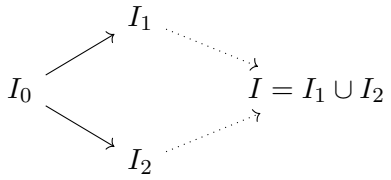
Let $I = I_1 \cup I_2$ with I_1, I_2 lower subsets, and put $I_0 = I_1 \cap I_2$. Define $v : I \to \Psi = (1 \leftarrow 0 \to 2)$ by sending the overlap to 0, the points belonging only to I_1 to 1, and those belonging only to I_2 to 2. The lower-set condition makes this assignment order preserving: an arrow cannot travel from one exclusive part into the other. Its comma categories over $0, 1, 2$ are precisely I_0, I_1, I_2. Right Kan extension along v therefore produces the span

$$\varprojlim_{I_1} X \longrightarrow \varprojlim_{I_0} X \longleftarrow \varprojlim_{I_2} X.$$

Taking its pullback gives $\varprojlim_I X$. Indeed, a cone to X is exactly a pair of cones to its restrictions whose two cones on I_0 agree. This proves the ordinary limit identity by its universal property, including the cases in which the overlap is empty.

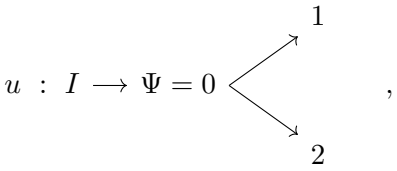
For a finite nonempty poset without a greatest element, partition its maximal elements into two nonempty sets M_1, M_2 and take $I_j = \bigcup_{m \in M_j} \{i : i \leq m\}$. Every point lies below a maximal

element, so the lower sets cover I, and neither is all of I. Their overlap is also smaller. The inductive argument is therefore well founded. If I has a greatest element a, the limit is X_a in the source's contravariant convention; the empty poset has the terminal object as its limit.



The homotopical step is to ensure that the span just constructed is fibrant. Right Kan extension preserves fibrancy, and a fibrant Ψ-diagram consists of fibrant objects A_0, A_1, A_2 with both arrows $A_j \to A_0$ fibrations. Its ordinary pullback then represents its homotopy pullback. The induction replaces "take an arbitrary pullback" by "take a pullback whose legs satisfy a lifting condition". The latter is the operation stable under weak equivalences of the input span.

Composition of admissible functors is also transparent at this point. If u and v preserve weak equivalences between fibrant diagrams after right Kan extension, then u_* first yields another fibrant diagram, to which v_* can be applied. The canonical identification $(vu)_* \cong v_* u_*$ proves admissibility of the composite. No new comparison of replacements is required. This explains why the elementary shape Ψ controls the whole finite induction.

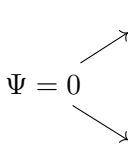


Si I n'a pas de plus grand élément, alors l'ensemble M des ses éléments maximaux est de cardinal ≥ 2, on peut donc l'écrire $M = M_1 \amalg M_2$, et on aura

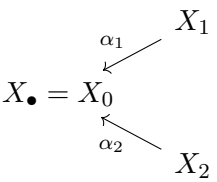
$$I \;=\; I_1 \cup I_2, \qquad \text{où } I_1 = I/M_1,\ I_2 = I/M_2$$

sont deux ouverts de I, différents de I, donc de cardinaux n_1, $n_2 \;<\; n$. Considérons aussi $I_0 = I_1 \cap I_2$, c'est un ouvert de cardinal $< n$. Le diagramme

correspond à une flèche p. 35



,



avec

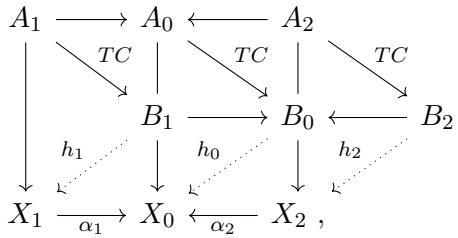
$$I_1 \;=\; I/1, \qquad I_2 \;=\; I/2, \qquad I_0 \;=\; I/0.$$

L'hypothèse de récurrence et *a*) impliquent que u est admissible. Comme un composé de foncteurs admissibles est admissible (tautologiquement, via $(vu)_* \simeq v_* u_*$), on est réduit finalement au [page 63]

Lemme. *La catégorie*  *est admissible.*

Ceci va résulter du

Corollaire ([36]). *Soit*  *dans $\mathcal{M}(\Psi)$. Pour que $X_\bullet$ soit fibrant, il faut*



et il suffit que l'on ait

36. **NB** Il y a une variante évidente, caractérisant les X tels que $X \longrightarrow e$ soit dans $TF(\Psi)$ comme ceux pour lesquels X_0, X_1, X_2 sont fibrants *triviaux,* et α_1, $\alpha_2 \in TF$.

a) X_0, X_1, X_2 *sont fibrants, et*

b) α_1, $\alpha_2 \in F$.

La nécessité de *a*) est cas particulier du corollaire 2, page 48, celle de *b*) est cas particulier du corollaire 1 page 50. Pour la suffisance (dont on n'aura pas besoin pour le théorème), on sait montrer que dans le diagramme commutatif à traits pleins

avec trois flèches marquées TC, on peut trouver h_1, h_0, h_2 laissant le diagramme commutatif (trois triangles et deux carrés commutatifs à respecter). Pour ceci, on commence par choisir h_0 de façon à rendre le triangle vertical médian commutatif – c'est possible car X_0 est fibrant, $A_0 \longrightarrow B_0$ dans TC.

p. 36
[page 64]

Commentary · Examples [ms. 63]

Matching objects explain the lifting diagram

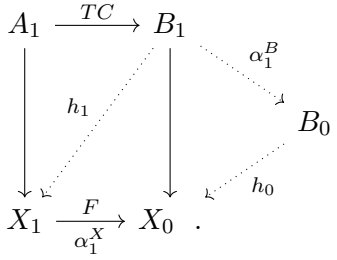
Grothendieck's three lifts express a recursive compatibility condition. The lift at X_0 must be chosen first, because the two remaining lifts are required to induce that same map after composition with $X_1 \to X_0$ and $X_2 \to X_0$. Choosing three unrelated lifts from objectwise fibrancy would not enforce the squares. The fibrations on the two legs are exactly what turns each final choice into a lifting problem with a prescribed target.

The calculation is the smallest instance of the matching-object description for an inverse diagram. Let I be a finite poset, still indexing contravariant diagrams. For $i \in I$ put

$$M_i X = \varprojlim_{j<i} X_j.$$

An injectively fibrant diagram is characterized by the requirement that each natural map $X_i \to M_i X$ be a fibration. When i has no smaller element, the matching object is terminal, so this says that X_i is fibrant. For $I = \Psi$, the matching objects are $M_0 X = e$ and $M_1 X = M_2 X = X_0$, giving exactly the corollary. This is the inverse-category case of the familiar Reedy description (Hovey, 1999a, Theorem 5.1.3).

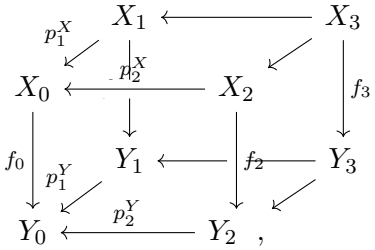
The lifting criterion can be proved without invoking the terminology. Choose a linear ordering of the finite set of vertices in which smaller vertices occur first. Given an objectwise trivial cofibration $A \to B$ and a map $A \to X$, suppose the lift $B_j \to X_j$ has been chosen for every $j < i$. These maps induce $B_i \to M_i X$. The desired map $B_i \to X_i$ is now a lift in the square whose left side is $A_i \to B_i$ and whose right side is $X_i \to M_i X$. Proceeding through the vertices gives a natural transformation $B \to X$.



For necessity, start with a lifting problem $A \to X_i$, $B \to M_i X$, where $A \to B$ is a trivial cofibration. Form two diagrams which equal X_j for $j < i$, take the values A and B at i, respectively, and equal the initial object outside the lower subset $\{j : j \le i\}$. The given maps to the matching object specify their transition maps. Extension by the initial object is consistent because this subset is lower. Their comparison is objectwise a trivial cofibration, and the first diagram maps to X by the identity below i and the given map at i. A lift against $X \to e$ supplies the required $B \to X_i$. This proves the converse. The same finite recursion, factoring $X_i \to M_i(RX)$ at each stage as a trivial cofibration followed by a fibration, constructs a fibrant replacement $X \to RX$.

The condition becomes more informative at a branching vertex. Consider the diamond $0 < 1 < 3$, $0 < 2 < 3$. Its top matching object is

$$M_3 X = X_1 \times_{X_0} X_2.$$



> In cochain complexes of vector spaces over a field k, take $X_0 = 0$ and $X_1 = X_2 = X_3 = k[0]$, with both maps from X_3 equal to the identity. All objects are fibrant in the usual model structure, and every nonidentity arrow of this diagram is a fibration: the maps are degreewise surjective. Yet
>
> $$X_3 \longrightarrow M_3X = k[0] \oplus k[0]$$
>
> is the diagonal and is not surjective. The diagram is not injectively fibrant. Thus the two separate legs happen to suffice for Ψ, whereas a general poset requires compatibility with the entire lower matching diagram. This distinction is why replacements of diagrams carry more information than separate replacements of their components.

Ensuite, on voit séparément pour h_1, h_2, qu'on peut les trouver en satisfaisant chacune aux deux contraintes de commutativité (1 triangle vertical et un carré penché). Pour h_1 p. ex. l'existence se voit sur le diagramme carré auxiliaire (traits pleins)

NB C'est la démonstration de la proposition 3, page 50.

Le corollaire (partie "il faut") étant vu, le lemme en résulte, car on sait que si on a un homomorphisme f de carrés cartésiens X, Y

avec

$$p_1^X,\ p_2^X,\ p_1^Y,\ p_2^Y \ \text{ fibrants } \texttt{[appartenant à } F\texttt{]} \text{ (il suffit même } p_1^X \text{ et } p_1^Y \text{ fibrant)},$$

et

$$f_0,\ f_1,\ f_2 \ \in\ W,$$

alors $f_3 \in W$. (Ça a été vu dans la théorie des produits fibrés W-homotopiques `[voir chapitre XII, p. 253]`, et la vérification directe est immédiate.) De l'hypothèse initiale [page 65]

pertinente que $\begin{matrix} & X_1 & \\ X_0 & & \\ & X_2 & \end{matrix}$ et $\begin{matrix} & Y_1 & \\ Y_0 & & \\ & Y_2 & \end{matrix}$ sont fibrants, on n'a besoin d'utiliser qu'un petit

bout, p. ex. que p_1^X et p_1^Y sont fibrants, qui assure que les deux carrés X, Y sont W-homotopiquement cartésiens, ce qui suffit à impliquer alors que $f_0,\ f_1,\ f_2 \in W \Longrightarrow f_3 \in W$.

Commentary · Examples [ms. 64]

A homotopy pullback computed as a complex

Grothendieck uses the pullback lemma to make finite gluing invariant under weak equivalences. A concrete calculation shows what fibrant replacement adds to an ordinary pullback. Work with cochain complexes over a field and consider maps $a : X_1 \to X_0$ and $b : X_2 \to X_0$. A model for their homotopy pullback is

$$H = \mathrm{Cone}(a - b : X_1 \oplus X_2 \to X_0)[-1].$$

With coordinates chosen so that

$$H^n = X_1^n \oplus X_2^n \oplus X_0^{n-1}, \quad d(x_1, x_2, h) = (dx_1, dx_2, -dh + a(x_1) - b(x_2)),$$

the equation $d^2 = 0$ follows from the fact that a and b are chain maps. The third coordinate records the homotopy witnessing equality of the first two images. A strict pullback asks those images to be equal without this additional coordinate.

To verify that this complex computes the derived pullback, replace a by the surjective map $\widetilde{X}_1 \to X_0$, where

$$\widetilde{X}_1^n = X_1^n \oplus X_0^n \oplus X_0^{n-1}, \quad d(x, z, h) = (dx, dz, -dh + a(x) - z),$$

and the map to X_0 is $(x, z, h) \mapsto z$. The inclusion $x \mapsto (x, a(x), 0)$ is a quasi-isomorphism: the projection back to X_1 has kernel the contractible complex with differential $(z, h) \mapsto (dz, -dh - z)$, contracted by $(z, h) \mapsto (-h, 0)$. The new map is degreewise surjective and hence a fibration. Its ordinary pullback along b imposes $z = b(x_2)$ and is exactly the displayed complex H.

There is a short exact sequence of complexes

$$0 \longrightarrow X_0[-1] \longrightarrow H \longrightarrow X_1 \oplus X_2 \longrightarrow 0.$$

Its connecting map on cohomology is induced by $a - b$. This gives the usual exact sequence for a homotopy pullback and also proves invariance directly: a componentwise quasi-isomorphism between two such spans induces an isomorphism on the two outside terms of the associated long exact sequences, and hence on the middle term. If $a - b$ is degreewise surjective, its ordinary kernel maps quasi-isomorphically to H. In particular this occurs when either a or b is degreewise surjective, exactly the fibration condition relevant to this model.

For the span $0 \to k[0] \leftarrow 0$, the ordinary pullback is zero, while $H = k[-1]$ has $H^1(H) = k$. A fibration replacement of one leg restores this missing class. This is the algebraic version of the familiar fact that the homotopy pullback of the basepoint maps $* \to Y \leftarrow *$ is the loop object of Y. It explains both why the manuscript requires fibrant legs and why its gluing step cannot be replaced by taking limits in the homotopy category with no coherent diagram behind them.

In the source's general framework, the corresponding invariance statement uses the W-fibration property included in $\mathbf{M}''$, or the equivalent derived-functor argument under the closed exact hypotheses. No failure of properness is being overlooked in the proof on pp. 64–65: the relevant base-change compatibility is already among its assumptions. The statement that one fibrant leg suffices concerns this particular pullback computation, not a claim that all transition maps in an arbitrary diagram can be ignored.

Je vais essayer de généraliser ce raisonnement, pour traiter le cas d'un ensemble ordonné I qui peut être infini, mais tel que I° soit noethérien et sobre, donc toute suite croissante de parties fermées de I, et toute suite décroissante de parties ouvertes, est stationnaire, et de plus toute partie ouverte filtrante croissante a un plus grand élément.

On veut prouver que I est admissible, et par "récurrence noethérienne" on est ramené p. 37
à prouver ceci : $(*)$ Si I est tel que pour tout ouvert $I' \subset I$, avec $I' \neq I$, I' soit admissible, alors I aussi.

$(*)$ admis, prouvons que $I = I_0$ est admissible.

S'il ne l'était, par $(*)$ il existerait $I_1 \subset I_0$, $I_1 \neq I_0$, tel que I_1 non admissible. De même, [page 66]
il y aurait $I_2 \subset I_1$, $I_2 \neq I_1$, non admissible etc. – on aurait construit une suite strictement décroissante d'ouverts I_n de I, contrairement au caractère noethérien de I°.

Prouvons $(*)$, et distinguons encore deux cas.

a) I° est irréductible, donc admet un point générique, *i.e.* un plus petit élément, *i.e.* I admet un plus grand élément. Ce cas a déjà été traité tantôt – toute catégorie avec objet final est admissible.

b) I° est réductible, donc réunion de deux fermés I_1°, I_2° distincts de I°, donc I est réunion de deux ouverts I_1, I_2 distincts de I. Alors par l'hypothèse dans $(*)$, I_1, I_2 et $I_0 = I_1 \cap I_2$ sont admissibles. On termine alors comme tantôt, étant ramené à l'admissibilité

de $\Psi = 0 \begin{cases} \nearrow 1 \\ \searrow 2 \end{cases}$!

Prouvons la partie *c*) du théorème-scholie, partie 1°). Cela résulte de *a*), une fois vu [page 67] que pour $s \in I$, I'/s satisfait aux mêmes hypothèses que I'. Or I étant ordonné, I/s est une sous-catégorie ouverte de I, donc I'/s une sous-catégorie ouverte de I', dont $(I'/s)^\circ$ un sous-ensemble ordonné fermé de I'°. Ce dernier étant noethérien et sobre, il en est de même de tout fermé, d'où la conclusion.

Commentary · Exposition [ms. 66]

The proposed noetherian enlargement is actually finite

Grothendieck's noetherian induction is patterned on the decomposition of a closed space into irreducible pieces. A generic point makes one piece have a greatest indexing object, and a reducible piece can be glued from two smaller ones. The induction is valid. For the specific Alexandrov topology of a poset, however, the combination "noetherian and sober" is stronger than it first appears: it forces the poset to be finite. Thus this paragraph does not in fact add infinite diagram shapes.

We verify the assertion in the precise order convention used here. Opens of I are lower subsets, so opens of I^{op} are upper subsets of I. Sobriety of I^{op} says that every nonempty directed lower subset of I has a greatest element. If $x_0 < x_1 < \cdots$ were a strictly increasing sequence, its downward closure would be directed. It could not have a greatest element: any alleged greatest element belongs below some x_n, whereas x_{n+1} is strictly larger. Consequently every nonempty subset of I has a maximal element; otherwise dependent choice would construct such a sequence. This is the order-theoretic sobriety criterion, with the order reversed, in Lindenhovius (2014, Proposition B.5).

Let X denote I with its upper topology, that is, the topology of I^{op}. Every nonempty subspace $S \subset X$ has an isolated point: take a maximal element m of S, so that $S \cap \{x : m \leq x\} = \{m\}$. We now use noetherianity. The union U of all finite open subsets of X is open. Every open subset of a noetherian space is quasi-compact, so the cover of U by its finite open subsets has a finite subcover. Hence U itself is finite. If $X \setminus U$ were nonempty, choose an isolated point x of that subspace. There would be an open $V \subset X$ with $V \cap (X \setminus U) = \{x\}$. Then $U \cup V = U \cup \{x\}$ would be a finite open subset not contained in U, contradicting the definition of U. Therefore $X = U$ is finite.

Conversely, every finite poset has a noetherian sober Alexandrov topology. Noetherianity is immediate. A nonempty irreducible closed subset has finitely many minimal elements in the lower-topology convention, and irreducibility forces exactly one of them; the closed subset is its closure. Thus the two hypotheses in the proposed enlargement are equivalent to finiteness for posets.

This observation should not be confused with the false assertion that every noetherian sober topological space is finite. Spectra supply abundant infinite examples. The essential extra hypothesis is the Alexandrov topology, in which arbitrary intersections of opens remain open. Nor is it necessary to insert a defect into the manuscript's induction: its irreducible and reducible cases work. The correction is to its claimed extra scope. Infinite towers and group actions on the following pages require another argument, which the Brown lemma supplies whenever the necessary diagram structures and limits exist.

Prouvons la partie 2°) du théorème-scholie. Considérons

$$\begin{array}{ccccc} \mathcal{M}(I')_{\mathrm{c}} & \hookrightarrow & \mathcal{M}(I') & \hookleftarrow & \mathcal{M}(I')_{\mathrm{f}} \\ \uparrow{\scriptstyle u_{\mathrm{c}}^*} & & \uparrow{\scriptstyle u^*} & & \downarrow{\scriptstyle u_*^{\mathrm{f}}} \\ \mathcal{M}(I)_{\mathrm{c}} & \hookrightarrow & \mathcal{M}(I) & \hookleftarrow & \mathcal{M}(I)_{\mathrm{f}}\ , \end{array}$$

où u^* et a fortiori u_{c}^* sont compatibles avec $W(I)$, $W(I')$, et par hypothèse u_* est compatible avec $W(I')_{\mathrm{f}}$, $W(I)_{\mathrm{f}}$. En passant aux catégories de fractions, on trouve

p. 38
[page 68]

$$\begin{array}{ccccc} \mathcal{M}(I')_{\mathrm{c}}W(I')_{\mathrm{c}}^{-1} & \xrightarrow{\sim} & \mathrm{HO}_W(I') & \xleftarrow{\sim} & \mathcal{M}(I')_{\mathrm{f}} \\ \uparrow{\scriptstyle u_W^*} & & & & \downarrow{\scriptstyle u_*^W} \\ \mathcal{M}(I)_{\mathrm{c}}W(I)_{\mathrm{c}}^{-1} & \xrightarrow{\sim} & \mathrm{HO}_W(I) & \xleftarrow{\sim} & \mathcal{M}(I)_{\mathrm{f}} \end{array}$$

`[plutôt` $\mathcal{M}(I')_{\mathrm{f}}W(I')_{\mathrm{f}}^{-1}$ `(resp.` $\mathcal{M}(I)_{\mathrm{f}}W(I)_{\mathrm{f}}^{-1}$`) au lieu de` $\mathcal{M}(I')_{\mathrm{f}}$ `(resp.` $\mathcal{M}(I)_{\mathrm{f}}$`)]` et on veut montrer que u_W^* et u_*^W sont adjoints, de façon précise trouver un isomorphisme bifonctoriel, pour F *dans* $\mathcal{M}(I)_{\mathrm{c}}$ et G' *dans* $\mathcal{M}(I')_{\mathrm{f}}$

$$(*) \qquad \mathrm{Hom}_W(u^*F, G') \xrightarrow{\sim} \mathrm{Hom}_W(F, u_*G')$$

(où Hom_W désigne le Hom dans $\mathrm{HO}_W(I')$ resp. $\mathrm{HO}_W(I)$). Comme F est dans $\mathcal{M}(I)_{\mathrm{c}}$, u^*F est dans $\mathcal{M}(I')_{\mathrm{c}}$, et comme G' est dans $\mathcal{M}(I')_{\mathrm{f}}$, u_*G' est dans $\mathcal{M}(I)_{\mathrm{f}}$. Il s'ensuit que les deux membres de $(*)$ sont des quotients des deux membres dans la bijection canonique

$$(**) \qquad \mathrm{Hom}_{\mathcal{M}(I')}(u^*F, G') \xrightarrow[\sim]{\alpha} \mathrm{Hom}_{\mathcal{M}(I)}(F, u_*G').$$

Il faut simplement montrer que cette dernière transforme la relation d'équivalence pertinente R' du premier membre, en celle R du second. [page 69]

Commentary · Exposition [ms. 68]

The adjunction after localization, with both inverses

Grothendieck wants the limit functor to retain its universal property after replacement. Knowing that it sends weak equivalences to weak equivalences makes it descend to the homotopy category; it does not alone identify its adjoint. The argument on pp. 68–71 checks that the ordinary adjunction identifies the two homotopy relations. We can make its two directions explicit without choosing a globally functorial replacement.

Choose F cofibrant in $\mathcal{M}(I)$ and G fibrant in $\mathcal{M}(I')$. Then u^*F is cofibrant and u_*G is fibrant. Every morphism between these objects in the respective homotopy categories is represented by an ordinary map. Restriction followed by the ordinary counit defines

$$\beta : \mathrm{Hom}_{\mathrm{HO}(I)}(F, u_*G) \longrightarrow \mathrm{Hom}_{\mathrm{HO}(I')}(u^*F, G).$$

It is well defined because restriction preserves all weak equivalences. It is surjective because every ordinary map $u^*F \to G$ has a strict adjoint $F \to u_*G$. This is the one direction available before admissibility has been used.

To construct the inverse, choose a trivial cofibration $i' : u^*F \to F'$ with F' fibrant, and let $i : F \to u_*F'$ be its strict adjoint. The object F' is also cofibrant. Composition with i' induces a bijection

$$\mathrm{Hom}_{\mathrm{HO}(I')}(F', G) \xrightarrow{\sim} \mathrm{Hom}_{\mathrm{HO}(I')}(u^*F, G).$$

For a class g on the right, let a be its unique inverse image and define

$$\gamma(g) = u_*^W(a) \circ [i].$$

This is where admissibility enters: u_*^W is a functor on the localization of fibrant objects, so it acts on the class a, independently of its representative. Naturality of the ordinary counit, together with the fact that i' is adjoint to i, gives $\beta\gamma(g) = a[i'] = g$.

For the other composite, represent a class $b : F \to u_*G$ by an ordinary map and let $g : u^*F \to G$ be its ordinary adjoint. Since i' is a trivial cofibration and G is fibrant, g extends to an ordinary map $a : F' \to G$ satisfying $ai' = g$. Its class is the inverse image used in defining γ. The ordinary adjunction then gives $u_*a \circ i = b$, proving $\gamma\beta([b]) = [b]$. Thus β is bijective. Its naturality, already built into restriction and the counit, gives the required bifunctorial adjunction.

This is the derived-adjunction construction; compare Hovey (1999a, Lemma 1.3.10). Independence of the chosen F' follows from uniqueness of the inverse of β, rather than from an additional comparison of arbitrary replacements. It also explains the manuscript's remark that functoriality in G appears a posteriori. The adjoint obtained is

$$u_W^* \dashv u_*^W.$$

The two occurrences of "adjoint à gauche" on p. 71 are slips in the source and must read "adjoint à droite". The Hom formula itself already fixes the orientation, so the proof is unaffected. Likewise the target containing u^*F' on p. 70 is ill typed: F' is already an I'-diagram, and the intended object is u^*F.

Je dis que l'on a de toute façon

$$R \;\leq\; \alpha(R')$$

sans hypothèse d'admissibilité sur u, *i.e.* que la bijection invese de $(**)$ donne par passage aux quotients un homomorphisme

$$(***) \qquad \mathrm{Hom}_W(u^*F, G') \longleftarrow \mathrm{Hom}_W(F, u_*G'),$$

forcément surjectif, et de plus fonctoriel en F `[, G' barré]`, variables dans $\mathrm{HO}_W(I)$ et $\mathrm{HO}_W(I')$ respectivement. En effet, on définit la flèche ($*$ bis) `[plutôt (***)]` comme composé

$$\mathrm{Hom}_W(F, u_*G') \longrightarrow \mathrm{Hom}_W(u^*F, u^*u_*G') \longrightarrow \mathrm{Hom}_W(u^*F, G').$$

car u^* est compatible avec $W(I)$, $W(I')$ sur $\mathcal{M}(I)$ tout entier, et on interprète les deux membres comme des Hom dans $\mathcal{M}(I)W(I)^{-1}$ et $\mathcal{M}(I')W(I')^{-1}$.

composition avec l'homomorphisme d'adjonction $u^*u_*G' \longrightarrow G'$

Cela implique donc que le foncteur sur $\mathrm{HO}_W(I)$ $F \longmapsto \mathrm{Hom}_{\mathrm{HO}_W(I')}(u^*F, G')$ est, sinon représentable, du moins quotient terme à terme du foncteur représenté par u_*G' ([37]). p. 39

Mais supposons maintenant que u soit admissible. Alors je vais définir la flèche en sens initial ($*$) (p. 68) de la façon suivante : Je choisis une flèche [page 70]

$$i' \;:\; u^*F \longrightarrow F' \qquad \text{avec } i' \in TC \subset C \cap W,\; F' \in \mathrm{Ob}\mathcal{M}(I')_{\mathrm{f}}$$

(donc en fait $F' \in \mathrm{Ob}\mathcal{M}(I')_{\mathrm{cf}}$, car u^*F est cofibrant), et par adjonction la flèche i' correspond à

$$i \;:\; F \longrightarrow u_*F'.$$

37. Mais il n'est pas clair, sans hypothèse supplémentaire sur la situation, que ce foncteur représentable puisse être choisi en dépendance fonctorielle de G', envisagé dans $\mathrm{HO}_W(I')$.

Je considère le diagramme (commutatif!)

$$\begin{array}{ccc} \mathrm{Hom}(F', G') & \xrightarrow{\ \alpha\ } & \mathrm{Hom}(u_*F', u_*G') \\ \Big\downarrow{\scriptstyle \lambda : f' \longmapsto f' \circ i'} & & \Big\downarrow{\scriptstyle \mu : f \longmapsto f \circ i} \\ \mathrm{Hom}(u^*F, G') & \xrightarrow{\ \text{adj.}\ } & \mathrm{Hom}(F, u_*G')\ . \end{array}$$

On note que l'on a encore F' cofibrant (car u^*F l'est et $i' \in TC \subset C$), donc $\mathrm{Hom}_W(F', G')$ est un quotient de $\mathrm{Hom}(F', G')$, et λ induit un isomorphisme

$$\mathrm{Hom}_W(F', G') \xrightarrow{\ \sim\ } \mathrm{Hom}_W(u^*F', G')$$

(car $i' \in TC \subset W$). Comme F', $G' \in \mathrm{Ob}\mathcal{M}(I')_{\mathrm{f}}$ et que u_*^{f} est compatible avec $W(I')_{\mathrm{f}}$, $W(I)_{\mathrm{f}}$, il s'ensuit que la flèche horizontale α est compatible avec les relations d'équivalence définies par [page 71]

$$\mathrm{Hom}(F', G') \longrightarrow \mathrm{Hom}_{W(I')}(F', G') \quad \text{resp.} \quad \mathrm{Hom}(u_*F', u_*G') \longrightarrow \mathrm{Hom}_{W(I)}(u_*F', u_*G')\ .$$

Et il en est de même de la flèche $\mu : f \longmapsto f \circ i$, trivialement. Donc la flèche d'adjonction $\mathrm{Hom}(u^*F, G') \longrightarrow \mathrm{Hom}(F, u_*G')$ est compatible avec les relations R, R', ce qui achève de prouver que (∗∗), page 68, induit une bijection (∗), page 68.

Ceci montre donc

1°) que pour un objet fixé G' dans $\mathrm{HO}_W(I')$ (qu'on peut toujours supposer, à isomorphisme près, provenir de $\mathcal{M}(I')_{\mathrm{f}}$), le foncteur

$$F \longmapsto \mathrm{Hom}_{\mathrm{HO}_W(I')}(u_W^*F, G')$$

est représentable – *i.e.* le foncteur u_W^* admet un adjoint à gauche, et

2°) que cet adjoint à gauche se calcule comme $u_*(G')$ (quand l'argument G' est pris fibrant) – vu que l'homomorphisme (∗∗∗), page 69, est *fonctoriel en* F. (A posteriori il s'ensuit qu'il est aussi fonctoriel en G' …)

Commentary · Exposition [ms. 71] p. 40

Pointwise right images require fibrant restriction [page 72]

Grothendieck now wants more than an abstract right adjoint: he wants to compute its value at an object by a homotopy limit over a comma category. The comparison is canonical, but it becomes an isomorphism only after the same replacement is known to be suitable on both sides. This is the content of the invocation of local isomorphisms on p. 72.

Fix $s \in I$, let $q : I'/s \to I'$ be the projection, and write $p_s : I'/s \to e$. If $X' \to RX'$ is fibrant replacement and q^* preserves fibrant objects, then q^*RX' is a fibrant replacement of q^*X', because restriction always preserves the objectwise weak equivalences. The ordinary pointwise formula therefore identifies

$$\left(\mathbf{R}u_*X'\right)_s = \left(u_*RX'\right)_s \cong \varprojlim_{I'/s} q^*RX' \cong \mathbf{R}(p_s)_*q^*X'.$$

The last step uses admissibility of p_s. Thus the comparison is computed on one common representative, rather than by comparing two unrelated fibrant replacements.

For clarity, there is a simple sufficient condition for the fibrancy assertion. The functor q is a discrete fibration: an arrow $j \to j'$ in I' and an object $(j', u(j') \to s)$ have a unique lift with source $(j, u(j) \to u(j') \to s)$. In our contravariant convention, when the necessary coproducts exist, its left Kan extension has the formula

$$(q_!A)_j \cong \coprod_{x \in q^{-1}(j)} A_x.$$

Coproducts of trivial cofibrations have the left lifting property against every fibration, so $q_!$ preserves the objectwise trivial cofibrations. Its right adjoint q^* consequently preserves fibrations and fibrant

objects. This is the contravariant version of the discrete-opfibration argument in Groth (2013, Lemma 1.31).

If I is a poset, each fiber has at most one element, so only the initial object is needed for this coproduct formula. In the large cocomplete model examples, all small fibers are allowed. In a setting with only finite limits and finite colimits, an arbitrary infinite fiber requires an additional existence hypothesis; it must not be supplied by notation. This is why the general admissibility result and the pointwise formula have been stated separately in the commentary. The finite-poset corollary satisfies the needed conditions, and the usual combinatorial model setting satisfies them for every small functor.

Modern derivator theory packages this calculation as the pointwise Kan-extension axiom. The square of shapes contains the canonical natural transformation $uq \Rightarrow sp_s$; its mate is exactly the displayed comparison. Thinking in terms of that mate explains its compatibility with composition and base change, while the fibrant-representative calculation proves that it is invertible in the present models.

The same proof gives a useful class of base-change squares, with a condition that can be checked directly. Let $v : I_1 \to I$ be a discrete fibration, form the strict pullback $I'_1 = I' \times_I I_1$, and denote its projections by $v' : I'_1 \to I'$ and $u_1 : I'_1 \to I_1$. Assume that the required right Kan extensions and the coproducts over the fibers exist. For each $t \in I_1$ the natural functor

$$I'_1/t \longrightarrow I'/v(t)$$

is an isomorphism. Indeed, an object of the target is an arrow $u(i') \to v(t)$. Its unique lift along v is an arrow $t' \to t$ with $v(t') = u(i')$, and therefore supplies the object $((i', t'), t' \to t)$ of the source. The uniqueness of lifts gives the inverse also on morphisms. This proves the ordinary base-change identity by the pointwise limit formula.

The pullback v' is again a discrete fibration, so the preceding coproduct argument shows that $(v')^*$ preserves fibrant objects. Evaluate both sides of the ordinary identity on a fibrant replacement of X'. They then compute the two derived functors, proving the canonical isomorphism

$$v^*\mathbf{R}u_*X' \cong \mathbf{R}(u_1)_*(v')^*X'.$$

This is the same discrete-fibration mechanism used in the comma calculation, applied to a family of objects at once; it is part of the standard pointwise derivator calculus cited above.

A strict pullback square without this hypothesis need not have such an isomorphism. Take $I = (0 \to 1)$, let $I' = \{0\}$ and $I_1 = \{1\}$ be the two endpoint inclusions, and use complexes over a field. Their pullback is empty. For $X' = k[0]$, the left side evaluated at 1 is $k[0]$, because $\{0\}/1$ is terminal. The right side is zero, the limit of the empty diagram in complexes. Thus the base-change map cannot be an isomorphism. The pointwise axiom guarantees the designated comma squares; additional squares require the corresponding exactness argument.

Le dernier énoncé dans 2° du théorème-scholie résulte du calcul de u_*^W, compte tenu que $I'/s \longrightarrow I'$ est un isomorphisme local, donc le foncteur image inverse envoie

$$\mathcal{M}(I')_{\mathrm{f}} \longrightarrow \mathcal{M}(I'/s)_{\mathrm{f}},$$

donc si G' est dans $\mathcal{M}(I')_{\mathrm{f}}$,

$$u_*(G')(s) \;\simeq\; p_{s\,*}(G'|I'/s)$$

est un calcul de $p_{s\,*}^W(G'|I'/s)$.

Cela achève la démonstration du théorème-scholie sur les images directes.

Commentaires.

1) Ce théorème me paraît loin d'être satisfaisant, c'est un pis-aller. J'avais espéré, avec les hypothèses du paragraphe 3, qu'on aurait l'existence des u_*^W pour *toute* flèche $u : I' \longrightarrow I$ dans Cat. Je doute à présent que ce soit le cas, mais n'ai pas encore réussi de faire un contre-exemple. Les cas test les plus importants pour la question d'admissibilité d'une catégorie I me paraissent les suivants :

a) I catégorie discrète infinie (disons dénombrable). La question revient ici à celle-ci : soient $f_i : X_i \longrightarrow Y_i$ dans W, avec X_i, Y_i fibrants, *i.e.* dans F `[i.e.` $X_i \longrightarrow e$`,` $Y_i \longrightarrow e$ `dans` F`]`. Alors $f = \prod f_i : \prod X_i \longrightarrow \prod Y_i$ est-il dans W ?

[page 73]

Commentary · Present state [ms. 72]

Products and towers have a positive answer

Grothendieck's test cases isolate two ways in which an infinite limit could lose a weak equivalence. The first takes infinitely many independent factors; the second imposes infinitely many compatibility equations. Under the closed model hypotheses he explicitly mentions, both questions have affirmative answers. Their difficulty is the availability of suitable replacements, not a failure of weak equivalence to survive the limit of a fibrant diagram.

For a set S, equip $\mathcal{M}^S$ with the product structure. The diagonal functor preserves cofibrations and trivial cofibrations componentwise. Its right adjoint, whenever it exists, is $\prod_S$. The Brown argument therefore shows that a product of weak equivalences between fibrant objects is a weak equivalence. This remains true for uncountable S whenever the required products exist. No assumption about exact filtered colimits is used. The derived product is consequently computed by the product of fibrant replacements; the same conclusion appears explicitly in Hovey (1999a, Example 1.3.11).

For the tower shape, use the matching-object description already seen in finite posets. A tower

$$X_0 \longleftarrow X_1 \longleftarrow X_2 \longleftarrow \cdots$$

is fibrant precisely when X_0 is fibrant and every bonding map is a fibration; all other X_n are then fibrant by composition. The recursive lifting proof has one step for each natural number and defines a compatible lift on the whole tower. Taking the limit is right adjoint to the constant-tower functor, which preserves the objectwise cofibrations and trivial cofibrations. Brown's lemma again gives invariance under levelwise weak equivalences between these towers. In the ordinary complete model setting this is also the inverse Reedy construction.

The manuscript correctly observes that the tower assertion implies the countable product assertion. For a countable family (X_n) of fibrant objects, put $P_r = \prod_{0 \le n \le r} X_n$. The projection $P_{r+1} \to P_r$ is a pullback of $X_{r+1} \to e$, hence a fibration. A family of weak equivalences induces weak equivalences between the finite products, by the finite case; the inverse limit of the resulting map of towers is the original map of infinite products. This reduction proves the stated implication, although the direct product adjunction is shorter once the general lemma is recognized.

The affirmative answer does not mean that ordinary inverse limits preserve all levelwise weak equivalences. The following example shows exactly where the bonding-map condition matters. It is also a useful safeguard when replacing an abstract existence theorem by an explicit tower of complexes.

b) I catégorie

$$0 \longrightarrow 1 \longrightarrow 2 \longrightarrow 3 \longrightarrow \cdots,$$

i.e. la catégorie ordonnée associée à l'ensemble ordonné $\mathbf{N}$, pour la relation d'ordre ordinaire $m \le n$. Donc $\mathcal{M}(I)$ est formée des systèmes *projectifs* dans $\mathcal{M}$, indexés par $\mathbf{N}$. On prouve facilement (en procédant comme dans le corollaire du lemme p. 63) que $\mathcal{M}(I)_{\mathrm{f}}$ est formée des systèmes projectifs

$$X_0 \longleftarrow X_1 \longleftarrow X_2 \longleftarrow \cdots \longleftarrow X_n \xleftarrow{p_n} X_{n+1} \longleftarrow \cdots$$

tels que les X_i soient dans $\mathcal{M}_{\mathrm{f}}$, et les p_n dans F. La question est donc : si $X_\bullet$, $Y_\bullet$ sont fibrants et $f_\bullet : X_\bullet \longrightarrow Y_\bullet$ est telle que $f_i \in W$ pour $i \in \mathbf{N}$, alors a-t-on $\varprojlim f_i : X_\infty \longrightarrow Y_\infty$ dans W ?

Si la reponse est affirmative pour $\mathbf{N}$ (pour un W et une quillénisation donnée), elle l'est aussi pour toute catégorie discrète dénombrable, comme on le voit aussitôt. Mais je ne vois pas comment déduire même *a*) des axiomes, disons pour un triplet de Quillen clos

(closed model category) tel que $\mathcal{M}$ soit de plus stable par $\varinjlim$ filtrantes, que celles-ci soient exactes, et qu'il y ait un petit ensemble de générateurs dans $\mathcal{M}$ (donc $\mathcal{M}$ est accessible), que W soit stable par $\varinjlim$ filtrantes. Je devrais demander à Thomason s'il connait un contre-exemple. p. 41 [page 74]

Commentary · Examples [ms. 73]

An inverse limit of acyclic complexes can have cohomology

The insistence on fibrant towers is mathematically necessary, even in the most familiar algebraic model. Fix a prime p and, for $n \geq 1$, form the cochain complex

$$A_n = \left[\mathbb{Z} \xrightarrow{p^n} \mathbb{Z} \xrightarrow{\bmod p^n} \mathbb{Z}/p^n\right]$$

in degrees $0, 1, 2$. It is acyclic: the first map is injective, the image of that map is the kernel of the second, and the second is surjective. Define $A_{n+1} \to A_n$ by multiplication by p in degree 0, the identity in degree 1, and reduction modulo p^n in degree 2. These maps commute with both differentials. The maps of towers $A_n \to 0$ are therefore quasi-isomorphisms at every level.

Their ordinary inverse limit is readily computed. A compatible sequence in degree 0 satisfies $a_n = pa_{n+1}$. Its first coordinate is divisible by every power of p, and hence vanishes; then every coordinate vanishes. The limit in degree 1 is $\mathbb{Z}$, and the limit in degree 2 is $\mathbb{Z}_p$. Thus

$$\varprojlim_n A_n = \left[0 \longrightarrow \mathbb{Z} \longrightarrow \mathbb{Z}_p\right].$$

The map $\mathbb{Z} \to \mathbb{Z}_p$ is injective but not surjective. For example, $\mathbb{Z}_p$ is uncountable, since a sequence of digits in $\{0, \ldots, p-1\}$ uniquely determines a p-adic integer, while $\mathbb{Z}$ is countable. Consequently

$$H^2\left(\varprojlim_n A_n\right) = \mathbb{Z}_p/\mathbb{Z} \neq 0.$$

The inverse limit of the levelwise quasi-isomorphism $A_\bullet \to 0$ is not a quasi-isomorphism.

There is no conflict with the positive result on the preceding page. In the projective model structure on unbounded complexes of abelian groups every object is fibrant, but a fibration is degreewise surjective. The bonding map of this tower is multiplication by p in degree 0, so it is not a fibration. Individual fibrancy has not made the *diagram* fibrant. A fibrant tower replacement would have an acyclic inverse limit by the Brown argument.

This example separates three statements which can otherwise look deceptively similar: ordinary inverse limit is not exact; inverse limit need not preserve levelwise quasi-isomorphisms of arbitrary towers; inverse limit does preserve weak equivalences between fibrant towers in the model structure under discussion. Only the third statement is the admissibility problem posed in the manuscript. Its positive answer is compatible with the failure exhibited here.

c) Les deux exemples précédents étaient des catégories ordonnées. Comme exemple typique de catégorie non-ordonnée, où je ne vois pas ce qui se passe, je signale $I = B_G$, G un groupe (donc un seul objet, avec un groupe d'automorphismes G). Aussi le cas de $\mathbf{\Delta}[1] = \{\mathbf{\Delta}_0, \mathbf{\Delta}_1\}$ (sous-catégorie pleine de $\mathbf{\Delta}$) n'est pas clair pour moi.

Commentary · Examples [ms. 74]

A group action detects the difference between fixed and homotopy fixed points

Grothendieck introduces B_G because automorphisms are absent from the finite-poset argument. The limit of a G-diagram is a fixed-point object. Its derived version measures the coherence of invariance under the whole action, and a single fibrant value does not guarantee that the action diagram is injectively fibrant. The algebraic example below makes the difference explicit and at the same time answers the boundedness question from §5.

Let $G = C_p = \langle g \mid g^p = 1\rangle$, let k be a field of characteristic p, and give k the trivial action. Using inversion to change a right action into a left action if necessary, diagrams of complexes on B_G

are complexes of $R = k[G]$-modules. With $t = g - 1$, one has $R \cong k[t]/(t^p)$. The trivial module has the free resolution

$$\cdots \xrightarrow{t} R \xrightarrow{t^{p-1}} R \xrightarrow{t} R \longrightarrow k \longrightarrow 0.$$

Its exactness follows immediately from

$$\ker(t : R \to R) = (t^{p-1}), \qquad \ker(t^{p-1} : R \to R) = (t).$$

Applying $\mathrm{Hom}_R(-, k)$ makes every differential zero, since t acts by zero on k. Tensoring with k does the same. Therefore

$$\mathrm{Ext}^n_R(k, k) \cong k, \qquad \mathrm{Tor}^R_n(k, k) \cong k \qquad (n \geq 0).$$

For the projection $p : B_G \to e$ this gives

$$\mathbf{R}p_* k = \mathbf{R}\,\mathrm{Hom}_{k[G]}(k, k), \qquad \mathbf{L}p_! k = k \otimes^{\mathbf{L}}_{k[G]} k.$$

The first object has nonzero cohomology in every nonnegative degree, and the second in every nonpositive degree. Both exist in $D(k)$. Neither belongs to $D^{\mathrm{b}}(k)$, although the input is concentrated in degree zero. Finite cohomological dimension is therefore a boundedness condition in this example, not a prerequisite for the unbounded operations.

Ordinary invariants of the original diagram give only $k[0]$. Moreover, over a field its underlying complex is already fibrant. The additional cohomology arises because injective fibrancy in the diagram category is a condition on the $k[G]$-complex, not merely on the underlying k-complex. Replacing that diagram by a K-injective $k[G]$-complex and taking ordinary invariants computes $\mathbf{R}p_*$. The Brown lemma proves invariance between such fibrant diagrams, so the presence of a nontrivial automorphism group creates no exception to admissibility.

Exactly the same general argument applies to the full subcategory of $\mathbf{\Delta}$ on [0] and [1] mentioned next in the manuscript. It is not the walking arrow: it contains all maps between those two ordinals, including the two sections and the retraction. It has two objects and seven morphisms: the four Hom sets have respectively $1, 2, 1, 3$ elements. Thus its ordinary limit uses only the finite limits of $\mathbf{M}0$. Its relations matter when constructing a coherent diagram, but the assumed uniform structure and the lifting-adjunction proof already give admissibility; no further infinite-completeness assumption is needed for this test.

2) On aimerait pouvoir traiter de façon duale l'existence des $u^W_!$, à défaut de mieux. Dans l'hypothèse de départ du paragraphe 4 sur $(\mathcal{M}, W)$, cela amène donc à changer de tactique. Cette fois, on devra supposer l'existence d'une quillénisation close *exacte à droite* pour W (ce qui est plus exigeant, semble-t-il, qu'une telle structure exacte à gauche, dans le cas envisagé), donc

$$TF \;=\; F \cap C,$$

et de plus encore C, TC tels qu'on ait [page 75]

$$C \;=\; \widetilde{C_0}, \qquad TC \;=\; \widetilde{TC_0}$$

avec C_0, TC_0 petits ([38]). On posera maintenant

$$\begin{aligned} F(I) \;&=\; \{f \in \mathrm{Fl}\,\mathcal{M}(I) \;\mid\; f_s \in F \quad \forall\, s \in \mathrm{Ob}I\} \\ TF(I) \;&=\; \{f \in \mathrm{Fl}\,\mathcal{M}(I) \;\mid\; f_s \in TF \;\; \forall\, s \in \mathrm{Ob}I\}, \end{aligned}$$

puis

$$\begin{aligned} C(I) \;&=\; TF(I)^* \\ TC(I) \;&=\; F(I)^* \;. \end{aligned}$$

L'espoir (que je devrai vérifier ultérieurement), c'est qu'on obtient ainsi une quillénisation uniforme à droite de W, sur Cat tout entier. Le seul problème, c'est la validité des axiomes de factorisation de $f \in \mathrm{Fl}\,\mathcal{M}(I)$ en $f = pi$, avec $i \in TC$, $f \in F$, et aussi avec $i \in C$, $f \in TF$.

38. On dit alors que C, TC (en tant que parties closes à droite `[plutôt à gauche]`) sont "accessibles".

J'ai bon espoir que c'est vrai – cela se réduit essentiellement à voir que $(C(I), TF(I))$ et $(TC(I), F(I))$, soit $(\Phi(I), \Psi(I))$, satisfont en plus de $\Phi(I) = \Psi(I)^*$, à $\Psi(I) = \Phi(I)_*$ (*i.e.* $\Psi(I)$ est clos à droite), et que $\Phi(I)$ est accessible (tout comme $\Phi = \Phi(e)$). Si ça marche, on aura donc l'existence de $u_!$ pour u un foncteur entre catégories ordonnées finies, et sous des conditions légèrement plus générales. (P. ex. $u : I' \longrightarrow I$ avec I ordonnée, I' ordonnée et à espace sous-jacent noethérien et sobre.) Peut-être que cette fois, l'hypothèse que W est stable par $\varinjlim$ filtrantes va quand même servir! Ainsi, le cas des catégories discrètes, et des catégories filtrantes à gauche comme $\mathbf{N}^\circ$, ne va plus poser de problèmes à cause de cela. Il y a donc de l'espoir! Tout ensemble ordonné qui est $\varinjlim$ filtrante de sous-ensembles ordonnés *fermés* noethériens et sobres, est alors W-admissible à droite. Mais qu'en est-il de catégories de type $\Gamma = B_G$ p. ex. ? ? ? p. 42 [page 76]

Commentary · Later developments [ms. 75]

The projective construction supplies the dual theory

Grothendieck's change of tactic is the right one for left images. To derive a colimit, fibrations should be defined objectwise, so restriction becomes a right Quillen functor and its left adjoint acts on cofibrant diagrams. The extra small generating sets are needed to construct these projective diagram structures. Once they have been constructed, the dual Brown argument supplies homotopy invariance for every existing left Kan extension, rather than only for finite posets.

Here is the construction with its size hypothesis visible. Suppose that $\mathcal{M}$ is a locally presentable, cofibrantly generated model category, with generating cofibrations C_0 and generating trivial cofibrations T_0. For $i \in I$, evaluation has a left adjoint L_i, given in the contravariant convention by

$$(L_i A)_j = \coprod_{I(j,i)} A.$$

Use the sets $\{L_i c : i \in I, c \in C_0\}$ and $\{L_i t : i \in I, t \in T_0\}$. By the evaluation adjunction, their right lifting classes are exactly the objectwise trivial fibrations and the objectwise fibrations, respectively. The sets really are small: I and the two generating collections are small. For a sufficiently large regular cardinal the domains are presentable, because evaluation preserves filtered colimits and

$$\mathrm{Hom}_{\mathcal{M}^{(I)}}(L_i A, X) \cong \mathrm{Hom}_{\mathcal{M}}(A, X_i).$$

The small object argument therefore gives both desired factorizations.

One also checks the weak equivalences in the transferred structure. A relative cell complex built from the $L_i t$ is componentwise a composite of pushouts of coproducts of trivial cofibrations. The base trivial cofibrations form a left lifting class and are closed under these operations, so the resulting map is an objectwise trivial cofibration and hence an objectwise weak equivalence. Taking retracts gives the same conclusion for every map in $TC(I)$. Moreover $TC(I) \subset C(I)$, because the objectwise trivial fibrations are objectwise fibrations. If $f \in C(I) \cap W(I)$, factor it as $f = pj$ with $j \in TC(I)$ and $p \in F(I)$. Two-out-of-three gives $p \in W(I)$, so $p \in TF(I)$ by the objectwise definitions. The lifting property of f against p makes f a retract of j, hence $f \in TC(I)$. This identifies the required acyclic class and completes the model-structure verification. It is the projective transfer argument sought in the paragraph following the two formulas on p. 75. See Groth (2013, Theorem 1.28 and Lemma 1.29); the small object argument itself is recorded in Hovey (1999a, Theorem 2.1.14).

For $u : I' \to I$, restriction now preserves the objectwise fibrations and trivial fibrations. Adjointness makes $u_!$ preserve cofibrations and trivial cofibrations. The dual Brown lemma shows that it preserves weak equivalences between cofibrant diagrams, and the derived adjunction is

$$\mathbf{L}u_! \dashv u^*.$$

The hypotheses of local presentability and cofibrant generation make all small diagram shapes available, including B_G. An objectwise construction of fibrations does not mean that cofibrant diagrams are objectwise cofibrant with no further condition; the latter would miss precisely the relations that the free diagrams $L_i A$ impose.

Two slips in the source obscure this otherwise correct programme. Exactness on the right is $TF = F \cap W$, not $F \cap C$. In the factorizations $f = pi$, the membership assertions must refer to $p \in F$ or $p \in TF$, not to f. They are retained as printed and explained in the correction register.

The role of filtered colimits also deserves precision: in the projective transfer just described, closure of trivial cofibrations under transfinite composites follows from their lifting property. A separate assertion that all weak equivalences are closed under filtered colimits is not what proves that step.

[page 77]

Commentary · Context [ms. 76]

Why the homotopy problem returns to SGA 4

Grothendieck turns to cardinal filtrations because a construction on every diagram category needs a controlled supply of small pieces. The issue is already visible in the proposed right uniform quillenisation: a lifting condition must be generated by a set of maps, and the factorisations built from that set must remain available after changing the indexing category. The return to SGA 4, I, §9 is therefore part of the homotopical argument. It supplies a way of bringing a large category within reach of set-indexed constructions.

The later letter to Thomason makes this connection explicit. In its opening pages Grothendieck describes his renewed work on accessible categories and accessible parts as a rebuilding of the provisional account in SGA 4. In the next section of the letter, he distinguishes the relative category $(\mathcal{M}, W)$, which specifies the homotopy theory, from the cofibrations and fibrations used to construct its operations (Grothendieck, 1991a, pp. 2–4 of the electronic edition). The present chapter places these two concerns next to one another: first find enough replacements to derive direct images; then explain the smallness that makes such replacements possible. This is also why the size of a *diagram*, rather than just the sizes of its values, becomes decisive near the end of §7.

There are two historical cautions. The word "accessible" here follows the cardinal conventions of SGA 4: "grand devant π" bounds every subset of size at most π, and thus corresponds to π^+-directedness in the regular-cardinal terminology now customary. Also, the closing definition tests membership in a part against *every* perfectly adapted presentation. It is stronger than merely exhibiting the part as a category of sufficiently directed colimits of small objects. The distinction is mathematically effective: the counterexamples below separate those conditions even in a powerset ordered by inclusion. The later development of accessibility does not license us to identify formulations whose quantifiers differ.

Commentary · Present state [ms. 76]

What has been settled before the cardinal detour

The final questions of §6 can now be separated by the task they perform. For the uniform closed exact structures assumed in the theorem-scholie, the Brown lemma settles admissibility of every functor with the requisite ordinary right adjoint; its dual settles left admissibility. Products, towers, group actions and the truncated simplex category are all included. The finite-poset proof remains a direct construction of the finite calculus, while the noetherian sober Alexandrov condition adds no infinite posets.

The next question is existence of those uniform structures. In the usual combinatorial setting, injective and projective diagram model structures, derived adjunctions, and the pointwise comma-category formulas furnish a strong derivator on all small categories. This is the later theorem corresponding most directly to Grothendieck's programme. In smaller categories such as bounded complexes, one retains finite operations and must check each infinite ordinary limit or colimit separately. The bounded-product example above prevents a blanket completeness assertion.

Section 7 addresses the remaining constructive burden: how a large lifting class or a large collection of objects can be controlled by a small family at a sufficiently large cardinal. That question is substantial even though the preceding homotopy-invariance doubts have a formal answer. It is also where the older SGA 4 language of accessibility and the later language of presentability need to be compared with particular care. The change of subject is therefore motivated by the production of factorizations, rather than by a need to repair Brown's argument.

7 Filtrations cardinales et parties accessibles d'une grosse catégorie

Commentary · Exposition [ms. 77]

A size filtration and a presentability rank

Grothendieck returns to cardinal estimates because the constructions of model structures need a controlled supply of small objects. A replacement construction may be performed object by object and still fail to be controlled uniformly over a category. The filtration is intended to provide that control: a large object is assembled from bounded pieces, while bounded constructions on bounded pieces remain bounded. The categorical purpose of the estimates should remain visible through the set theory.

There is a one-cardinal shift in the language. Throughout these pages, "grand devant π" means that every subset of cardinal at most π has an upper bound. In modern terminology such a nonempty poset is π^+-directed, where π^+ is the successor cardinal. Write $\kappa = \pi^+$ when translating the assertions. An object called π-accessible in the sense of SGA 4 is correspondingly κ-presentable: its covariant Hom functor preserves these directed colimits. This meaning of "accessible object" must also be kept distinct from the new meaning of "accessible part" introduced on manuscript page 86. The latter concerns a full subcategory and its position inside the ambient category.

The three filtration conditions do not say that every object of $\mathrm{Filt}^\pi(E)$ is π^+-presentable. They say that this stage is essentially small, is closed under the specified bounded colimits, and generates E under sufficiently directed colimits. Preservation of such colimits by Hom is an additional hypothesis. This explains why the hypothesis $\mathrm{Filt}^\pi(E) \subset E_\pi$, initially left tacit, becomes necessary on pages 90–94. Under suitable accessibility hypotheses, SGA 4 supplies useful cardinals at which size and presentability do coincide; see Artin et al. (1972, I, 9.16–9.18). It does not identify the two notions at every index of an arbitrary filtration.

The universe convention is also doing real work. "Essentially small" means that a skeleton belongs to the fixed universe; it does not mean that there are finitely or countably many objects. Once a skeleton is chosen, the relevant comma categories are small because E is a $\mathfrak{U}$-category. All diagrams below remain small relative to this universe. No assertion that the whole large category has a set of objects in that same universe is needed.

Finally, the filtration is exhaustive even though exhaustiveness is not listed separately. Choose the presentation from condition (c) at π_0, and choose $\rho \geq \pi_0$ larger than the cardinality of its indexing poset. Its terms lie in $\mathrm{Filt}^\rho(E)$, and condition (b) places its colimit in the same stage. Thus every object eventually enters the filtration. This short argument is the content of footnote 39.

Je me réfère à la théorie des foncteurs et catégories accessibles de SGA 4, I, §9 (p. 138-178). Je me donne une grosse catégorie (toujours une $\mathfrak{U}$-catégorie) E avec une *filtration cardinale* (croissante)

$$\Big(\mathrm{Filt}^\pi(E)\Big)_{\pi \geq \pi_0}, \qquad \pi_0 \text{ un cardinal infini fixé,}$$

par les sous-catégories strictement pleines $\mathrm{Filt}^\pi(E)$. On a `[SGA 4, I, 9.12]`

a) $\mathrm{Filt}^\pi(E)$ essentiellement petite, *i.e.* équivalente à une petite catégorie (*i.e.* à une catégorie appartenant à $\mathfrak{U}$).

b) E satisfait L_{π_0} (*i.e.* E est stable par $\varinjlim$ de type I, quand I est un ensemble ordonné grand devant π_0), et $\mathrm{Filt}^\pi(E)$ est stable par les limites inductives filtrantes indexées par I grand devant π_0, et tel que $\mathrm{card}\, I \leq \pi$.

c) Pour tout $\pi \geq \pi_0$, et pour tout $X \in \mathrm{Ob}E$, on a

$$X \simeq \varinjlim_{i \in I} X_i,$$

où les X_i `[sont]` dans $\mathrm{Filt}^\pi(E)$, et où I est un ensemble ordonné grand devant π. De plus, si $X \in \mathrm{ObFilt}^{\pi'}(E)$, avec $\pi' > \pi$, on peut prendre I tel que $\mathrm{card}\, I \leq \pi'^\pi$ (donc

si $\pi' = 2^{c'}$ avec $c' \geq \pi$, d'où $(\pi')^\pi = (2^{c'})^\pi = 2^{c'\pi} = 2^{c'} = \pi'$, on aura $\operatorname{card} I \leq \pi'$). (**NB** Si on admet l'hypothèse du continu généralisée, on aura toujours $\pi'^\pi = \pi'$, donc $\operatorname{card} I \leq \pi'$.) ([39])

Commentary · Examples [ms. 77]

The useful exponent bound and the singular-cardinal exception

The bound $(\pi')^\pi$ measures how many small pieces may be needed to describe an object of size π'. It should be retained until an actual cardinal identity permits its replacement by π'. The calculation for a power-set cardinal is correct: if $\pi' = 2^{c'}$ and $c' \geq \pi$ are infinite, then

$$(\pi')^\pi = (2^{c'})^\pi = 2^{c'\cdot\pi} = 2^{c'} = \pi'.$$

Thus arbitrarily large useful choices are available without a continuum hypothesis.

The subsequent claim about the generalized continuum hypothesis is false as written. If μ is singular and $\operatorname{cf}(\mu) \leq \pi < \mu$, then $\mu^\pi > \mu$, independently of GCH. Here is the elementary obstruction. Choose increasing infinite cardinals $\mu_\alpha < \mu$, for $\alpha < \delta = \operatorname{cf}(\mu)$, with supremum μ. König's diagonal argument gives

$$\mu = \sum_{\alpha<\delta} \mu_\alpha < \prod_{\alpha<\delta} \mu_\alpha^+ \leq \mu^\delta \leq \mu^\pi.$$

For completeness, the strict inequality follows by partitioning a purported list of all elements of the product into pieces S_α of size μ_α. In coordinate α, choose a value outside the α-coordinates of S_α; the resulting element is absent from every piece of the list. Taking $\mu = \aleph_\omega$ and $\pi = \aleph_0$ already disproves the printed assertion.

Under GCH the conclusion does hold when $\pi < \operatorname{cf}(\pi')$. In that case each map $\pi \to \pi'$ has bounded image. For every infinite $\nu < \pi'$, GCH gives

$$\nu^\pi \leq (2^\nu)^\pi = 2^{\max(\nu,\pi)} = \max(\nu,\pi)^+ \leq \pi',$$

and the union of π' such sets has size at most π'. The constant functions give the reverse inequality. The missing cofinality condition matters precisely at singular cardinals. Nothing later in the construction requires the erroneous unconditional simplification: the bound $(\pi')^\pi$, and the unconditional power-set choices, suffice.

Considérons la représentation de c), p. 43 [page 78 barrée] [page 79]

$$X \;=\; \varinjlim_{I} X_i \qquad \begin{cases} X_i \in \operatorname{Filt}^\pi, \\ I \text{ grand devant } \pi. \end{cases}$$

Soit

$$\tilde{I} \;=\; \{I' \subset I \mid \operatorname{card} I' \leq \pi, \quad I' \text{ grand devant } \pi_0\},$$

muni de la relation d'ordre d'inclusion. Pour

$$I' \;\in\; \tilde{I}, \qquad \text{soit} \;\; X_{I'} = \varinjlim_{I'} X_i \;,$$

cette limite existe par L_{π_0} (hypothèse b), elle est dans Filt^π par b), donc on a un système inductif

$$(X_{I'})_{I'\in\tilde{I}}, \qquad X_{I'} \in \operatorname{Filt}^\pi,$$

avec

$$\operatorname{card} \tilde{I} \;\leq\; (\operatorname{card} I)^\pi,$$

et si $X \in \operatorname{Filt}^{\pi'}$ $(\pi' > \pi)$, prenant

$$\operatorname{card} I \;\leq\; \pi'^\pi,$$

39. NB b) et c) impliquent que $E = \bigcup_{\pi\geq\pi_0} \operatorname{Filt}^\pi(E)$.

on aura $\operatorname{card} \tilde{I} \leq (\pi'^{\pi})^{\pi} = \pi'^{\pi^2} = \pi'^{\pi}$, donc

$$\operatorname{card} \tilde{I} \ \leq \ \pi'^{\pi}.$$

Je dis que $\tilde{I}$ est lui aussi *grand devant* π, tout comme I. En effet, soit [page 80]

$$(I_\alpha)_{\alpha \in A}, \qquad I_\alpha \in \tilde{I}, \qquad \operatorname{card} A \ \leq \ \pi,$$

prouvons qu'il existe $I' \in \tilde{I}$ qui majore les I_α, *i.e.* qui contient $I'_0 = \bigcup_{\alpha \in A} I_\alpha$. On aura $\operatorname{card} I'_0 \leq \pi^2 = \pi$ (car $\operatorname{card} A \leq \pi$ et $\operatorname{card} I_\alpha \leq \pi$ pour tout α), et il suffit de voir ceci :

[En fait, l'assertion est évidente : comme $\operatorname{card} I'_0 \leq \pi$, et comme I est grand devant π, I'_0 admet un majorant i'_0 dans I, et on peut prendre $I' = I'_0 \cup \{i'_0\}$.]

Lemme 1 : *Soient π_0, π deux cardinaux, avec $\pi \geq \pi_0$, I un ensemble ordonné grand devant π, et I'_0 une partie de I de cardinal $\leq \pi$. Alors il existe une partie I' de I satisfaisant les conditions :* ([40])

a) $I' \supset I'_0$.

b) $\operatorname{card} I' \leq \pi$.

c) I' *grand devant* π_0. p. 44

[Le lemme tel qu'il est énoncé est évident pour les mêmes raisons que ci-dessus (même sans l'hypothèse de la note de bas de page). La démonstration qui suit prouve en fait un résultat plus fin :

LEMME 1′ : *Soient π_0, π deux cardinaux, avec $\pi_0 < \pi$ et $\pi^{\pi_0} = \pi$, I un ensemble ordonné grand devant π_0, et I'_0 une partie de I de cardinal $\leq \pi$. Alors il existe une partie I' de I satisfaisant les conditions :*

a) $I' \supset I'_0$.

b) $\operatorname{card} I' \leq \pi$.

c) I' *grand devant* π_0.]

On va essayer de construire I' par récurrence transfinie, en définissant les $I'_\alpha \subset I$ ainsi :

$$I'_0 = I'_0 \,,$$
$$I'_\alpha = \textstyle\bigcup_{\beta<\alpha} I'_\beta \quad \text{si } \alpha \text{ est un ordinal limite,}$$
$$I'_{\alpha+1} = \begin{cases} \text{déduit de } I'_\alpha \text{ ainsi : pour toute partie } J \text{ de } I'_\alpha \text{ telle que} \\ \operatorname{card} J \leq \pi_0, \text{ qui n'est pas majorée dans } I'_\alpha, \text{ on choisit} \\ \text{un majorant } i_J \text{ dans } I \text{ ([qui] existe, car } I \text{ [est] grand} \\ \text{devant } \pi, \text{ donc devant } \pi_0) \text{ et } I'_{\alpha+1} \text{ s'obtient en adjoignant} \\ \text{ces } i_J \text{ à } I'_\alpha. \end{cases}$$

Soit alors α_0 le premier ordinal qui soit de cardinal $> \pi_0$, et considérons

$$I' \ = \ I'_{\alpha_0} \ = \ \bigcup_{\substack{\alpha<\alpha_0 \\ i.e.\ \operatorname{card}\alpha\leq\pi_0}} I'_\alpha. \qquad \text{[page 81]}$$

Alors I' contient I'_0, il est grand devant π_0, mais quel est son cardinal ? Prouvons par récurrence transfinie que

$$\operatorname{card} I'_\alpha \ \leq \pi \qquad \text{si } \alpha < \alpha_0, \quad i.e. \ \operatorname{card}\alpha \leq \pi_0.$$

C'est O.K. pour $\alpha = 0$ par hypothèse sur I'_0. Si c'est vrai pour I'_α, est-ce vrai pour $I'_{\alpha+1}$? On adjoint à I'_α un ensemble d'éléments i_J qui est de cardinal $\leq \operatorname{card} \mathfrak{P}_{\leq\pi_0}(I'_\alpha)$, donc de cardinal $\leq \operatorname{card} (I'_\alpha)^{\pi_0} \leq \pi^{\pi_0}$, et si on suppose

$$\pi^{\pi_0} \ = \ \pi,$$

40. Pourvu qu'on suppose $\pi > \pi_0$, et de plus $\pi^{\pi_0} = \pi$ (p. ex. $\pi = 2^c$ avec $c \geq \pi_0$).

on gagne. Supposons enfin que α soit un ordinal limite (de cardinal $\leq \pi_0$). Donc on a

$$I'_\alpha \;=\; \bigcup_{\beta<\alpha} I'_\beta,$$

donc p. 45

$$\operatorname{card} I'_\alpha \;\leq\; \underbrace{(\operatorname{card}\alpha)\pi}_{\leq\pi\pi=\pi^2=\pi} \qquad \text{puisque les } \operatorname{card} I'_\beta \leq \pi, \qquad \text{[page 82]}$$

on gagne encore.

On trouve enfin, par le même argument,

$$\operatorname{card} I'_{\alpha_0} \;\leq\; \underbrace{(\operatorname{card}\alpha_0)\pi \leq \pi^2}_{\substack{\text{si } \operatorname{card}\alpha_0\leq\pi,\\ \textit{i.e.}\ \text{si } \pi_0<\pi}} = \pi,$$

donc on gagne encore.

Commentary · Exposition [ms. 82]

Why the transfinite closure has to run far enough

The editors distinguish two different closure problems. If I is already grand devant π and $S \subset I$ has size at most π, a single upper bound s gives the required subposet $S \cup \{s\}$. It has a largest element, so it is grand devant every cardinal. This proves the stated Lemma 1 without any exponent assumption. The longer proof is useful when the ambient poset is only grand devant π_0; that is the corrected Lemma 1′.

Put $\lambda = \pi_0^+$. Starting with $S_0 = S$, adjoin at each successor stage an upper bound for every subset of S_α having cardinal at most π_0, and take unions at limit stages. Suppose $\pi > \pi_0$ and $\pi^{\pi_0} = \pi$. Each successor step adds at most $\pi^{\pi_0} = \pi$ elements. A union of at most π sets of size at most π again has size at most π, so every S_α, including S_λ, satisfies the desired bound.

The omitted verification is that S_λ is grand devant π_0. Given $A \subset S_\lambda$ with $|A| \leq \pi_0$, choose a stage containing each of its elements. Since $\lambda = \pi_0^+$ is regular, these at most π_0 stages are bounded below λ. Hence $A \subset S_\alpha$ for some $\alpha < \lambda$, and the next stage contains an upper bound for A. This is why merely iterating the operation finitely many times, or through a sequence of cofinality at most π_0, would not prove the assertion.

The exponent hypothesis is sufficient rather than intrinsic. For example, when the desired bound is exactly π_0^+, enumerate the initial subset in a sequence of length π_0^+ and recursively choose an upper bound for the elements enumerated so far and the previously chosen bounds. At each proper stage there are at most π_0 requirements. Adjoining the resulting increasing sequence to the initial subset produces a subposet grand devant π_0, of cardinal at most π_0^+, without assuming $(\pi_0^+)^{\pi_0} = \pi_0^+$. We will use this elementary successor-cardinal improvement when returning to the unfinished final lemma.

These are two applications of the same method: control the number of requirements at a successor step, then choose a length whose cofinality catches every small family of requirements. Modern accessibility arguments still use this mechanism. The explicit stronger size assumption in Lurie (2009, Lemma 5.4.2.8) serves exactly this purpose in the setting of ∞-categories.

Ainsi, on a trouvé un deuxième système inductif

$$(X_{\tilde{\imath}})_{\tilde{\imath}\in\tilde{I}}$$

du même type que le système initial, ayant comme limite inductive X (qu'il ait même limite inductive est immédiat). Mais qu'a-t-on gagné ? Ceci : dans $\tilde{I}$ toute partie de cardinal $\leq \pi$ et grande devant π_0 est non seulement *majorée* dans $\tilde{I}$, mais même y admet une borne supérieure. Cela résulte du

Lemme 2 : *Soit I grand devant $\pi > \pi_0$, avec $\pi^{\pi_0} = \pi$* `[il suffit $\pi \geq \pi_0$]` *(cf. lemme 1). Soit $(I'_\alpha)_{\alpha\in A}$ un ensemble de parties de I qui sont dans $\tilde{I}$,* i.e. [page 83]

a) *de cardinal $\leq \pi$, et*

b) *grandes devant* π_0,

et supposons que $\operatorname{card} A \leq \pi$ *et que* A, *ordonné par inclusion, soit grand devant* π_0. *Alors* $I' = \bigcup_{\alpha \in A} I'_\alpha$ *est encore dans* $\tilde{I}$, i.e. I' *est de cardinal* $\leq \pi$ *(car de cardinal* $\leq \pi^2 = \pi$*), et de plus, grande devant* π_0. (Vérification immédiate.)

Ainsi, on a prouvé ceci :

Proposition 1. *Soit* E `[une]` *grosse catégorie, avec filtration cardinale* $(\mathrm{Filt}^\pi)_{\pi \geq \pi_0}$. *Soit* π *un cardinal avec*

$$\pi > \pi_0, \qquad \pi^{\pi_0} = \pi \qquad \textit{(p. ex. } \pi = 2^c\textit{, avec } c \geq \pi_0\textit{)} \quad \texttt{[}\pi \geq \pi_0 \texttt{ suffit]}.$$

Alors pour tout X *dans* E, *on peut trouver un système inductif* $(X_i)_{i \in I}$, *de limite* X, *avec*

a)
$$\begin{cases} X_i \in \mathrm{Filt}^\pi \ \textit{ pour tout } i \in I, \\ I \textit{ grand devant } \pi, \end{cases}$$

satisfaisant aux conditions supplémentaires suivantes :

b) *Toute partie* J *de* I *de cardinal* $\leq \pi$, *et grande devant* π_0, *admet une borne supérieure* i_J *dans* I.

c) *On a, sous ces conditions*

$$X_{i_J} \xleftarrow{\sim} \varinjlim_{i \in J} X_i. \qquad \text{p. 46 [page 84]}$$

De plus, si $X \in \mathrm{Filt}^{\pi'}$ *avec* $\pi' > \pi$, *on peut prendre* I *de cardinal* $\leq \pi'^{\pi}$ *(donc de cardinal* $\leq \pi'$ *si* $\pi'^{\pi} = \pi'$, *p. ex. si* $\pi' = 2^{c'}$, *avec* $c' \geq \pi$*).*

Définition. On appelle un système inductif $(X_i)_{i \in I}$, satisfaisant les conditions *a*), *b*), *c*) ci-dessus, un *système inductif bien adapté* (à la filtration cardinale donnée, pour les cardinaux π_0, π donnés), et la représentation correspondante

$$X \xleftarrow{\sim} \varinjlim X_i$$

une *représentation bien adaptée* de X en termes d'objets de Filt^π.

Commentary · Exposition [ms. 84]

A presentation that is continuous on its small pieces

Grothendieck wants the indexing set to remember small colimits already performed. An arbitrary directed presentation has upper bounds, but its value at an upper bound need not equal the colimit of the stages below it. Replacing indices by small directed subsets builds this continuity into the presentation.

Take $X = \varinjlim_{i \in I} X_i$ as in condition (c), and let P consist of the subposets $S \subset I$ of size at most π which are grand devant π_0. Order P by inclusion and put $Z_S = \varinjlim_{s \in S} X_s$. The ambient hypothesis on I gives an upper bound for the union of at most π members of P; adjoining that element produces another member of P. Thus P is grand devant π. Condition (b) gives $Z_S \in \mathrm{Filt}^\pi(E)$, while the elementary bound on subsets gives $|P| \leq |I|^\pi$.

The equality of the two colimits can be verified directly, without a cofinality convention. A compatible family of maps $Z_S \to Y$ gives maps $X_i \to Y$ by using the singleton subset $\{i\}$. For $i \leq j$, the two-element subset $\{i, j\}$, which has largest element j, ensures compatibility. Conversely a cocone on the X_i induces one on every Z_S, and these two operations are inverse. Hence $\varinjlim_P Z_S \simeq X$.

Now let $A \subset P$ be grand devant π_0 and have cardinal at most π. Its union $S = \bigcup_{T \in A} T$ has size at most π. For a subset $B \subset S$ of size at most π_0, choose one $T_b \in A$ containing each b. An upper bound $T \in A$ for these members contains B, and an upper bound for B inside T belongs to S. Thus $S \in P$, and S is the supremum of A. A cocone on the diagrams over all $T \in A$ is exactly a cocone over their union, so

$$Z_{\sup A} = Z_S \simeq \varinjlim_{T \in A} Z_T.$$

This proves the continuity clause in Proposition 1, not merely the existence of suprema in its indexing poset.

When all filtered colimits exist and the filtration is strict in the bounded sense of footnote 41, the same proof uses ordinary directed subposets S and ordinary directed families A. A union of a directed family of directed subposets is directed. A subset of I of size at most π can be enlarged to a directed subset of that same size by adding upper bounds for finite subsets through countably many stages. This yields Proposition 1 bis. The word "perfectly" records the stronger continuity, with no change to the cardinality bound on the partial diagrams. The inverse-limit sign in the preceding display on manuscript page 85 is a source slip: the construction uses a colimit.

NB Quand E est stable par petites $\varinjlim$ filtrantes, la situation se simplifie considérablement. On peut alors prendre

$$\tilde{I} \;=\; \{I' \subset I \mid \operatorname{card} I' \leq \pi,\ I' \text{ filtrant}\}$$

(sans s'encombrer de la condition I' grand devant π_0) et définir encore le système inductif $(X_{I'})_{I' \in \tilde{I}}$ par

$$X_{I'} \;=\; \varinjlim_{i \in I'} X_i \ .$$

On a encore [page 85]

$$\operatorname{card} \tilde{I} \;\leq\; (\operatorname{card} I)^{\pi} \;\leq\; \pi'^{\pi} \qquad \text{si} \ \ \operatorname{card} I \leq \pi'^{\pi}$$

(notamment, si $X \in \mathrm{Filt}^{\pi'}$, et qu'on prenne I comme indiqué dans la condition c des filtrations cardinales). De plus, cette fois, le fait que $\tilde{I}$ soit grand devant π est trivial, on a même mieux, à part que I soit filtrante :

(∗) *Toute* partie $(I'_\alpha)_{\alpha \in A}$ de $\tilde{I}$ filtrante et de cardinal $\leq \pi$ admet une borne supérieure $\tilde{\imath}_A$,

savoir la réunion (qui est bien filtrante). De plus, le système inductif $(X_{\tilde{\imath}})_{\tilde{\imath} \in \tilde{I}}$ a la propriété plus forte que

$$X_{\tilde{\imath}_A} \xleftarrow{\sim} \varprojlim_{\tilde{\imath} \in A} X_{\tilde{\imath}} \ .$$

Ainsi on a la

Proposition 1 bis. *Supposons E stable par petites $\varinjlim$ filtrantes, et Filt^π stable par celles-ci, où $\pi \geq \pi_0$ est donné. Alors pour tout X dans E, on peut trouver un système inductif $(X_i)_{i \in I}$ de limite inductive X, avec*

a) *$X_i \in \mathrm{Filt}^\pi$ pour tout $i \in I$, I ensemble ordonné grand devant π.*

b) *Toute partie J de I filtrante de cardinal $\leq \pi$ admet une borne supérieure i_J dans I.*

c) *Sous ces conditions*

p. 47
[page 86]

$$X_{i_J} \;=\; \varinjlim_{i \in J} X_i \ .$$

De tels systèmes inductifs seront dits *"parfaitement adaptés"* (à la filtration cardinale donnée, pour le cardinal π donné – π_0 n'y figure plus, si ce n'est comme début de la filtration cardinale sans plus).

Commentary · Examples [ms. 86]

Sets and modules as perfectly adapted presentations

The basic example makes every condition concrete. In $E = \mathrm{Set}$ put $\mathrm{Filt}^\pi(E) = \{S : |S| \leq \pi\}$. A skeleton is a set of cardinals, so the stage is essentially small. A colimit of a diagram with at most π objects, each of size at most π, is a quotient of a disjoint union of size at most $\pi \cdot \pi = \pi$. Thus the required bounded closure holds, even for arbitrary colimits of that size.

For a set X consider

$$I = [X]^{\leq \pi}, \qquad X_A = A \quad (A \in I),$$

with inclusion maps. The union of at most π members has size at most π, so I is grand devant π. Every nonempty directed family $J \subset I$ of size at most π has supremum $\bigcup J$, and its colimit in sets is this same union. The colimit of the entire diagram is X, since the singletons cover it. If $|X| \leq \pi'$, then $|I| \leq (\pi')^{\pi}$ for infinite X; finite X causes no difficulty. This is a perfectly adapted representation with the precise bound appearing in the source.

A set A of size at most π is π^+-presentable. To factor a map $A \to \varinjlim_I Y_i$ through one stage, choose representatives for its at most π values, and then one upper bound for their indices. If two such factorizations induce the same map, each of their at most π component equalities holds at some later stage; another upper bound makes the maps equal. Both surjectivity and injectivity of the Hom comparison are used. They are the categorical counterparts of choosing generators and then checking relations.

For modules over a ring R, fix an infinite $\pi \geq |R|$. Use modules whose underlying sets have size at most π. They form an essentially small class, and bounded filtered colimits preserve the size bound. Every module X is the union of its submodules of size at most π. Any set of at most π elements generates such a submodule: a linear combination uses finitely many coefficients, so there are at most π combinations. The poset of these submodules is grand devant π, and directed unions of at most π of them again have size at most π. This gives the same perfectly adapted presentation.

The module presentability assertion also includes relations. A module of size at most π has a surjection from a free module on at most π generators. That free module and its kernel have size at most π, so the kernel is generated by at most π elements. Factoring a homomorphism through a π^+-directed colimit requires at most π choices for generators and at most π equations for relations; a common later stage handles them all. Equality of two factorizations is checked on the generators. Thus the chosen stage consists of π^+-presentable modules.

These examples also locate an omission in the glossary. There, "strict filtration" is stated as closure of each stage under all filtered colimits, with no bound on the indexing cardinal. Together with condition (c), that statement would force $E = \mathrm{Filt}^{\pi}(E)$ for every π, hence would make E essentially small. The definition actually used here is the bounded one in footnote 41: closure under filtered diagrams of cardinal at most π. For instance, the union of π^+ many successively larger subsets of a set of cardinal π^+ shows why the bound cannot be discarded.

Comme pratiquement, on aura à manier surtout des E stables par petites $\varinjlim$ filtrantes, et des filtrations cardinales stables en conséquence (renforcement de la condition b) des filtrations cardinales), c'est le cas, et la notion de *représentation parfaitement adaptée* de X comme $\varinjlim_I X_i$ ($X_i \in \mathrm{Filt}^{\pi}$), que je mettrai en avant. Le cas "général", où on suppose seulement `[que]` E satisfait L_{π_0}, est plus alambiqué et se traite moins joliment ([41]).

Définition 2. Soit E munie d'une filtration cardinale stricte $(\underline{\mathrm{Filt}}^{\pi})_{\pi \geq \pi_0}$. Soit M une partie de ObE, $\underline{M}$ la sous-catégorie pleine de E qu'elle définit, et soit π un cardinal $\geq \pi_0$. On dit que M est π-*accessible,* où que $\underline{M}$ est π-*accessible*, si les conditions suivantes sont satisfaites. Pour tout système inductif [page 87]

$$(X_i)_{i \in I}$$

parfaitement adapté à la filtration cardinale pour π (donc I ensemble ordonné filtrant tel que toute partie filtrante J de cardinal $\leq \pi$ ait une borne supérieure i_J, et $X_{i_J} \xleftarrow{\sim} \varinjlim_{j \in J} X_j$) ; soit I_M l'ensemble des $i \in I$ tels que $X_i \in M$. Ceci posé, on veut ceci : pour que X $(= \varinjlim X_i)$ soit dans M, il faut et il suffit que I_M soit cofinal dans I (de sorte que X apparaît comme $\varinjlim$ filtrante, avec ensemble d'indices I_M grand devant π, d'éléments de $M \cap \underline{\mathrm{Filt}}^{\pi} \overset{\text{déf}}{=} M^{\pi}$).

J'ai envie de reprendre la définition de la π-accessibilité de M, pour une filtration cardinale donnée, à coups de conditions équivalentes. Pour tout système inductif $(X_i)_{i \in I}$ dans M `[plutôt dans` E`]`, je garde la notation [page 88]

$$I_M \;=\; \{i \in I \mid X_i \in M\}.$$

41. On parlera de filtration cardinale *stricte,* si les $\underline{\mathrm{Filt}}^{\pi}$ sont stables par $\varinjlim$ filtrantes de cardinal $\leq \pi$ (et que ces limites filtrantes petites existent dans E).

Je pose, pour tout cardinal $\pi \geq \pi_0$,

$$M^\pi \;=\; M \cap \mathrm{Filt}^\pi.$$

(a$_\pi$) M est l'ensemble des objets de la forme

$$\varinjlim_{i\in I} X_i \ ,$$

où les X_i sont dans M^π, et I est grand devant π.

(b$_\pi$) Soit $(X_i)_{i\in I}$ un système inductif dans M [plutôt dans E] parfaitement adapté à la filtration cardinale pour π, *i.e.* I filtrante et toute partie filtrante J de I de cardinal $\leq \pi$ admet une borne supérieure i_J, et $X_{i_J} \xleftarrow{\sim} \varinjlim_J X_i$, et enfin $X_i \in \mathrm{Filt}^\pi$ pour tout $i \in I$. p. 48

Soit $X = \varinjlim X_i$. Pour que l'on ait $X \in M$, il faut et il suffit que I_M soit cofinal dans I.

(c$_\pi$) $\underline{M}^\pi = \underline{M} \cap \underline{\mathrm{Filt}}^\pi$ est une sous-catégorie de $\underline{M}$ génératrice par épimorphismes stricts, $\underline{M}$ est stable par $\varinjlim$ grandes devant π, enfin pour tout $X \in M$, $\underline{M}^\pi/X$ est une catégorie filtrante.

Je présume que ces conditions sont équivalentes.

[page 89]

Commentary · Exposition [ms. 89]

Three different ways to recognize a part

The purpose of the new definition is to recognize membership in a class M from small approximations. This would be particularly useful when E is an arrow category and M is a class of weak equivalences. Grothendieck proposes three tests, but their logical strengths differ.

The first, a_π, says that M is exactly the class of π^+-directed colimits of objects of $M^\pi = M \cap \mathrm{Filt}^\pi(E)$. It includes a closure assertion as well as an existence assertion. The second, b_π, says that *every* perfectly adapted presentation detects membership by a cofinal set of M-stages. It therefore imposes a condition on the individual stages of a chosen presentation, beyond the existence of some good presentation. The third, c_π, combines strict generation, closure under π^+-directed colimits, and ordinary filteredness of M^π/X.

At a useful cardinal, with M^π consisting of π^+-presentable objects, a_π is the familiar description by an Ind_{π^+}-completion. Indeed the canonical colimit functor out of that completion is fully faithful; the Hom calculation is the one in Artin et al. (1972, I, 9.18(a)). It follows in particular that the resulting full subcategory is closed under π^+-directed colimits. This explains the modern accessibility of the inclusion, but it does not make b_π automatic.

There are two distinct issues in the proposed equivalence. Ordinary filteredness controls finite diagrams, whereas a_π asks for compatibility of up to π constraints at once. Separately, two cofinal collections of small approximations need not meet: one may pick only successor stages and another only limit stages. Continuity of the second presentation does not force membership to pass to its countable colimits. The following examples isolate these two failures while keeping all objects in the small stage genuinely presentable.

Commentary · Development (commentators') [ms. 89]

Two counterexamples to the proposed equivalence

The distinction just made can be checked in a category with no nontrivial parallel arrows. This removes any possible ambiguity about coherence and leaves the cardinal issue exposed. We give the examples as our own verification of the conjecture on page 89. We did not find these particular examples in the relevant portions inspected of SGA 4 I, §9, *Les Dérivateurs* XVIII, §4.13 and Lemma 4.16.7.11, and the accessible-category references listed below; no priority is asserted.

Proposition: the implication $a_\pi \Rightarrow b_\pi$ fails at the same cardinal. [ours] Take $\pi = \aleph_0$ and let E be the poset $\mathcal{P}(\omega_1)$, viewed as a category under inclusion. Give it the strict filtration by cardinality, $\mathrm{Filt}^\rho(E) = \{S \subset \omega_1 : |S| \leq \rho\}$. Let

$$M = \{\alpha + 1 : \alpha < \omega_1\} \cup \{\omega_1\},$$

where ordinals denote their sets of predecessors. Then a_π and c_π hold, while b_π fails. Every object of $\mathrm{Filt}^\pi(E)$ is π^+-presentable in E.

Proof. Colimits in E are unions. Each filtration stage is small, since it is a subset of the universe-small set $\mathcal{P}(\omega_1)$. A union of at most ρ sets of size at most ρ again has size at most ρ, proving the bounded closure axiom for every infinite ρ. Each $S \subset \omega_1$ is the union of its subsets of size at most ρ; their poset is ρ^+-directed because a union of at most ρ such subsets is another one. If $|S| \le \rho'$ and $\rho' > \rho$, the number of indices is at most $(\rho')^\rho$; the finite cases satisfy this bound as well. This verifies the full filtration axiom (c), including its size estimate. Finally, in a π^+-directed union every countable subset of the union is contained in one stage. Since Hom sets in E have at most one element, this factorization assertion proves presentability of all the countable objects.

The objects of M^π are exactly the countable successor ordinals. Each is a constant directed colimit of such objects, and ω_1 is the union of all countable successor ordinals; their ordered set is countably directed. Conversely, consider a countably directed family of countable successor ordinals. If its union β is countable and is not attained, choose a countable cofinal subfamily. A single member bounding this subfamily would contain its union, contradicting nonattainment. Therefore a countable union arising this way is an attained successor ordinal. An uncountable union is ω_1. This proves a_π and closure of M under countably directed colimits.

For $X \in M$, the slice M^π/X is a nonempty linearly ordered set, hence is filtered. Its union is X. In a poset this says exactly that the canonical family of arrows from M^π is strictly epimorphic: any common upper bound of that family in M is an upper bound of X, and the required factorization is unique. Thus c_π holds as well.

Now index a diagram by the nonzero countable limit ordinals $\delta < \omega_1$, and set $X_\delta = \delta$. The index is countably directed: the supremum of any countable family is still countable, and a larger countable limit ordinal is an upper bound. Every nonempty directed subset of this index of cardinal at most $\aleph_0$ has its supremum in the index; a supremum of nonzero limit ordinals is again a nonzero limit ordinal. At that supremum the diagram value is the union of the earlier values. The presentation is therefore perfectly adapted, and its colimit is $\omega_1 \in M$. Nevertheless no stage belongs to M. Its set I_M is empty. This disproves b_π. □

Proposition: the implication $c_\pi \Rightarrow a_\pi$ also fails. [ours] In the same filtered category E, replace M by

$$N = \{S \subset \omega_1 : S \text{ is finite}\} \cup \{\omega_1\}.$$

Then c_π holds for N, but a_π does not.

Proof. Here N^π consists of the finite subsets. For a finite X, the slice N^π/X has largest element X; for $X = \omega_1$, it is the directed set of finite subsets, whose union is ω_1. These unions prove strict generation, as in the first example. A countably directed family of finite subsets has finite union. Otherwise choose countably many distinct elements of the union and a stage containing each; an upper bound for these countably many stages would be a finite set containing infinitely many elements. A countably directed diagram in N that contains ω_1 has union ω_1. Thus N is closed under the required colimits, proving c_π.

But no countably directed colimit of objects of N^π can equal ω_1, by the same finite-union argument. Hence a_π fails. □

The examples are legitimate $\mathfrak{U}$-categories. If one requires the ambient category itself to be non-small, take $E \times \mathrm{Set}$ with

$$\mathrm{Filt}^\rho(E \times \mathrm{Set}) = \{(S,T) : |S| \le \rho,\ |T| \le \rho\}.$$

A small skeleton is obtained by retaining the actual subsets $S \subset \omega_1$ and replacing T by a cardinal. Colimits are computed in each coordinate, so bounded closure follows from the union calculation above and the set-colimit calculation in the block "Sets and modules as perfectly adapted presentations." For condition (c), use the product poset $[S]^{\le\rho} \times [T]^{\le\rho}$. It is ρ^+-directed and has colimit (S,T). If both coordinates have size at most $\rho' > \rho$, its cardinal is at most $(\rho')^\rho \cdot (\rho')^\rho = (\rho')^\rho$. Countable objects are $\aleph_1$-presentable by the same simultaneous choice of representatives and equations in the two coordinates. Restrict the second coordinate of M or N to the empty set. All presentations, strict generating families and counterexample diagrams used above then have empty second coordinate, so every preceding verification remains valid. The repair to c_π is substantial: one needs a π^+-filtered canonical slice with the asserted canonical colimit, rather than merely an ordinary filtered slice. The first example shows that even this repaired generation condition does not recover the universal-presentation condition b_π at the same rank.

$b_\pi \Longrightarrow a_\pi$. On suppose b) vérifié, on veut prouver a). D'abord que tout $X \in M$ est de la forme dite $\varinjlim_I X_i$, avec les $X_i \in M^\pi$ et I grand devant π. Par [la] proposition 1, on sait qu'on a une présentation parfaite adaptée pour π, $X = \varinjlim_{i\in I} X_i$. Par b) "il faut", la partie I_M de I est cofinale dans I, donc comme I est grand devant π, I_M aussi, et on aura (posant $J = I_M$)

$$X \;=\; \varinjlim_{i\in J} X_i, \qquad\qquad X_i \in M^\pi, \quad J \text{ grand devant } \pi,$$

O.K. Inversement, prouvons que si X se met sous la forme dite dans a), il est dans M. Cela va résulter du

Lemme 1 : *Si la condition* b) (*ou* a)) *est satisfaite, M est stable par limites inductives grandes devant π.*

Il faut prouver que si [page 90]

$$X \;=\; \varinjlim_{i\in I} X_i \;,$$

avec I grand devant π, les X_i dans M, alors $X \in M$. La condition b) "il suffit" l'assure quand on suppose de plus les X_i dans Filt^π (donc dans M^π), de sorte que l'on aura $I_M = I$, donc I_M cofinal, donc $X \in M$ ([42]). Si on ne suppose pas les X_i dans Filt^π, il faut travailler un peu plus.

Passer tout de suite à la partie de la démonstration ci-dessous, page 96, qui prouve $b) \Longrightarrow a$). Le reste de la démonstration va prouver le

Lemme 2. *Si tout élément de Filt^π est π-accessible, alors* b_π) *(et même* a_π*) implique que M est stable par $\varinjlim$ grandes devant π.*

les flèches

$$(Z, i, \alpha) \;\longrightarrow\; (Z', i', \alpha')$$

sont les couples (u, λ) avec

$$u : Z \longrightarrow Z', \qquad \lambda : i \longrightarrow i', \qquad (\textit{i.e.} \text{ on a } i \leq i' \text{ et } \lambda \text{ est l'unique flèche de } i \text{ dans } i'),$$

tels que le diagramme

$$\begin{array}{ccc} Z & \xrightarrow{\ \alpha\ } & X_i \\ {\scriptstyle u}\downarrow & & \downarrow{\scriptstyle \text{transition } \lambda_{i',i}} \\ Z' & \xrightarrow{\ \alpha'\ } & X_{i'} \end{array}$$

commute. On peut donc définir $\mathcal{C}$ comme le produit fibré dans le carré cartésien

$$\begin{array}{ccccc} & & \mathcal{C} & \xrightarrow{\text{cofibré}} & I \\ & {\scriptstyle \mathcal{Z}}\swarrow & \downarrow & & \downarrow{\scriptstyle \mathcal{X}:X\longmapsto X_i} \\ \underline{M}^\pi & \xleftarrow{\ \text{source}\ } & \underline{M}^\pi/E & \xrightarrow[\text{cofibré}]{\text{but}} & E. \end{array}$$

La fibre $\mathcal{C}_i$ de $\mathcal{C}$ en $i \in I$ est Filt^π/X_i [plutôt M^π/X_i]. On a, comme $b) \Longrightarrow$ première moitié de a), que $\underline{M}^\pi$ est un système de générateurs stricts de $\underline{M}$ [cela n'est pas clair sans

42. Pas tout à fait – on y suppose plus, sur le système inductif. On ne peut se dispenser, même dans le cas $X_i \in M^\pi\ \forall\, i \in I$, faire le raisonnement des pages suivantes. [page 92]

`autres hypothèses sur` $\underline{M}$`]`, et $X_i \in \mathrm{Ob}\,\underline{M}$ par hypothèse,

$$X_i \;=\; \varinjlim_{Z \in \mathrm{Ob}\,\underline{M}^\pi/X_i} Z \;=\; \varinjlim_{\mathcal{C}_i} \mathcal{Z}|\mathcal{C}_i,$$

donc le système inductif donné $(X_i)_{i\in I}$ sur I à valeurs dans X, se déduit du système inductif (non ordonné en général) sur $\mathcal{C}$, à valeurs dans $\underline{M}^\pi$, en "intégrant sur les fibres" de $\mathcal{C} \longrightarrow I$. D'ailleurs, comme $\underline{M}^\pi/E \longrightarrow E$ est cofibrée, donc propre, il en est de même de $\mathcal{C} \longrightarrow I$, donc les $\varinjlim$ de $\mathcal{Z}$ sur les fibres $\mathcal{C}_i$ $(= \underline{M}^\pi/X_i)$ forment bien un foncteur covariant $I \longrightarrow E$, dont la limite inductive est celle de $\mathcal{Z}$ ([43]).

Soit, pour tout $i \in I$, $\tilde{\mathcal{C}}_i$ l'ensemble ordonné

p. 50
[page 93]

$$\tilde{\mathcal{C}}_i = \{\text{sous-catégories } \mathcal{C}'_i \text{ de } \mathcal{C}_i = \underline{M}^\pi/X_i \mid \mathrm{card}\,\mathcal{Z}(\mathcal{C}'_i) \leq \pi, \;\; \mathcal{C}'_i \text{ filtrante}\}.$$

J'admets pour l'instant le

Lemme ([44]). *Pour tout $X \in M$, la catégorie $\underline{M}^\pi/X$ est filtrante. (Sous l'hypothèse* b), *ou que tout objet de M est de la forme dite dans* a).*)*

Commentary · Exposition [ms. 93]

Presentability supplies the strict generators

Grothendieck now tries to replace a diagram of large M-objects by one diagram of small M-objects. The comma category is the right construction: it records a small object together with the map by which it participates in a particular large object. The editors' reservation on page 92 concerns the claim that a chosen colimit presentation already makes *all* maps from small objects into a canonical colimit presentation. Presentability supplies the missing comparison.

Here is the precise assertion. Let $\kappa = \pi^+$, let $A \subset E$ be an essentially small full subcategory of κ-presentable objects, and suppose

$$X \simeq \varinjlim_{j\in J} Y_j, \qquad J \text{ } \kappa\text{-directed}, \qquad Y_j \in A.$$

Then A/X is κ-filtered, and its canonical diagram has colimit X. This is the canonical-diagram form of the fully faithful Ind_κ construction in Artin et al. (1972, I, 9.18(a)).

To prove the assertion, take any diagram of fewer than κ morphisms in A/X. Each of its objects is a map $T \to X$ with T κ-presentable, so it factors through a Y_j. Choose one common upper bound for the indices used. For every arrow in the given diagram, the two resulting maps into this common stage agree after passage to X. Presentability of its source makes that equality hold at some later stage. There are fewer than κ equalities, so another common upper bound makes them all hold together. The resulting object $Y_{j'} \to X$ is a cocone in A/X. This proves κ-filteredness, including the case of the empty diagram.

To identify the colimit, let a compatible family $T \to Z$ be given for all objects $(T \to X)$ of A/X. Restrict it to the chosen presentation $Y_j \to X$, producing a unique map $h : X \to Z$. Any $T \to X$ factors through a Y_j, and compatibility with that factorization says that the prescribed map $T \to Z$ is h composed with $T \to X$. Thus h induces the whole family, uniquely. This proves the universal property of the canonical colimit. In particular its canonical family is strictly epimorphic in the ambient category, hence also in any full subcategory containing X and A.

Apply this with $A = M^\pi$. The first half of a_π, already obtained from b_π, supplies the required presentations. The tacit hypothesis in footnote 44 supplies presentability. Under those hypotheses the lemma on page 93 is correct, and in fact its slice is π^+-filtered, a stronger conclusion than printed. The precise missing step is factorization and eventual equality for *arbitrary* maps from M^π, not an additional assumption about epimorphisms in M.

The same argument explains why this construction is stable under a sufficiently directed change of the large object. For a κ-directed diagram (X_i) in M, form the category C of triples $(T, i, T \to X_i)$.

43. **NB** Si on admet la validité de *a*), alors il en résulte déjà que $\varinjlim_{i\in I} X_i \simeq \varinjlim_{\alpha\in C} Z_\alpha$ est dans M. (Stabilité de M par $\varinjlim$ grandes devant π).

44. Utilise l'hypothèse tacite que les éléments de Filt^π sont π-accessibles.

A diagram of fewer than κ arrows in C can first be moved into one fibre over I, and then given a cocone in that fibre by the preceding paragraph. Thus C is κ-filtered. Its colimit is $\varinjlim_I X_i$, because giving a cocone on C is giving compatible cocones on all the fibres. After the usual cofinal directed-poset replacement, this is a presentation by objects of M^π. If a_π holds, it proves closure of M under κ-directed colimits. The directed-poset replacement is the ordinary-category case of Lurie (2009, Proposition 5.3.1.18); it changes the index, not the colimit.

Il en résulte, comme $X_i \in M$, que $\mathcal{C}_i$ est filtrante, donc la réunion des $\mathcal{C}'_i \in \tilde{\mathcal{C}}_i$ est $\mathcal{C}_i$; l'ensemble ordonné $\tilde{\mathcal{C}}_i$ est filtrant, et toute partie $(\mathcal{C}'_{i_\alpha})_{\alpha\in A}$ filtrante et de cardinal $\leq \pi$ de $\tilde{\mathcal{C}}_i$ y admet une borne supérieure $\mathcal{C}'_{i_A}$, savoir la réunion des $\mathcal{C}'_{i_\alpha}$. $\tilde{\mathcal{C}}_i$ est donc un ensemble ordonné π-adapté.

On peut considérer les ensembles ordonnés $\tilde{\mathcal{C}}_i$, pour $i \in I$ variable, comme les fibres d'une application croissante d'ensembles ordonnés

$$p \,:\, \tilde{\mathcal{C}} \longrightarrow \mathcal{C},$$

en écrivant

$$\begin{cases} (\mathcal{C}'_i \subset \mathcal{C}_i) \;\leq\; (\mathcal{C}'_j \subset \mathcal{C}_j) \\ \text{si et seulement si } i \leq j, \\ \text{et le foncteur canonique de transition } \mathcal{C}_i \longrightarrow \mathcal{C}_j \text{ applique } \mathcal{C}'_i \text{ dans } \mathcal{C}'_j. \end{cases}$$

On voit donc que $\tilde{\mathcal{C}}$ est lui aussi filtrant et grand devant π.

On définit un système inductif sur $\tilde{\mathcal{C}}$, à valeurs dans $\underline{\mathrm{Filt}}^\pi$, en posant [page 94]

$$Z_{\mathcal{C}'_i} \;=\; \varinjlim_{\alpha\,\in\,\mathcal{C}'_i\ (\subset \mathcal{C}_i = \underline{M}^\pi/X_i)} Z_\alpha$$

(où un $\alpha \in \mathcal{C}_i$ est formé, je le rappelle, de $Z_\alpha \xrightarrow{u_\alpha} X_i$, avec $Z_\alpha \in M^\pi \subset \underline{\mathrm{Filt}}^\pi$). Ces $Z_{\mathcal{C}'_i}$ ne sont plus forcément dans M^π, mais seulement dans Filt^π. (Alors à quoi ça a servi de définir les $\mathcal{C}_i$ eux-mêmes comme $\underline{M}^\pi/X_i$, au lieu de $\underline{\mathrm{Filt}}^\pi/X_i$?)

Le système inductif

$$(Z_{\mathcal{C}'_i})_{\mathcal{C}'_i\in\tilde{\mathcal{C}}_i}$$

est parfaitement bien adapté à la filtration cardinale pour le cardinal π, et il est immédiat que sa $\varinjlim$ est isomorphe à $\varinjlim_{\alpha\in \mathrm{Ob}\,\mathcal{C}_i=\underline{M}^\pi/X_i} Z_\alpha = X_i \in M$. Donc par b), l'ensemble $\tilde{\mathcal{C}}_M$ des $\mathcal{C}'_i \in \tilde{\mathcal{C}}_i$ tels que $Z_{\mathcal{C}'_i} \in M$ (donc $Z_{\mathcal{C}'_i} \in M^\pi$) est cofinal dans $\tilde{\mathcal{C}}_i$. Il s'ensuit donc que l'ensemble $\tilde{\mathcal{C}}_M$ est lui aussi cofinal dans $\tilde{\mathcal{C}}$.

On vérifie aussi immédiatement que p. 51 [page 95]

$$\varinjlim_{\alpha\in\tilde{\mathcal{C}}} Z_\alpha \;=\; \varinjlim X_i \;=\; X,$$

donc, $\tilde{\mathcal{C}}_M$ étant cofinal,

$$\varinjlim_{\alpha\in\tilde{\mathcal{C}}_M} Z_\alpha \;=\; X.$$

Au total, on est arrivé à représenter X sous la forme

$$X \;=\; \varinjlim_{\alpha\in A} X_\alpha,$$

où cette fois les X_α sont *dans* M^π (pas seulement dans M), et A est grand devant π. Mais on ne sait pas que toute partie filtrante B de cardinal $\leq \pi$ de A admet une borne supérieure

α_B dans A, et encore moins que $X_{\alpha_B} = \varinjlim_{\alpha\in B} X_\alpha$ ([45]). Donc on ne peut encore appliquer directement b). S'il ne s'agissait que de prouver la deuxième moitié de a), où on suppose déjà les $X_i \in M^\pi$ et I grand devant π, on n'a rien gagné du tout par nos labeurs !

Commentary · Development (commentators') [ms. 95]

The size of an indexing category cannot be replaced by the size of its image

The partial-colimit construction is meant to keep all intermediate objects within Filt^π. For that purpose it must bound the indexing category. The literal condition on page 93, $\operatorname{card}\mathcal{Z}(C'_i) \le \pi$, bounds only the image of the diagram. That is insufficient, even if its cardinal counts image morphisms as well as image objects.

A filtered counterexample to the image bound. [ours] Let $E = M = \mathrm{Set}$ with the usual cardinal filtration, let $\pi = \aleph_0$, and choose an uncountable set X. Inside M^π/X, take the category C' whose objects are injections $a : n \hookrightarrow X$ from the standard finite sets $n = \{0, \dots, n-1\}$. A morphism from $a : n \hookrightarrow X$ to $b : m \hookrightarrow X$ is a map $u : n \to m$ satisfying $bu = a$.

This category is filtered. Two objects map into an injection whose image is the union of their two finite images. Parallel arrows are equal, since their composites with the injective target map are equal. The source functor $\mathcal{Z} : C' \to \mathrm{Set}$ has image inside the countable category of standard finite sets and maps; hence $\operatorname{card}\mathcal{Z}(C') \le \aleph_0$. Yet

$$\varinjlim_{C'} \mathcal{Z} \simeq X.$$

Indeed every element of X occurs through a one-element injection, and two representatives determine the same element precisely when they become equal in a finite union of their images. Equivalently the compatible injections give the usual directed union of the finite subsets of X. This colimit is not in $\mathrm{Filt}^{\aleph_0}(E)$. □

The corrected construction uses filtered *indexing categories* $D \subset C_i$ with at most π morphisms, or directed indexing posets of that size mapping to C_i. This correction does not require a bound on every Hom set of C_i. The subcategories need not be full. Start with at most π specified objects and arrows; close under identities and composition, adjoin cones for finite diagrams, and repeat countably often. Each step adds at most π data, since π is infinite. The resulting filtered subcategory still has at most π morphisms. In particular the poset of these small filtered subcategories is grand devant π: perform this construction on the union of any at most π of them.

A directed union of at most π such subcategories is again a filtered subcategory of size at most π and is their supremum. Colimits over this union are the colimits of the partial colimits. To apply the source's filtration axiom, which is phrased for posets, a filtered category with at most π arrows can be replaced cofinally by a directed poset of size at most π: the usual finite-diagram construction adjoins finitely many compatibility data at each of countably many stages. Thus the corrected partial colimit lies in Filt^π, and its presentation over the poset of small subcategories is perfectly adapted.

This also repairs the rest of the argument on pages 93–95. The map from the total poset of pairs $(i, D \subset C_i)$ has target I, as its displayed order relation specifies; the printed target C is a slip. To bound at most π such pairs, move their indices to one index of I and enlarge the union of their images to a small filtered subcategory of the corresponding fibre. Cofinality of the good partial colimits in every fibre then gives their cofinality in the total poset. The final diagram so obtained need not itself be continuous at all small directed suprema, exactly as Grothendieck observes on page 95. The reindexing on page 96 is therefore still needed.

The counterexample concerns this particular image-size formulation. The corrected small-subcategory construction is the familiar filtered-diagram argument, already used in SGA 4 I, 9.13.1. We did not find the specific counterexample above in the literature checked; it records our verification of the printed hypothesis, not a claim of priority.

Mais revenons à ce cas [page 96]

$$X = \varinjlim X_i \;\Big|\; \begin{array}{l} X_i \in M^\pi \\ I \text{ grand devant } \pi, \end{array}$$

45. Si on suppose (a_π), cet argument prouve du moins que M est stable par $\varinjlim$ grandes devant π.

et introduisons à nouveau

$$\tilde{I} \;=\; \{I' \subset I \mid I' \text{ filtrant, de cardinal } \leq \pi\},$$

donc cette fois $\tilde{I}$ est bien adapté à π (filtrant, et toute partie filtrante de cardinal $\leq \pi$ a une borne supérieure), et si on pose

$$X_{\tilde{\imath}} \;=\; \varinjlim_{i \in I'_{\tilde{\imath}}} X_i,$$

on voit que le système inductif

$$(X_{\tilde{\imath}})_{\tilde{\imath} \in \tilde{I}}$$

est parfaitement adapté à π et la filtration cardinale. De plus, je dis que l'ensemble $\tilde{I}_M$ est *cofinal* dans $\tilde{I}$. En effet, $\tilde{I}_M$ contient le sous-ensemble $\tilde{I}_0$ formé des $I' \in \tilde{I}$ qui ont un plus grand élément – et $\tilde{I}_0$ est bien cofinal ! Maintenant, on peut appliquer le "il suffit" dans b), p. 52
qui conclue que $X = \varinjlim X_i \in M$, q.e.d. [page 97]

On a prouvé $b \Longrightarrow a$, sans utiliser l'hypothèse que tout objet de Filt^π est π-accessible. Mais on a utilisé cette hypothèse pour prouver que b (ou a) implique que M est stable par $\varinjlim$ grandes devant π (lemme 2, p. 90).

Commentary · Exposition [ms. 97]

The implication that does not need presentable objects

The short argument on pages 96–97 is more robust than the intervening attempt to prove closure under large colimits. It proves $b_\pi \Rightarrow a_\pi$ directly, using only the strict filtration and the existence of perfectly adapted presentations. In particular it should not inherit the tacit presentability hypothesis needed for the preceding comma-category construction.

First suppose $X \in M$. Choose a perfectly adapted presentation $X = \varinjlim_I X_i$ at π. By b_π, the subset I_M is cofinal. A cofinal subset of a π^+-directed poset is again π^+-directed: take an upper bound in the original poset for any at most π elements, and then move above it into the cofinal subset. Restricting to I_M therefore presents X as a π^+-directed colimit of objects of M^π.

For the other implication in a_π, suppose $X = \varinjlim_{i \in I} Y_i$ with $Y_i \in M^\pi$ and I grand devant π. Let P be the poset of nonempty directed subsets $S \subset I$ of cardinal at most π, and put $Z_S = \varinjlim_S Y_i$. Strictness places each Z_S in Filt^π. The union construction makes $(Z_S)_{S \in P}$ perfectly adapted, with colimit X.

The key cofinal family consists of the subsets having a largest element. For any $S \in P$, choose an upper bound s of all of S in I and put $S^+ = S \cup \{s\}$. Then $S^+ \in P$, it contains S, and

$$Z_{S^+} \simeq Y_s \in M^\pi.$$

Hence P_M is cofinal in P. The sufficiency direction in b_π gives $X \in M$. This completes both directions of a_π.

The earlier inference on page 90 applied b_π directly to an arbitrary directed presentation and omitted its continuity hypothesis; footnote 42 explicitly retracts that inference. The argument just given is the source's own repair. After it is established, the additional hypothesis that M^π consists of π^+-presentable objects permits the closure argument through canonical comma categories. These are two different uses of the hypotheses, and retaining that separation prevents an artificial circularity in the proof.

$a \overset{?}{\Longrightarrow} b$. Le "il suffit" dans b) est conséquence immédiate de a). Il reste à prouver que si, dans le système inductif π-adapté $(X_i)_{i \in I}$ de limite X, on a $X \in M$, alors I_M est cofinal dans I. Mais par hypothèse a), on aura $X = \varinjlim_J Y_j$, avec J grand devant π, les Y_j dans M^π. Admettons que $\mathrm{Filt}^\pi \subset E_\pi$, *i.e.* tout élément de Filt^π, en particulier les X_i, sont π-accessibles.

Je pense que je n'arriverai pas à prouver $a_\pi \Longrightarrow b_\pi$, mais seulement ceci : Si π' est un cardinal $> \pi$ (disons le successeur de π dans la suite ordinale des cardinaux), alors $a_\pi \Longrightarrow b_\pi$.

Ceci va résulter du [page 98]

Lemme 3. *Soient* $X \simeq \varinjlim_{I} X_i$, $X \simeq \varinjlim_{J} Y_j$ *deux représentations de* X *sous forme des* $\varinjlim$ *filtrantes, avec* I *grand devant* π', J *grand devant* π, *avec* π, π' *deux cardinaux tels que* $\pi' > \pi$. *On suppose* $(X_i)_{i\in I}$ π'*-adapté,* i.e. *pour toute partie filtrante* I' *de* I *de cardinal* $\leq \pi'$, I' *a une borne supérieure* $i_{I'}$, *et* $X_{i_{I'}} = \varinjlim_{i\in I'} X_i$. *Alors pour tout* $i \in I$, *on peut trouver une partie* I' *de* I, *contenant* i, grande devant π, *de cardinal* $\leq \pi'$, *et une partie* J' *de* J, *enfin un isomorphisme* $I' \xrightarrow[\sim]{\lambda} J'$ *et une application strictement croissante* $\mu : J' \longrightarrow I'$ *et des homomorphismes* `[fin du chapitre]`

Commentary · Exposition [ms. 98]

Where the manuscript ends

Grothendieck has reached the comparison of two presentations when the manuscript breaks off. The final words announce homomorphisms without specifying them. We therefore have a programme for a comparison lemma, not a completed statement whose omitted proof can simply be supplied. The separate larger-cardinal repair is a theorem with its own stated hypotheses; it does not turn this fragment retrospectively into a finished argument.

The material that follows belongs to the edition's apparatus. Its notation and terminology indices refer to manuscript page numbers. Thus the reference "77" beside cardinal filtrations points to manuscript page 77, on printed page 42 of this edition. The glossary then restates definitions from the whole chapter, including sections outside these pages. Its axiom list is particularly useful here: it records finite limits and colimits in **M 0**, two factorizations in **M 2**, the properness conditions in **M′**, and the separate requirement $W = TF \circ TC$ in **M 2 bis**. These distinctions explain why the names of the various Quillen structures cannot be replaced indiscriminately by the single modern phrase "model category".

The glossary is a guide to those definitions, and should be checked against their explicit formulation in the manuscript. In its account of a strict cardinal filtration, the qualification "of cardinality at most π" has disappeared; manuscript page 86, footnote 41, supplies it. Its final paragraph also says "well adapted" where the immediately preceding definition requires "perfectly adapted". The audit registers these two discrepancies separately, retaining the printed wording. The bound matters: by the representation axiom every object of E is a filtered colimit of objects in any fixed stage, so unrestricted filtered-colimit closure would identify that stage with all of E. The printed glossary would then express a substantially different definition.

Finally, the bibliography after the glossary is the edition's bibliography. It includes the 1996 publication of Verdier's thesis; its presence is not evidence that Grothendieck had consulted that publication while writing these pages in 1990–1991. Our later references and our repairs are placed in the commentary and its own bibliography, where the date and the responsibility for each statement remain visible.

Commentary · Development (commentators') [ms. 98]

A complete comparison after one successor step

The chapter stops while Grothendieck is constructing a comparison between two presentations. The final Lemma 3 has no completed conclusion or proof, and we do not supply words to its unfinished sentence. His preceding proposal does, however, suggest a precise statement which can be proved under explicit presentability assumptions. The printed implication on page 97 repeats b_π; the surrounding reference to a larger cardinal indicates $b_{\pi'}$ as the intended target.

Successor comparison. [ours] Let E carry a strict cardinal filtration and let $\pi \geq \pi_0$ be infinite. Put $\kappa = \pi^+$ and $\mu = \kappa^+$. Assume that objects of $\mathrm{Filt}^\pi(E)$ are κ-presentable and that objects of $\mathrm{Filt}^\kappa(E)$ are μ-presentable. Let M be a replete full subcategory satisfying a_π. Then M satisfies b_κ, that is, b_{π^+} in the manuscript's notation.

We prove the statement rather than infer it from a general assertion that increasing a cardinal preserves every accessibility property. The literature checked includes SGA 4 I, 9.18, Grothendieck's later Chapter XVIII, §4.13 and Lemma 4.16.7.11, and Lieberman et al. (2020, §8). The argument below is a formulation for the particular continuous presentations used here; its use of alternating factorizations belongs to the standard comparison method for filtrations. We make no priority claim.

Proof. The canonical-slice argument above shows first that M is closed under κ-directed colimits. Indeed every object of M has a presentation by objects of M^{π}, these objects are κ-presentable, and a κ-directed diagram of such presentations can be combined into one κ-filtered diagram of their small terms. The closure half of a_{π} then applies.

We next obtain a more highly directed presentation of each $X \in M$, while keeping its terms in M. Write $X = \varinjlim_{j \in J} Y_j$ as in a_{π}. Any subset $S \subset J$ of cardinal at most κ lies in a κ-directed subposet $K \subset J$ of size at most κ. To see this, first adjoin any element of the nonempty poset J if S is empty, then enumerate S in length at most κ, repeating elements if necessary. At stage $\alpha < \kappa$, choose an upper bound in J for the current enumerated element and all previously chosen bounds. There are at most π of them. The increasing sequence of bounds, together with S, is κ-directed: any fewer than κ of its elements is accounted for before some stage, since κ is regular.

Let H be the poset of all these κ-directed subposets of J of size at most κ. It is μ-directed. The union of at most κ of its members has size at most κ, and the construction just given places that union in another member of H. Put

$$Z_K = \varinjlim_{j \in K} Y_j \qquad (K \in H).$$

The closure already proved gives $Z_K \in M$, and strictness of the filtration gives $Z_K \in \mathrm{Filt}^{\kappa}(E)$. Thus Z_K is μ-presentable by hypothesis. The union-of-subdiagrams argument gives $X \simeq \varinjlim_{K \in H} Z_K$.

Now take a perfectly adapted presentation $X = \varinjlim_{i \in I} X_i$ at cardinal κ. Its index I is μ-directed and its objects are μ-presentable. Fix $i_0 \in I$. We will construct increasing sequences $(i_{\alpha})_{\alpha<\kappa}$ in I and $(K_{\alpha})_{\alpha<\kappa}$ in H, together with maps over X

$$X_{i_{\alpha}} \xrightarrow{u_{\alpha}} Z_{K_{\alpha}} \xrightarrow{v_{\alpha}} X_{i_{\alpha+1}},$$

such that

$$v_{\alpha} u_{\alpha} = X(i_{\alpha} \le i_{\alpha+1}),$$

and, for $\alpha < \beta < \kappa$,

$$u_{\beta} X(i_{\alpha+1} \le i_{\beta}) v_{\alpha} = Z(K_{\alpha} \subset K_{\beta}). \tag{SC}$$

The first equality makes a trip through the other presentation agree with a transition in the X-diagram; the second does the same for the Z-diagram. They will give inverse maps on colimits.

Here are all the inductive choices. At a limit stage $\beta < \kappa$, choose i_{β} above the earlier i_{α} and $i_{\alpha+1}$; at a successor it has already been chosen. Since $X_{i_{\beta}}$ is μ-presentable, its map to $X = \varinjlim_{H} Z_K$ factors through some Z_K. Enlarge K above all the previously chosen K_{α}. For each $\alpha < \beta$, the two maps from $Z_{K_{\alpha}}$ to this stage occurring in (SC) agree after passage to X. Presentability of $Z_{K_{\alpha}}$ makes that equality hold at some later H-stage. There are fewer than κ, hence fewer than μ, such equalities. The μ-directedness of H permits one enlargement making all of them hold. Call the resulting index K_{β} and the factorization u_{β}.

Next factor $Z_{K_{\beta}} \to X$ through an X-stage, using its μ-presentability. Enlarge that stage above i_{β}. The composite with u_{β} and the transition out of $X_{i_{\beta}}$ have equal images in X; presentability of $X_{i_{\beta}}$ allows a further enlargement on which they are equal. This gives $i_{\beta+1}$ and v_{β}. The same process starts at $\beta = 0$, when there are no equations (SC) from earlier stages. Every choice takes place in a small diagram, and the regularity and directedness just used justify every limit stage.

Equations (SC) imply that the u_{α} define a map between the two chain colimits: compose (SC) with u_{α} and use $v_{\alpha} u_{\alpha} = X(i_{\alpha} \le i_{\alpha+1})$. They also imply that the v_{α}, followed by the structural maps to the X-chain colimit, are compatible. The two resulting maps are inverse, by the same displayed equalities. Consequently

$$\varinjlim_{\alpha<\kappa} X_{i_{\alpha}} \simeq \varinjlim_{\alpha<\kappa} Z_{K_{\alpha}} \in M.$$

The membership assertion uses closure of M under κ-directed colimits, since the regular ordinal κ is a κ-directed poset.

The perfectly adapted X-diagram has a supremum $i_* = \sup_{\alpha<\kappa} i_{\alpha}$ and is continuous there: the image of this chain is a directed subset of I with at most κ elements. Therefore $X_{i_*} \simeq \varinjlim_{\alpha<\kappa} X_{i_{\alpha}}$ belongs to M, and $i_* \ge i_0$. Thus I_M is cofinal whenever $X \in M$. Conversely, if I_M is cofinal then it is μ-directed, hence κ-directed, and closure of M gives $X = \varinjlim_{I_M} X_i \in M$. This proves b_{κ}. $\square$

The cardinal shift has a definite function. It permits a comparison chain of length π^+ whose final colimit remains a single stage of the larger adapted presentation. At the original cardinal, that chain is too large for the continuity clause. The counterexample with successor and limit ordinals shows that this obstruction can be real. No continuum hypothesis entered the proof, but presentability at both filtration levels did; the filtration axioms alone do not provide it.

Commentary · Later developments [ms. 98]

Canonical slices, later accessibility, and weak equivalences

Grothendieck returned to these questions at much greater length in Chapter XVIII. Definition 4.13.1 there asks that a full subcategory be replete, accessible, and accessibly included in the ambient accessible category. Lemma 4.16.7.11 tests membership by cofinality of the small canonical slice inside the ambient small-object slice. That is an intrinsic form of the generation condition, with presentability built into the indexing category. It does not assert that every continuous presentation already has cofinally many stages in the subcategory at the original rank. The two powerset examples above therefore leave the later criterion intact. The edition consulted is dated 17 December 2025; the cited lemma lies on manuscript pages 488–490 (Grothendieck, 1990–1991n).

In present terminology, accessibility and accessible inclusion are distinct conditions, and a rank belongs to the statement. The definition and the description as a completion under directed colimits are given by Adámek and Rosický (1994, Definition 2.1 and Theorem 2.26). The earlier monograph of Makkai and Paré (1989) situates these constructions within categorical model theory. For the higher-categorical formulation, Lurie (2009, Proposition 5.4.2.2) characterizes accessible ∞-categories by small generating subcategories of κ-compact objects for a suitable regular κ. Its nearby rank-enlargement results retain explicit cardinal conditions; a bare change from one regular cardinal to a larger one is not a general theorem.

The modern theory of filtrations also distinguishes a directed presentation from a continuous chain. Lieberman et al. (2020, §8, especially Lemma 8.4 and the following paragraph) discusses continuous filtrations and their agreement on a closed unbounded set of indices when the size has the appropriate regularity. This helps explain the example above: the successor-ordinal presentation of ω_1 is not continuous at its countable limit stages. The comparison theorem for two smooth filtrations therefore cannot turn its stages into stages of the continuous limit-ordinal presentation. We checked that discussion and Theorem 8.8 in the authors' 5 June 2019 version; we do not identify its notion of filtration with Grothendieck's cardinal filtration of the whole category.

For homotopical algebra, the relevant application is to a full subcategory of the arrow category. Raptis and Rosický (2015, Proposition 2.2 in author version 2; Proposition 2.3 in the journal) gives a controlled accessibility rank for weak equivalences in a combinatorial model category after the replacement functors preserve the specified presentable objects. Their Theorem 4.2 supplies better bounds under additional hypotheses, and Corollary 5.1 proves finite accessibility for weak equivalences of simplicial sets. These are genuine refinements of the small-generation problem motivating this chapter. They do not show that weak equivalences in every combinatorial model category are finitely accessible, nor do they establish the source's universal-presentation condition for an arbitrary filtration. The present status of the local questions is thus precise: $b_\pi \Rightarrow a_\pi$ is proved in the manuscript; the three-way equivalence as stated is false; the unfinished comparison has the explicit conditional completion proved above.

p. 57

$\mathcal{M}$ catégorie
$W \subset \mathrm{Fl}(\mathcal{M})$, $C, F, TC, TF \subset \mathrm{Fl}(\mathcal{M})$

M 0 La catégorie $\mathcal{M}$ admet des limites projectives finies et des limites inductives finies.

M 1 Les flèches appartenant à C ont la propriété de relèvement à gauche relativement à celles appartenant à TF, et les flèches appartenant à F ont la propriété de relèvement à droite relativement à celles appartenant à TC.

M 2 Toute flèche de $\mathcal{M}$ se décompose en une flèche de C suivie d'une flèche de TF, et en une flèche de TC suivie d'une flèche de F.

M 3 La partie F de $\mathrm{Fl}(\mathcal{M})$ est stable par composition et changement de base, C est stable par composition et cochangement de base, F et C contiennent les isomorphismes.

M 4 La partie TF de $\mathrm{Fl}(\mathcal{M})$ est stable par composition et changement de base, TC est stable par composition et cochangement de base, TF et TC contiennent les isomorphismes.

M 5 Si dans un triangle commutatif de $\mathcal{M}$ deux des trois flèches sont dans W, il en est de même de la troisième ; W contient les isomorphismes.

M′ $TC \subset C \cap W, TF \subset F \cap W$.

M″ Les flèches appartenant à C sont des W-cofibrations, et les flèches appartenant à F sont des W-fibrations.

M′$_0$(g) $TC = C \cap W$.

M′$_0$(d) $TF = F \cap W$.

M 2 bis $W = TF \circ TC$.

Glossaire

p. 58

Section 1

— $\Phi \subset \mathrm{Fl}(\mathcal{M})$
Φ est *clos à gauche* : il existe $\Psi \subset \mathrm{Fl}(\mathcal{M})$ tel que Φ soit formé des flèches ayant la propriété de relèvement à gauche relativement aux flèches de Ψ.

— $\Psi \subset \mathrm{Fl}(\mathcal{M})$
Ψ est *clos à droite* : il existe $\Phi \subset \mathrm{Fl}(\mathcal{M})$ tel que Ψ soit formé des flèches ayant la propriété de relèvement à droite relativement aux flèches de Φ.

— $\Phi, \Psi \subset \mathrm{Fl}(\mathcal{M})$
(Φ, Ψ) a la *propriété de factorisation de Quillen* :
a) les flèches de Φ ont la propriété de relèvement à gauche relativement aux flèches de Ψ ;
b) toute flèche f de $\mathcal{M}$ se factorise en

$$f = pi \quad , \qquad i \in \Phi \ , \quad p \in \Psi \ .$$

— (Φ, Ψ) *couple de Quillen* :
a) (Φ, Ψ) a la propriété de factorisation de Quillen ;
b) Φ est clos à gauche et Ψ clos à droite.

Section 2

— $W \subset \mathrm{Fl}(\mathcal{M})$
W *faiblement saturé* :
a) W contient les isomorphismes ;
b) si deux parmi les trois flèches d'un triangle commutatif sont dans W, la troisième aussi.

— $W \subset \mathrm{Fl}(\mathcal{M})$
Un morphisme $p : X \longrightarrow Y$ de $\mathcal{M}$ est une *W-fibration* ($p \in \mathrm{Fib}_W$) si pour tout diagramme de carrés cartésiens

p. 59

$$\begin{array}{ccccc} X & \longleftarrow & X' & \xleftarrow{t} & X'' \\ {\scriptstyle p}\downarrow & & \downarrow & & \downarrow \\ Y & \longleftarrow & Y' & \xleftarrow[s]{} & Y'' \end{array} \quad ,$$

si $s \in W$, alors $t \in W$.

- $W \subset \mathrm{Fl}(\mathcal{M})$
Un morphisme $i : A \longrightarrow B$ de $\mathcal{M}$ est une *W-cofibration* ($i \in \mathrm{Cof}_W$) si pour tout diagramme de carrés cocartésiens

$$\begin{array}{ccccc} A'' & \xleftarrow{s} & A' & \longleftarrow & A \\ \downarrow & & \downarrow & & \downarrow{\scriptstyle i} \\ B'' & \xleftarrow[t]{} & B' & \longleftarrow & B \end{array} \quad ,$$

si $s \in W$, alors $t \in W$.

- $W \subset \mathrm{Fl}(\mathcal{M})$
  Un morphisme $p : X \longrightarrow Y$ de $\mathcal{M}$ est *universellement dans* W, ou une W*-équivalence universelle* ($p \in W_{\mathrm{univ}}$) si pour tout carré cartésien

$$\begin{array}{ccc} X & \longleftarrow & X' \\ {\scriptstyle p}\downarrow & & \downarrow{\scriptstyle p'} \\ Y & \longleftarrow & Y' \end{array} \quad ,$$

  la flèche p' appartient à W.
- $W \subset \mathrm{Fl}(\mathcal{M})$
  Un morphisme $i : A \longrightarrow B$ de $\mathcal{M}$ est *coüniversellement dans* W, ou une W*-équivalence coüniverselle* ($i \in W^{\mathrm{univ}}$) si pour tout carré cocartésien

$$\begin{array}{ccc} A' & \longleftarrow & A \\ {\scriptstyle i'}\downarrow & & \downarrow{\scriptstyle i} \\ B' & \longleftarrow & B \end{array} \quad ,$$

  la flèche i' appartient à W.

p. 60

- *Pré-Q-catégorie de modèles à gauche* (resp. *à droite*) :
  $\mathcal{M}$ et W, C, F, TC, $TF \subset \mathrm{Fl}(\mathcal{M})$ satisfaisant aux axiomes **M 0** à **M 5**, **M′**, **M″** et $\mathbf{M'_0(g)}$ (resp. $\mathbf{M'_0(d)}$).
- *Q-catégorie de modèles*, *triple de Quillen* :
  catégorie de modèles au sens de Quillen.
- *Q-catégorie de modèles "close"*, *triple clos de Quillen*, *catégorie de Quillen close*, *système de Quillen clos* :
  catégorie de modèles fermée au sens de Quillen.
- *Pré-Quillen à gauche* (resp. *à droite*) :
  pré-Q-catégorie de modèles à gauche (resp. à droite).
- *Pré-quintuplet de Quillen clos* :
  W, C, F, TC, $TF \subset \mathrm{Fl}(\mathcal{M})$ satisfaisant aux axiomes **M 0** à **M 5**, **M′**, **M″**, C, TC étant clos à gauche et F, TF clos à droite.
- *Système de Quillen faible* :
  W, C, F, TC, $TF \subset \mathrm{Fl}(\mathcal{M})$ satisfaisant aux axiomes **M 0** à **M 5**, **M′**, **M″**.
- *Système de Quillen faible exact à gauche* (resp. *à droite*) :
  W, C, F, TC, $TF \subset \mathrm{Fl}(\mathcal{M})$ satisfaisant aux axiomes **M 0** à **M 5**, **M′**, **M″** et $\mathbf{M'_0(g)}$ (resp. $\mathbf{M'_0(d)}$).

Section 3

- $(\mathcal{M}, W)$ *catégorie de modèles* :
  $\mathcal{M}$ catégorie satisfaisant à l'axiome **M 0** ;
  $W \subset \mathrm{Fl}(\mathcal{M})$ faiblement saturé.
- *Structure de Quillen faible associée à la catégorie de modèles* $(\mathcal{M}, W)$:
  quadruplet (C, F, TC, TF) de parties de $\mathrm{Fl}(\mathcal{M})$ satisfaisant aux axiomes **M 1** à **M 5**, **M′**, **M″**.

p. 61

- *Structure de Quillen faible exacte* :
  structure de Quillen faible satisfaisant en outre à l'axiome **M 2 bis**.
- *Structure de Quillen faible exacte à gauche* (resp. *à droite*) :
  structure de Quillen faible satisfaisant en outre à l'axiome $\mathbf{M_0'(g)}$ (resp. $\mathbf{M_0'(d)}$).
- *Structure de Quillen faible close à gauche* (resp. *à droite*) :
  structure de Quillen faible (C, F, TC, TF) telle que C, TC (resp. F, TF) soient clos à gauche (resp. à droite).
- *Structure de Quillen faible close* :
  structure de Quillen faible à la fois close à gauche et à droite.
- *Structure de Quillen* :
  structure de Quillen faible "biexacte" :
  structure de Quillen faible à la fois exacte à gauche et à droite
  = catégorie de modèles de Quillen propre.
- *Structure de Quillen parfaite* :
  structure de Quillen faible "biexacte" et close
  = catégorie de modèles fermée de Quillen propre.

Section 5

- Catégorie de modèles $(\mathcal{M}, W)$ *quillénisable* :
  il existe une structure de Quillen faible *exacte* (C, F, TC, TF) associée à $(\mathcal{M}, W)$.
- $(\mathcal{M}, W)$ *quillénisable sur* Diag $\subset$ Cat :
  pour tout I dans Diag, la catégorie des modèles $(\mathcal{M}(I), W(I))$ est quillénisable.

Section 6

- Catégorie de modèles $(\mathcal{M}, W)$ *quillénisable uniformément à gauche sur* Diag :
  il existe une structure de Quillen faible *close* (C, F, TC, TF) pour $(\mathcal{M}, W)$ telle que pour tout I dans Diag, si l'on définit $C(I)$ et $TC(I)$ "argument par argument" (*), et $F(I)$ et $TF(I)$ par la propriété de relèvement à droite relativement à $TC(I)$ et $C(I)$ respectivement (†), le quadruplet $(C(I), TC(I), F(I), TF(I))$ soit une structure de Quillen faible *close exacte* pour $(\mathcal{M}(I), W(I))$. On dit alors que (C, F, TC, TF) est une *quillénisation uniforme à gauche* de $(\mathcal{M}, W)$ sur Diag).

p. 62

- Catégorie de modèles $(\mathcal{M}, W)$ *quillénisable sur* Diag *uniformément et exactement à gauche* :
  $(\mathcal{M}, W)$ admet une quillénisation uniforme à gauche sur Diag (C, F, TC, TF) telle que $TC = C \cap W$ (autrement dit, telle que (C, F, TC, TF) soit une strucure de Quillen faible *exacte à gauche*). On dit alors que (C, F, TC, TF) est une *quillénisation uniforme et exacte à gauche* de $(\mathcal{M}, W)$ sur Diag.

∗. Un morphisme de foncteurs $u : X \longrightarrow Y$ de I° vers $\mathcal{M}$ étant dans $C(I)$ (resp. $TC(I)$) si et seulement si pour tout objet i de I, u_i est dans C (resp. TC).

†. Un morphisme de $\mathcal{M}(I)$ étant dans $F(I)$ (resp. $TF(I)$) si et seulement si il a la propriété de relèvement à droite relativement aux flèches appartenant à $TC(I)$ (resp. $C(I)$).

Section 7

- I ensemble ordonné filtrant, π cardinal
  I *grand devant* π :
  toute partie de I de cardinal inférieur ou égal à π admet un majorant dans I.
- E catégorie
  Une *filtration cardinale* de E est une filtration croissante

$$\Big(\mathrm{Filt}^{\pi}(E)\Big)_{\pi\geq\pi_0} \quad , \qquad \pi_0 \text{ un cardinal infini fixé,}$$

  de E par des sous-catégories strictement pleines $\mathrm{Filt}^{\pi}(E)$, indexée par les cardinaux $\pi \geq \pi_0$ appartenant à un univers donné, et satisfaisant aux conditions suivantes :
  a) pour tout $\pi \geq \pi_0$, $\mathrm{Filt}^{\pi}(E)$ est équivalente à une petite catégorie ;
  b) la catégorie E admet des limites inductives filtrantes indexées par des ensembles ordonnés I grands devant π_0, et pour tout $\pi \geq \pi_0$, $\mathrm{Filt}^{\pi}(E)$ est stable par les dites limites si $\mathrm{card}\, I \leq \pi$;
  c) Pour tout $\pi \geq \pi_0$, et pour tout $X \in \mathrm{Ob}\, E$, il existe un isomorphisme

$$X \;\simeq\; \varinjlim_{i\in I} X_i \ ,$$

  où $(X_i)_{i\in I}$ est un système inductif filtrant dans E, indexé par un ensemble ordonné I grand devant π, et où les X_i sont des objets de $\mathrm{Filt}^{\pi}(E)$. De plus, si $X \in \mathrm{Ob}\,\mathrm{Filt}^{\pi'}(E)$, $\pi' \geq \pi$, on peut prendre I tel que $\mathrm{card}\, I \leq \pi'^{\pi}$.
- E catégorie, $(\mathrm{Filt}^{\pi}(E))_{\pi\geq\pi_0}$ filtration cardinale de E, $\pi \geq \pi_0$ cardinal
  Un *système inductif bien adapté* (à la filtration cardinale donnée, pour les cardinaux π_0, π donnés) est un système inductif filtrant $(X_i)_{i\in I}$ satisfaisant aux conditions suivantes :
  a) I est grand devant π, et pour tout $i \in I$, $X_i \in \mathrm{Filt}^{\pi}(E)$;
  b) Toute partie J de I de cardinal $\leq \pi$, et grande devant π_0, admet une borne supérieure i_J, et on a

$$X_{i_J} \;\xleftarrow{\sim}\; \varinjlim_{i\in J} X_i \ .$$

  Si X est un objet de E, une *représentation bien adaptée* de X, en termes d'objets de $\mathrm{Filt}^{\pi}(E)$, est la donnée d'un système inductif bien adapté $(X_i)_{i\in I}$, à la filtration cardinale donnée, pour les cardinaux π_0, π, et d'un isomorphisme p. 63

$$X \;\xleftarrow{\sim}\; \varinjlim_{i\in I} X_i \ .$$

- E catégorie admettant des petites limites inductives filtrantes
  Une *filtration cardinale stricte* de E est une filtration cardinale $(\mathrm{Filt}^{\pi}(E))_{\pi\geq\pi_0}$ telle que pour tout cardinal $\pi \geq \pi_0$, $\mathrm{Filt}^{\pi}(E)$ soit stable par limites inductives filtrantes.
- E catégorie admettant des petites limites inductives filtrantes
  $(\mathrm{Filt}^{\pi}(E))_{\pi\geq\pi_0}$ filtration cardinale stricte de E, $\pi \geq \pi_0$ cardinal
  Un *système inductif parfaitement adapté* (à la filtration cardinale donnée, pour le cardinal π) est un système inductif filtrant $(X_i)_{i\in I}$ satisfaisant aux conditions suivantes :
  a) I est grand devant π, et pour tout $i \in I$, $X_i \in \mathrm{Filt}^{\pi}(E)$;
  b) Toute partie J de I filtrante de cardinal $\leq \pi$, admet une borne supérieure i_J, et on a

$$X_{i_J} \;\xleftarrow{\sim}\; \varinjlim_{i\in J} X_i \ .$$

Si X est un objet de E, une *représentation parfaitement adaptée* de X, en termes d'objets de $\mathrm{Filt}^{\pi}(E)$, est la donnée d'un système inductif bien adapté $(X_i)_{i\in I}$, à la filtration cardinale donnée, pour le cardinal π, et d'un isomorphisme

$$X \xleftarrow{\sim} \varinjlim_{i\in I} X_i \ .$$

Overview · XIII-b

The second part of Chapter XIII joins two constructions that Grothendieck needs for the same purpose. He wants a homotopy theory to provide a coherent calculus of diagrams and their direct images. He also wants the replacements used in that calculus to be obtainable from a controlled set of small data. Sections 5 and 6 address the first problem through quillenisation; section 7 returns to the cardinal filtrations of SGA 4 to address the second. The manuscript ends during the statement of its final comparison lemma. The break is part of the surviving source, and the commentary does not supply a purported continuation of Grothendieck's text (Grothendieck, 1990–1991q).

Throughout these pages, $\mathcal{M}(I)$ means the category of contravariant diagrams $I^{\mathrm{op}} \to \mathcal{M}$, and $W(I)$ consists of objectwise weak equivalences. This variance explains both the right Kan extension formula over I'/s and the fact that a greatest element of a poset computes the ordinary limit by evaluation. Grothendieck's phrase "catégorie de modèles" initially specifies much less than a modern Quillen model category: it is a category with finite limits and colimits and a two-out-of-three class of morphisms. Cofibrations, fibrations, closedness, and exactness are additional data or properties. Keeping those qualifications visible is necessary both to understand the proofs and to avoid attributing modern theorems to a weaker hypothesis.

A closed exact structure has more force than the subsequent doubts suggest. Exactness says that every weak equivalence factors as a trivial cofibration followed by a trivial fibration. Closedness supplies closure under retracts for the lifting classes. The elementary retract argument therefore gives $TC = C \cap W$ and $TF = F \cap W$. In a uniformly left quillenised diagram theory, restriction preserves the objectwise cofibrations and trivial cofibrations, so its ordinary right adjoint preserves trivial fibrations. The graph-factorisation proof of Ken Brown's lemma then shows that this right adjoint preserves weak equivalences between fibrant diagrams. Consequently every u for which the ordinary u_* exists is admissible under those uniform closed exact hypotheses. This answers the product, tower, and group-indexing questions in the scope where the required ordinary operations exist. The argument uses only finite products, the specified factorizations, lifting, and two-out-of-three; it does not infer the existence of missing infinite limits (Hovey, 1999a, Lemmas 1.1.9 and 1.1.12).

Grothendieck nevertheless gives a useful geometric proof for finite posets. A downward-closed cover reduces a limit to a pullback, and the fibrancy of the cospan makes that pullback homotopy invariant. The construction exposes the local geometry behind pointwise derived direct images. His subsequent noetherian induction is correct, but its proposed larger class has an unexpected limitation: a sober noetherian Alexandrov space associated to a poset is finite. The commentary proves the assertion directly. Pointwise computation for a general comma category also deserves its own hypothesis: restriction to that comma category must preserve the chosen fibrant diagrams. This holds for the finite-poset situation and in the usual cocomplete diagram-model setting, where the left adjoint to restriction along a discrete fibration is computed by fibrewise coproducts. Admissibility and the pointwise comparison are thus separately justified.

The derived-category examples illuminate a different boundary. For a finite shape, a diagram of bounded-below complexes has a common lower bound. For an infinite discrete shape, its components may be bounded below at degrees that tend to minus infinity. Accordingly, $\mathrm{Ch}^+(\mathcal{A}(I))$ and $\mathrm{Fun}(I^{\mathrm{op}}, \mathrm{Ch}^+(\mathcal{A}))$ need not agree, and products need not stay in $D^+(\mathcal{A})$. An explicit family of shifted copies of a field k makes the obstruction visible. Unbounded resolutions answer the substantive existence question in the standard module and sheaf settings: K-injective resolutions allow right derived functors to be defined on the full unbounded derived category. Spaltenstein's work predates the present manuscript, and the general Grothendieck-category theorem is recorded precisely in the references. Beke's construction of the combinatorial injective model structure on unbounded complexes, combined with the diagram-model theorem, gives the all-small-category derivator for any Grothendieck abelian

category (Beke, 2000, Proposition 3.13). As a direct later algebraic treatment under the additional assumption of enough projectives, Alonso Tarrío, Álvarez Díaz, and Jeremías López prove the all-small-category strong derivator theorem for a Grothendieck category with enough projectives (Alonso Tarrío et al., 2023, Theorem 3.4, arXiv version 3).

The modern comparison also separates pointedness from stability. Fibre and cofiber sequences are available in pointed homotopy theories without making their homotopy categories additive or their suspension functors invertible. The manuscript's deliberately broad "triangulée" language must be read accordingly. Strong stable derivators give actual canonical triangulations, with exact diagram operations, as proved by Groth (2013, Theorem 4.16 and Proposition 4.18). His Theorem 1.28 and Proposition 1.30 provide the combinatorial model-category construction of the full derivator. These results explain the successful modern form of the programme without replacing the original finite-limit framework by an unstated cocompleteness assumption.

Section 7 changes the technical language but keeps the construction problem in view. A cardinal filtration $(\mathrm{Filt}^{\pi}(E))$ consists of essentially small stages, bounded colimit-closure conditions, and presentations of every object by sufficiently directed diagrams in each stage. "Grand devant π" means that every subset of cardinality at most π has an upper bound, hence means π^{+}-directed in the customary regular-cardinal convention. Membership in $\mathrm{Filt}^{\pi}(E)$ is a size condition; preservation of these colimits by $\mathrm{Hom}(A,-)$ is a presentability condition. The filtration axioms do not identify the two. SGA 4's comparison results explain why suitable cardinals permit one to use both, and why the extra hypothesis becomes visible in the discussion of canonical slice categories (Artin et al., 1972, I, 9.12 and 9.16–9.18).

The adapted-presentation construction itself survives the audit well. Replace an indexing poset by its small sufficiently directed subposets and take the colimit over each piece. The new index admits the relevant small suprema, and the new diagram preserves them. The editors correctly observe that the first enlargement lemma is immediate under its stated hypotheses: one may simply adjoin an upper bound to the given small subset. The transfinite proof does something more useful when only the weaker directedness of the ambient poset is assumed. Its cardinal equation controls the number of newly imposed bounds. The commentary proves both versions and checks their different assumptions. The separate assertion that generalized continuum hypothesis always makes $(\pi')^{\pi} = \pi'$ is false at singular π' with small cofinality; the displayed power-of-two case remains valid without that hypothesis.

The proposed equivalence of the three conditions on a part M needs a more substantial correction. Condition a_{π} describes M as the objects obtainable by π^{+}-directed colimits from $M \cap \mathrm{Filt}^{\pi}(E)$. Condition b_{π} asks, for every perfectly adapted presentation, that its colimit belong to M if and only if its M-stages are cofinal. Condition c_{π} combines strict generation, closure under sufficiently directed colimits, and ordinary filteredness of a canonical slice. These quantify over different data. The commentary gives two fully checked counterexamples in $E = \mathcal{P}(\omega_1)$ with $\pi = \aleph_0$. Taking M to be the countable successor initial segments together with ω_1 satisfies a_{π}, but a continuous diagram of countable limit initial segments violates b_{π}. Taking M to be the finite subsets together with ω_1 satisfies c_{π} but violates a_{π}. Both examples use the ordinary cardinality filtration, whose stages have the required presentability. They therefore cannot be removed by adding only the compactness hypothesis mentioned in the manuscript.

What does remain is substantial. Grothendieck's proof of $b_{\pi} \Rightarrow a_{\pi}$ is completed without any presentability assumption, using a cofinal family of small subposets with greatest elements. With presentable small stages, the canonical slice construction gives the stronger directedness needed to prove colimit closure. Near page 94 there is a distinct size error: bounding the image of an indexing category does not bound that category itself. A filtered diagram of finite sets can have an uncountable colimit even though only countably many finite sets and maps occur as values. The repair bounds the indexing morphisms. Finally, the enlarged-cardinal

idea is developed as a separate conditional result, with every object of $\mathrm{Filt}^{\pi}(E)$ assumed π^{+}-presentable and every object of $\mathrm{Filt}^{\pi^{+}}(E)$ assumed π^{++}-presentable, and with a complete alternating-chain proof. It is not presented as the missing end of Lemma 3. The powerset counterexamples and this conditional completion are marked as the commentators' work, with no claim of priority.

The accompanying registers preserve the distinction between a transcription mistake, a slip already present in the edition, and a mathematical claim requiring a proof or a correction. Every doubtful reading and every `[sic]` marker of the transcription is accounted for. The editorial indices, axiom list, and glossary have also been checked, including the missing cardinal bound in the glossary's definition of strict filtration. References report the portions actually verified. The purpose throughout is to let the reader follow the mathematical argument while retaining an exact account of what this fragment establishes, what later theory supplies, and what the present commentary proves separately.

Chapter XIV

Carrés h-cartésiens et h-cocartésiens

LES DÉRIVATEURS

ALEXANDRE GROTHENDIECK

Chapitre XIV

Carrés h-cartésiens et h-cocartésiens

Ce texte a été déchiffré et transcrit en LaTeX 2_ε par M. Künzer. Il a été édité par M. Künzer, J. Malgoire, et G. Maltsiniotis. La transcription est aussi fidèle que possible au manuscrit. Pour les quelques corrections évidentes, ou rares commentaires des éditeurs, ainsi que pour la numérotation originale des pages du manuscrit, les caractères de machine à écrire `[typewriter]` entre crochets sont utilisés. Un point d'interrogation entre crochets signifie que l'on n'est pas sûr du mot qui précède.

Ce chapitre est inachevé. Dans la première section, Grothendieck introduit une notion de "catégorie quadrangulée" à gauche (resp. à droite). Le texte s'interrompt brutalement au début de la deuxième section, consacrée aux exemples, quand Grothendieck réalise, sans doute, que l'exemple principal qu'il a en vue (la catégorie homotopique d'une catégorie de modèles munie des carrés homotopiquement cartésiens (resp. cocartésiens)) ne satisfait *pas* à l'axiomatique des catégories quadrangulées. Cela est brièvement expliqué dans une postface des éditeurs.

Cette édition est provisoire. Les remarques, commentaires et corrections sont bienvenus. Envoyer un message à :

G. Maltsiniotis

p. 1 [page 1]

1 Axiomes de structures quadrangulées (une tentative avortée)

Soit $(\mathcal{M}, W)$ une catégorie de modèles admettant une théorie de la fibre homotopique. Alors on a dans $\mathrm{Ho}_W = \mathcal{M}W^{-1}$ une notion de *carré W-cartésien* (ou W-homotopiquement cartésien), par quoi on entend un diagramme carré

$$\begin{array}{ccc} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{array}$$

dans Ho_W provenant, à isomorphisme près, d'un carré W-cartésien dans $\mathcal{M}$ – donc isomorphe, dans $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1, \mathrm{Ho}_W)$, a un carré *cartésien* `[dans` $\mathcal{M}$`]`

$$\begin{array}{ccc} Y_1 & \longleftarrow & Y_3 \ (\simeq Y_1 \times_{Y_0} Y_2) \\ {\scriptstyle p_1}\downarrow & & \downarrow \\ Y_0 & \underset{p_2}{\longleftarrow} & Y_2 \end{array} \quad ,$$

avec $p_1,\ p_2 \in \mathrm{Fib}_W$. (En fait, il suffit de p_1 ou p_2 dans Fib_W pour assurer le caractère W-cartésien du carré cartésien envisagé.) Je voudrais axiomatiser cette situation, histoire surtout de faire la liste des propriétés serviables essentielles de cette notion, et de la notion duale de carré W-cocartésien (ou W-homotopiquement cocartésien), dans le cas où $(\mathcal{M}, W)$ admet une théorie de la cofibre homotopique. L'espèce de structure, savoir celle des "catégories quadrangulées" (à gauche, à droite, bilatères) est une variante, dans un cas non additif, de [page 2]
la notion de catégorie triangulée dégagée par Verdier. Comme celle-ci, cette notion est en fait trop faible – ce n'est *pas* "la bonne" – mais elle a un intérêt pratique provisoire. La "bonne" notion (s'il en est une à part celle de dérivateur) devrait travailler avec une notion plus fine de carré et de carré W-cartésien, en travaillant systématiquement dans $\mathrm{HO}_W(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1) = \mathcal{M}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1)W(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1)^{-1}$ (où vivent les "vrais" carrés W-cartésiens !), et catégories similaires, telles que $\mathrm{HO}_W(\Psi)$, $\mathrm{HO}_W(\Phi)$. Mais les inclure dans une axiomatique ne faisant pas mention d'une catégorie de modèles $(\mathcal{M}, W)$, revient manifestement à mettre le doigt dans l'engrenage de la notion de dérivateur, et ce n'est pas mon propos pour l'instant.

Commentary · Exposition [ms. 1]

What a square must remember

Grothendieck wants a usable calculus of homotopy pullbacks on the category of homotopy types. The attraction is clear: four objects and four arrows are much easier to manipulate than a model category. The difficulty is already identified in his next paragraph. The comparison

$$\mathrm{dia}_{\square} : \mathcal{M}^{\square}(W^{\square})^{-1} \longrightarrow (\mathcal{M}W^{-1})^{\square}$$

forgets part of a diagram. Here $\square$ has arrows $3 \to 1 \to 0$ and $3 \to 2 \to 0$, with the two composites equal; $\Phi \subset \square$ omits 3. We use covariant diagrams, following the arrows actually drawn. An object on the left is a *coherent square*; on the right it is an ordinary commutative square in the localized category. Calling an object coherent does not mean that its chosen representative has stopped commuting strictly. It means that the whole diagram was localized together.

Write $\mathrm{Cart}_{\mathrm{im}}$ for the replete image, on the right, of the homotopy-cartesian objects on the left. Membership says that *some* coherent realization is cartesian. Proposition 1 will assert, incorrectly, that *every* strict realization is then cartesian. An isomorphism of underlying squares need not lift to an isomorphism of coherent squares. Likewise, four arrows forming a cube after localization need not form a morphism of the chosen coherent squares. These are the two losses that the postface makes explicit.

The opening fibration formula belongs to the assumed theory of homotopy fibres. For an arbitrary Quillen model category, a safe version is that $Y_1 \times_{Y_0} Y_2$ computes the homotopy pullback when $Y_1 \to Y_0$ is a fibration and Y_0, Y_2 are fibrant; right properness permits the familiar version without these fibrancy assumptions (Hovey, 1999b, Theorem 5.2.5 and the mixed Reedy argument of Lemma 5.2.6, dualized). Thus the opening paragraph should not be detached from its hypotheses or used to diagnose a false formula in the transcription. The editors state the precise Quillen version below.

The commentary on Chapter I, manuscript p. 7 ("Coherent squares and what the axioms remember"), and on Chapter IV, manuscript p. 75 ("Constructing the loop square without choosing homotopies"), supplies the general background. The new issue here is reflection of a universal property through $\mathrm{dia}_{\square}$, and the chapter itself supplies a counterexample.

Définition 1. J'appelle *"catégorie à carrés h-cartésiens",* ou *"catégorie quadrangulée à gauche",* une catégorie $\mathcal{H}$, munie d'un sous-ensemble Cart de l'ensemble $\mathrm{Hom}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1, \mathcal{H})$
p. 2 des diagrammes carrés `[par carré on entend carré commutatif]`

$$\begin{array}{ccc} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{array}$$

dans $\mathcal{H}$, carrés appelés *"h-cartésiens"* (h comme "homotopiquement"), cette donnée étant [page 3]
soumise aux axiomes qui suivent, Cart (1) à Cart (…).

Commentary · Context [ms. 2]

The earlier reason for keeping diagram categories

The retreat to diagram categories on manuscript page 2 is part of a long-standing programme. In *Pursuing Stacks*, §69, Grothendieck relates it to the difficulty of formulating trace additivity and determinant multiplicativity using only a derived category. His proposed object retains the derived categories of diagram categories, including filtered complexes of varying lengths (Grothendieck, 1983, pp. 1–2 of the edited excerpt). The letter to Thomason of 2 April 1991 returns to the mapping-cone problem and the need for this whole family (Grothendieck, 1991a, §2, pp. 5–6). These passages explain why an apparently modest square calculus leads back to derivators.

Heller's *Homotopy Theories* already organizes homotopy Kan extensions on diagram categories (Heller, 1988, Introduction, pp. 1–2). This is a historical parallel, not a warrant for all the proposed square rules. The point of the present fragment is precisely to test how much of that structure can survive on the single category $\mathcal{H}$.

Two different judgments in the source must therefore be distinguished. The ordinary square is too impoverished to carry the desired coherent universal property; nevertheless, some of the axioms imposed on such squares are too strong for their intended examples. There is no contradiction between these diagnoses. Nor should the editors' suggestion that Grothendieck stopped when he noticed the failure be converted into a documented account of his decision: the editors' postface proves the mathematical obstruction, not that biographical explanation.

Comme je ne suis pas sûr de connaître d'avance toutes les propriétés essentielles, le nombre de ces axiomes reste pour le moment ouvert.

Cart (1) (Symétrie). Si un carré

$$\begin{array}{ccc} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{array}$$

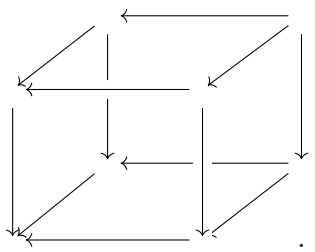
est h-cartésien, de même le carré symétrique (obtenu en échangeant le rôle de X_1 et de X_2).

Cart (2) (Carrés triviaux). Soit

$$\begin{array}{ccc} X_1 & \xleftarrow{q_2} & X_3 \\ {\scriptstyle p_1}\downarrow & & \downarrow{\scriptstyle q_1} \\ X_0 & \xleftarrow[p_2]{} & X_2 \end{array}$$

un carré dans $\mathcal{H}$, avec p_1 un isomorphisme. Alors le carré est h-cartésien si et seulement si q_1 est un isomorphisme.

Cart (3) (Carrés composés). Soit un diagramme commutatif



$$\begin{array}{ccccc} X'_0 & \longleftarrow & X'_1 & \longleftarrow & X'_2 \\ \downarrow & \text{I} & \downarrow & \text{II} & \downarrow \\ X_0 & \longleftarrow & X_1 & \longleftarrow & X_2 \end{array} \quad ,$$

d'où les carrés I, II et III :

$$\begin{array}{ccc} X'_0 & \longleftarrow & X'_2 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{array}$$

p. 3 (qu'on appelle *carré composé* ("horizontal") des carrés I et II). Supposons I h-cartésien. Alors II est h-cartésien si et seulement si III l'est `[voir postface des éditeurs]`.

Corollaire. *Soit un diagramme commutatif cubique, qu'on peut considérer comme homomorphisme d'un carré (face supérieure du cube) dans un autre (face inférieure) :*

Si toutes les faces du cube[1] *sauf la face supérieure sont des carrés h-cartésiens (savoir la face inférieure et les quatre faces latérales), il en est de même de la face supérieure.*[2] [page 4]

Commentary · Exposition [ms. 3]

Pasting, cancellation, and the cube

The first three axioms try to isolate the part of pullback calculus that can be used without constructing a pullback. Cart (2) has exactly the usual orientation: if the left vertical arrow is invertible, a square is distinguished precisely when the right vertical arrow is invertible. Cart (1) supplies the transposed assertion. Cart (3) then includes both composition and cancellation, with the left square held cartesian. Its failure for $\mathrm{Cart}_{\mathrm{im}}$ will be a failure of cancellation; the postface should not be read as disproving each implication separately.

We can fill in the cube argument entirely formally. Regard the cube as two horizontal squares S_X, S_Y and name the opposite lateral faces

$$B = \begin{pmatrix} X_1 & \leftarrow & X_3 \\ \downarrow & & \downarrow \\ Y_1 & \leftarrow & Y_3 \end{pmatrix}, \qquad F = \begin{pmatrix} X_0 & \leftarrow & X_2 \\ \downarrow & & \downarrow \\ Y_0 & \leftarrow & Y_2 \end{pmatrix}.$$

[1] En fait, il suffit de la face inférieure, et des deux faces parallèles latérales (p. ex. celle de devant et celle de derrière).

[2] **Corollaire** (de Cart (3) et Cart (2)) : *tout carré isomorphe à un carré h-cartésien est h-cartésien.*

If B and S_Y are distinguished, their vertical composite R is distinguished. The same rectangle is obtained by composing S_X with F. If F is distinguished, vertical cancellation implies that S_X is distinguished. Vertical pasting is horizontal pasting after Cart (1). This proves exactly the stronger three-face version in the first footnote; the other two lateral faces are unnecessary. An isomorphism of squares makes B, F distinguished by Cart (2), so the second footnote follows as well.

There is also an economy in the later list: Cart (5)(b) is already a consequence of Cart (1)–(3). For a cube between distinguished S_X, S_Y, suppose p_0, p_1, p_2 are isomorphisms. Then F is distinguished. Composing S_X and F makes R distinguished; cancelling S_Y makes B distinguished. Applying Cart (2) to B and p_1 forces p_3 to be an isomorphism. This deduction concerns the abstract axioms. The editors' two counterexamples will show why the intended class cannot satisfy them.

Ces axiomes sont dans la nature d'axiomes de stabilité, nous donnant des critères affirmant que certains carrés sont h-cartésiens, si telles conditions sont remplies (p. ex. que certains autres carrés sont déjà h-cartésiens). J'ai l'impression d'avoir épuisé ici les propriétés pertinentes de ce type (*i.e.* que les autres devraient pouvoir s'en déduire). À présent, je m'occupe de propriétés d'existence et d'unicité de carrés h-cartésien.

Cart (4) (Axiome du produit fibré). Tout diagramme

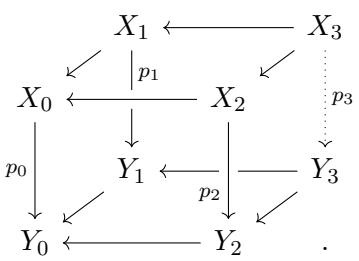
$$\begin{array}{ccc} X_1 & & \\ \downarrow & & \\ X_0 & \longleftarrow & X_2 \end{array}$$

dans $\mathcal{H}$ peut se compléter en un carré h-cartésien

$$\begin{array}{ccc} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{array} \quad .$$

L'axiome suivant (*cf.* son corollaire) assurera entre autres que le carré h-cartésien en question est *unique à isomorphisme près* – mais on fera attention qu'il n'est en général pas unique "à isomorphisme unique près".

p. 4 **Cart (5) (Axiome d'exactitude)** Considérons deux carrés h-cartésiens



$$X = \begin{pmatrix} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{pmatrix} \qquad \text{et} \qquad Y = \begin{pmatrix} Y_1 & \longleftarrow & Y_3 \\ \downarrow & & \downarrow \\ Y_0 & \longleftarrow & Y_2 \end{pmatrix}$$

et un homomorphisme $p = (p_0, p_1, p_2)$ entre les diagrammes de type

$$\Phi \;=\; \begin{array}{ccc} 1 & & \\ \downarrow & & \\ 0 & \longleftarrow & 2 \end{array}$$

associés (*cf.* diagramme en traits pleins ci-dessous) :

[page 5]

.

Alors :

a) Il existe un homomorphisme $\bar{p} : X \longrightarrow Y$ induisant p, *i.e.* il existe une flèche p_3 de façon à compléter le diagramme cubique commutatif (en respectant donc la contrainte de commutativité pour les deux carrés adjacents à l'arête p_3).

b) Si de plus p_0, p_1, p_2 sont des isomorphismes, il en est de même de p_3 `[voir postface des éditeurs]`.

Prenant le cas où p_0, p_1, p_2 sont des identités, on trouve :

Corollaire 1. *Sous les conditions de* Cart (4)*, si on a* deux *carrés h-cartésiens X, X' qui complètent*

$$\begin{array}{ccc} & & X_1 \\ & \swarrow & \\ X_0 & & \\ & \nwarrow & \\ & & X_2 \end{array} \quad ,$$

il existe un homomorphisme de X dans X' qui induise l'identité sur les sommets d'indices 0, 1, 2*, et un tel homomorphisme est toujours un isomorphisme.*

Mais cet isomorphisme n'est pas forcément unique, en d'autres termes, un automorphisme d'un carré h-cartésien peut induire l'identité sur les sommets X_0, X_1, X_2, sans être l'identité.

Commentary · Exposition [ms. 5]

Existence of a comparison is not a chosen comparison

Cart (4) supplies an object over each cospan. Cart (5)(a) asks that a map of cospans extend to some map of these objects; it does not specify a choice compatible with composition. Cart (5)(b), with its universal quantifier on the already chosen p_3, says that *every* such extension over an isomorphism of cospans is invertible. Replacing "every" by "there exists an invertible extension" would be a different axiom.

For a fixed cospan $A \to C \leftarrow B$, consider the category of cones whose objects are triples $(T, a : T \to A, b : T \to B)$ satisfying $fa = gb$, and whose arrows preserve a, b. The first corollary says that the full subcategory consisting of distinguished completions is nonempty, that any two of its objects admit a comparison, and that every comparison is invertible. This is a connected groupoid, not a proof that it is a terminal category. Existence follows by Cart (5)(a) with three identities; invertibility follows by (b). The source's nonuniqueness remark records the distinction between these conclusions. It supplies no separate example satisfying all five axioms with a nontrivial automorphism group.

For the intended homotopy class, the distinction is quite visible: the square with vertices $\Omega X, 0, 0, X$ and all edges zero permits every automorphism of ΩX over the fixed cospan. It also permits every *noninvertible* endomorphism, including zero. Thus this example illustrates nonuniqueness but simultaneously invalidates (b); it cannot validate the literal axiom system. In an additive category satisfying the whole system, the development below proves that no such nonuniqueness is possible.

In the coherent repair the relevant base is itself a category of coherent cospans. Restriction from cartesian coherent squares to that category is an equivalence. This gives an honest functorial construction there, while forgetting coherence can again identify distinct maps. Neither a noncanonical choice of apex nor an arbitrary commuting cube restores the information that was forgotten.

p. 5 **Corollaire 2.** *Considérons un carré commutatif* [page 6]

$$Y = \begin{pmatrix} Y_1 & \longleftarrow & Y_3 \\ \downarrow & & \downarrow \\ Y_0 & \longleftarrow & Y_2 \end{pmatrix} \quad ,$$

et un objet T de $\mathcal{H}$, d'où (posant $\mathrm{Hom}(T,X) = X(T)$*) un carré commutatif dans* (Ens)

$$\begin{array}{ccc} Y_1(T) & \longleftarrow & Y_3(T) \\ \downarrow & & \downarrow \\ Y_0(T) & \longleftarrow & Y_2(T) \end{array} \quad ,$$

et par suite

$$(*) \qquad Y_3(T) \longrightarrow Y_1(T) \times_{Y_0(T)} Y_2(T) \quad .$$

Si Y est h-cartésien, cette application $(*)$ *est* surjective *quel que soit T.*

On applique Cart (5) à Y et au carré constant X de valeur T

$$X = \begin{array}{ccc} T & \xleftarrow{\mathrm{id}} & T \\ {\scriptstyle \mathrm{id}}\downarrow & & \downarrow{\scriptstyle \mathrm{id}} \\ T & \xleftarrow{\mathrm{id}} & T \end{array} \quad ,$$

en notant que la donnée de $p = (p_0, p_1, p_2)$ de

$$\begin{array}{ccc} T & & Y_1 \\ \downarrow & \text{dans} & \downarrow \\ T & \longleftarrow T & Y_0 \longleftarrow Y_2 \end{array}$$

revient à la donnée d'un élément du deuxième membre de $(*)$,

$$\begin{array}{ccc} Y_1 & \xleftarrow{p_1} & T \\ \downarrow & \swarrow^{p_0} & \downarrow{\scriptstyle p_2} \\ Y_0 & \longleftarrow & Y_2 \end{array} \quad ,$$

et que les éléments de $Y_3(T)$ qui s'envoient (par $(*)$) dans cet élément ne sont autres que les p_3 dont l'axiome Cart (5) affirme l'existence.

N.B. On notera que l'application surjective $(*)$ n'est en général *pas* bijective, *i.e.* le carré h-cartésien n'est en général pas cartésien.

Commentary · Exposition [ms. 6]

Weak universality and the information in a homotopy

The second corollary identifies the positive content of the existence axiom. A distinguished square is a *weak pullback*: every compatible pair of maps from T factors through its apex, without uniqueness. The constant square on T is distinguished by Cart (2), and applying Cart (5)(a) to it gives exactly the surjection displayed in the text. Conversely, if every distinguished square is a weak pullback, apply its weak property to $T = X_3$ and the two composites $X_3 \to X_i \to Y_i$. This supplies Cart (5)(a). Thus, given the constant squares, the Hom-set assertion and that part of Cart (5) are equivalent.

For an actual homotopy pullback the surjection has a geometric explanation. In an enhanced homotopy theory, put

$$M_i = \mathrm{Map}(T, Y_i). \qquad \mathrm{Map}(T, Y_3) \simeq M_1 \times^h_{M_0} M_2.$$

A point of the homotopy pullback consists of two maps and a path between their composites. Equality in $\pi_0 M_0$ ensures that such a path exists, which proves surjectivity after taking components. Different choices of path can give different components. For the loop square, taking $T = S^0$ in pointed spaces and $X = S^1$ gives the map $\pi_0 \Omega S^1 \cong \mathbb{Z} \to \{*\}$, a fully explicit failure of injectivity.

This statement is about the intended homotopy class, not an example of all five literal axioms. Mapping spaces supply the universal property before π_0 is taken; compare Lurie (2009, §1.2.13).

There is a useful rigidity argument whenever an ordinary pullback $P = A \times_C B$ already exists in $\mathcal{H}$. Let Q be a distinguished completion. Its canonical map $q : Q \to P$ has a section $s : P \to Q$ by weak universality. The endomorphism sq of Q is over the identity cospan, so Cart (5)(b) makes it invertible. But $(sq)^2 = sq$; an invertible idempotent is the identity. Hence q is an isomorphism, and Q is an ordinary pullback. Conversely, Cart (4) and invariance under isomorphisms show that every existing ordinary pullback square is distinguished. Consequently, if $\mathcal{H}$ has all ordinary pullbacks, the proposed class is forced to be precisely that class. This is the familiar minimality argument for weak universal objects; its weak-kernel form is explicitly recorded by Krause (2016, §1, "Weak kernels", p. 6 of the 2014 manuscript).

p. 6 **N.B.** Il y a une notion duale de *catégorie à carrés h-cocartésiens,* ou *catégorie quadrangulée à droite.* Le plus souvent, les deux structures sont présentes simultanément. Il y a lieu de dégager des propriétés qui relient les deux structures duales sur une même catégorie. Ainsi, sauf erreur, dans le cas $\mathcal{H}$ additive, les deux espèces de carrés, les h-cartésiens et les h-cocartésiens, devraient *coïncider.* (Il me faudra revenir là-dessus par la suite.) Dans le cas $\mathcal{H}$ "ponctuée", il y a l'adjonction des foncteurs Σ, Ω liés l'un à la structure quadrangulée droite, l'autre à la structure quadrangulée gauche. Et il y a, quand il y a des $\underline{\mathrm{Hom}}$ internes ou externes, des propriétés éventuelles de $\underline{\mathrm{Hom}}(X, Y)$ par rapport aux quadrangles h-cocartésiens en X, h-cartésiens en Y – mais c'est à peine un lien entre les deux structures … [page 7]

Commentary · Later developments [ms. 7]

Additivity, stability, and the two variables of Hom

Grothendieck is looking for a common structure behind fibres and cofibres. Additivity alone cannot supply it. Take $\mathcal{H} = \mathrm{Vect}_k$, with ordinary pullback squares on the left and ordinary pushout squares on the right. Each structure satisfies the corresponding five axioms. For $V \neq 0$, the square

$$\begin{array}{ccc} 0 & \longleftarrow & 0 \\ \downarrow & & \downarrow \\ V & \longleftarrow & 0 \end{array}$$

is a pullback, since $0 \times_V 0 = 0$, but is not a pushout, since $0 \amalg_0 0 = 0$. This refutes the additive speculation within the literal framework, without using any defective homotopy example.

For coherent diagrams, the corrected hypothesis is *stability.* A pointed derivator is stable when its cartesian and cocartesian coherent squares coincide. The suspension–loop adjunction exists already in the pointed case; the equivalence of that adjunction characterizes stability (Groth, 2013, Proposition 3.17; Groth et al., 2014a, Theorem 7.1, arXiv v2). The corresponding higher-categorical statement appears in Lurie (2017, Proposition 1.1.3.4). These theorems concern coherent squares, and do not rescue Cart (3) on the ordinary homotopy category.

The Hom remark also has a precise scope. For fixed T, a derived mapping-space functor sends homotopy limits in its second variable to limits of spaces. In the first variable, mapping out of a homotopy colimit produces a homotopy limit. In a pointed enhancement this gives

$$\mathrm{Map}(\Sigma X, Y) \simeq \Omega\,\mathrm{Map}(X, Y) \simeq \mathrm{Map}(X, \Omega Y),$$

where loops in the mapping space are based at the zero map; taking components gives the adjunction. Cisinski constructs the external derived Hom for model-derived derivators and proves its continuity (Cisinski, 2003, Proposition 6.13, pp. 239–240). Internal Hom requires a specified closed monoidal structure and the appropriate derived adjunctions. Nothing on this page supplies such structure to an arbitrary category $\mathcal{H}$.

Commentary · Development (commentators') [ms. 7]

Binary products force the literal structure to be ordinary

The proposed axioms are meant to retain a weak universal property while allowing nonunique comparisons. The preceding rigidity argument shows that this freedom disappears wherever an ordinary pullback already exists. Pasting makes the restriction stronger: binary products alone force all the missing pullbacks to exist. This applies in particular to additive categories, without any assumption of kernels or of an abelian structure.

We assume Cart (1)–(5) literally throughout this block. The weak-kernel minimality argument has the antecedent cited above. We checked the editors' postface, the coherent-square discussion of Groth (2013, §3), and Krause (2016, §1), together with targeted literature searches. We did not find the following deductions from these particular axioms there. The marking identifies proofs supplied by us, not a claim of priority.

Pullback along a monomorphism. [ours] A distinguished square with a monomorphism among its two base arrows is an ordinary pullback.

Proof. Write the square as the left square below, with f monic. To test uniqueness of its lifting property, apply Cart (4) to $P \xrightarrow{q} B \xleftarrow{q} P$ and obtain the right square:

$$\begin{array}{ccccc} A & \xleftarrow{p} & P & \xleftarrow{r} & R \\ {\scriptstyle f}\downarrow & & \downarrow{\scriptstyle q} & & \downarrow{\scriptstyle s} \\ C & \xleftarrow[g]{} & B & \xleftarrow[q]{} & P. \end{array}$$

Cart (3) makes the outer rectangle distinguished. Its base cospan is $A \xrightarrow{f} C \xleftarrow{fp} P$, because $gq = fp$. Since f is monic, this cospan has ordinary pullback P with projections p and 1_P. The rigidity argument proved in the preceding exposition makes the canonical comparison $s : R \to P$ an isomorphism.

Weak universality of the right square supplies a diagonal $d : P \to R$ with $rd = sd = 1_P$. Thus $d = s^{-1}$ and $r = s$. If $u, v : T \to P$ satisfy $qu = qv$, the same weak property gives $w : T \to R$ with $rw = u$ and $sw = v$; hence $u = v$. Therefore q is monic. The original square is a weak pullback, and its factorization maps are unique because their composites with q agree. It is an ordinary pullback. Cart (1) treats the other base arrow. □

Collapse under binary products. [ours] If $\mathcal{H}$ has binary products and satisfies Cart (1)–(5), it has all pullbacks, and its distinguished squares are exactly its ordinary pullback squares.

Proof. Given $A \xrightarrow{f} C \xleftarrow{g} B$, form the cospan

$$C \xrightarrow{\Delta} C \times C \xleftarrow{f \times g} A \times B.$$

The diagonal is monic. A distinguished completion exists by Cart (4), and the preceding result makes it an ordinary pullback. Its apex is $A \times_C B$: a pair $a : T \to A$, $b : T \to B$ with $fa = gb$ gives the unique map (a, b) to $A \times B$ and the compatible map fa to C, so the displayed pullback property gives a unique map to the apex. All pullbacks therefore exist. Rigidity shows that each distinguished square is ordinary; Cart (4) and isomorphism invariance show that every ordinary pullback square is distinguished. □

No terminal object was used. Additivity supplies the required binary products as biproducts, so the theorem is stronger than an additive statement. It does not classify categories lacking binary products, and we draw no general nonexistence conclusion in that setting.

Pointed coincidence obstruction. [ours] If a pointed category carries both literal structures and their distinguished classes coincide, every object is isomorphic to zero.

Proof. For any X, the cospan $0 \to X \leftarrow 0$ has ordinary pullback 0. Cart (4), rigidity, and isomorphism invariance designate the square with base X and its other three vertices zero. Coincidence makes it distinguished cocartesian. Its upper span $0 \leftarrow 0 \to 0$ has ordinary pushout 0; dual rigidity therefore gives $X \cong 0$. □

Even without coincidence, the literal loop construction is always zero, by the same pullback argument, and the literal suspension is zero if the right structure is present. Their adjunction would be the vacuous zero-functor adjunction. The meaningful suspension and loop functors in homotopy theory belong to the coherent setting anticipated on manuscript page 2.

2 Exemples

Un premier exemple trivial, est celui où $\mathcal{H}$ est stable par produits fibrés, et où les carrés h-cartésiens sont définis comme les carrés cartésiens. Les axiomes Cart (1) à Cart (5) sont alors des propriétés bien connues, ± tautologiques de la notion de carré cartésien. Et en un [page 8] sens, le cas général doit se ramener à ce cas particulier banal.

Le seul type d'autre cas que je connaisse, est celui où $\mathcal{H} = \mathcal{M}W^{-1}$, où W est un localiseur admettant une théorie de la fibre W-homotopique (*cf.* chapitre XII). Dans ce cas, on l'a dit, on prend comme carrés h-cartésiens dans $\mathcal{H}$ ceux qui sont isomorphes, dans $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1, \mathcal{H})$, à un carré W-cartésien dans $\mathcal{M}$. Encore faut-il vérifier les axiomes Cart (1) à Cart (5). Je pense que je n'ai guère de chance d'y arriver que moyennant une

Proposition 1. *Moyennant des hypothèses sur $(\mathcal{M}, W)$ qui vont être dégagées ci-dessous, vérifiées en tous cas si $(\mathcal{M}, W)$ est quillénisable, sur la catégorie des ensembles ordonnés finis* (*cf.* XIII, p. 51)*, on a ceci : soit*

$$X = \begin{pmatrix} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{pmatrix}$$

un carré dans $\mathcal{M}$, et soit $\mathrm{ho}_W(X)$ *son image dans* $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1, \mathcal{H})$*. Pour que* $\mathrm{ho}_W(X)$ *soit h-cartésien, il* faut (*et il suffit, bien sûr*) *que X soit W-cartésien* `[voir postface des éditeurs]`*.*

Commentary · Exposition [ms. 8]

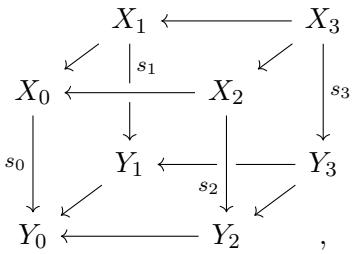
The precise assertion that fails in Proposition 1

Grothendieck hopes to verify the axioms by transporting a homotopy-cartesian criterion through localization. The sufficient direction of Proposition 1 is the definition of $\mathrm{Cart}_{\mathrm{im}}$: a homotopy-cartesian strict square has a distinguished underlying image. The necessary direction would make homotopy cartesianness a property of the ordinary underlying square alone. The editors disprove precisely this reflection statement.

It matters that the obstruction occurs in Quillen model categories with entirely familiar diagram model structures. It cannot be removed by the promised availability of models for finite ordered indexing categories. The walking square and the walking cube are already finite posets; the example below lives in complexes over a field, where all their diagram model structures are available. An additional hypothesis could restrict the homotopy theory drastically, but Quillen presentability of diagrams does not establish the proposition.

The preliminary example, ordinary pullbacks in an ordinary category, remains valid. Symmetry, the isomorphism test, and pasting follow directly from the pullback universal property; every cospan has a completion by hypothesis; a map of cospans induces a unique map of pullbacks; an invertible base map induces an invertible comparison. These statements also prove the stronger uniqueness omitted from the proposed homotopical axioms. The preceding development gives a precise circumstance in which the general axiom system really does reduce to this example: the existence of binary products. It does not vindicate the intended model-category example.

Postface des éditeurs



La proposition ci-dessus est fausse. On rappelle que si $\mathcal{M}$ est une catégorie de modèles fermée de Quillen de classe d'équivalences faibles W, un carré commutatif

$$X = \begin{pmatrix} X_1 & \longleftarrow & X_3 \\ \downarrow & & \downarrow \\ X_0 & \longleftarrow & X_2 \end{pmatrix}$$

de $\mathcal{M}$ est W-cartésien si et seulement si il existe un carré *cartésien*

$$Y = \begin{pmatrix} Y_1 & \longleftarrow & Y_3 \\ \downarrow & & \downarrow \\ Y_0 & \longleftarrow & Y_2 \end{pmatrix}$$

avec $Y_1 \longrightarrow Y_0$ une fibration, et Y_0 et Y_2 fibrants (cette dernière condition étant superflue si la catégorie de modèles $\mathcal{M}$ est propre à droite), et un morphisme de carrés $s : X \longrightarrow Y$, $s = (s_0, s_1, s_2, s_3)$, *i.e.* un cube commutatif

tel que s soit une équivalence faible argument par argument, *i.e.* $s_0, s_1, s_2, s_3 \in W$. Il est équivalent de demander que pour *tout* diagramme commutatif à flèches verticales des équivalences faibles

$$\begin{array}{ccccc} X_1 & \longrightarrow & X_0 & \longleftarrow & X_2 \\ \downarrow & & \downarrow & & \downarrow \\ Y_1 & \longrightarrow & Y_0 & \longleftarrow & Y_2 \end{array}$$

tel que $Y_1 \longrightarrow Y_0$ soit une fibration, et Y_0, Y_2 des objets fibrants, la flèche canonique $X_3 \longrightarrow Y_1 \times_{Y_0} Y_2$ soit une équivalence faible.

Commentary · Exposition [ms. 8]

Postface: why one strict comparison cube suffices

Editors' postface, printed p. 7. The editors replace the cospan before taking its limit. This makes the missing comparison map canonical, and explains the difference between a weak equivalence of whole squares and a mere isomorphism after applying $\mathrm{dia}_\square$.

Here is a verification with exactly their fibrancy hypotheses. Give $\Phi = (1 \to 0 \leftarrow 2)$ the Reedy degrees $\deg(2) = 0$, $\deg(0) = 1$, $\deg(1) = 2$, with $2 \to 0$ direct and $1 \to 0$ inverse. A diagram Y is Reedy fibrant precisely when Y_0, Y_2 are fibrant and $Y_1 \to Y_0$ is a fibration. The constant-diagram functor is left Quillen: for a (trivial) cofibration its relative latching maps at $1, 2$ are that map, and at 0 the identity. Hence its right adjoint, the pullback functor, is right Quillen. This is the mixed Reedy method of Hovey (1999b, Theorem 5.2.5 and the proof of Lemma 5.2.6), dualized.

For a cospan K, choose a Reedy trivial cofibration $K \to RK$ with fibrant target. Any objectwise weak equivalence $K \to Y$ to a cospan with the printed fibrancy conditions extends to a map $RK \to Y$ by lifting against $Y \to *$. It is a weak equivalence by two-out-of-three. Applying the right Quillen pullback functor preserves it, since both diagrams are fibrant. Consequently the two comparison

maps from the original fourth vertex are weak equivalences simultaneously. This proves "some" if and only if "every". Taking $Y_3 = \lim Y$ makes the fourth component of the strict cube the unique induced cone map, so it also proves the single-cube criterion.

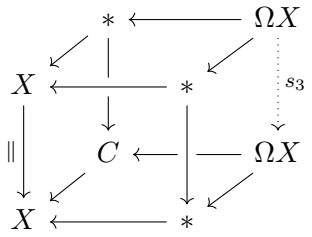
For completeness, right properness removes both objectwise fibrancy conditions. If $K_1 \to K_0$ is a fibration and $K \to R$ is a fibrant replacement of the cospan, put $K_1' = R_1 \times_{R_0} K_0$. Right properness and two-out-of-three make $K_1 \to K_1'$ a weak equivalence between fibrant objects of the slice $\mathcal{M}/K_0$. Pullback to K_2 is right Quillen, so

$$K_1 \times_{K_0} K_2 \longrightarrow R_1 \times_{R_0} K_2 \longrightarrow R_1 \times_{R_0} R_2$$

are weak equivalences: the first by that slice argument, the second by right properness. This verifies the parenthesis in the source, without adding a properness assumption to the fibrant version.

Supposons maintenant que la catégorie de modèles $\mathcal{M}$ soit ponctuée, autrement dit qu'elle admette un objet $*$ à la fois initial et final, et soit X un objet fibrant de $\mathcal{M}$. Choisissons une décomposition de la flèche $* \longrightarrow X$, en une équivalence faible suivie d'une fibration

$$* \longrightarrow C \longrightarrow X \quad ,$$



p. 8 et formons le carré cartésien

$$\begin{array}{ccc} C & \longleftarrow & \Omega X \\ \downarrow & & \downarrow \\ X & \longleftarrow & * \end{array} \quad ,$$

où par définition $\Omega X = C \times_X *$ est l'*espace des lacets* de X. Ce carré est W-cartésien. Par ailleurs, il est isomorphe dans $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1,\ \mathcal{M}W^{-1})$ au carré trivial

$$\begin{array}{ccc} * & \longleftarrow & \Omega X \\ \downarrow & & \downarrow \\ X & \longleftarrow & * \end{array} \quad .$$

Néanmoins, ce dernier n'est *pas* en général W-cartésien. En effet, s'il l'était, l'unique flèche $s_3 : \Omega X \longrightarrow \Omega X$ de $\mathcal{M}$ rendant commutatif le cube

serait une équivalence faible. Or, comme la flèche s_3 se factorise par $* \times_X * \simeq *$, cela impliquerait que $\Omega X \to *$ est une équivalence faible. Cette condition est très restrictive. Si, par exemple, $\mathcal{M}$ est la catégorie de modèles des espaces topologiques pointés, et X un CW-complexe pointé, elle équivaut à la contractibilité de la composante connexe de X contenant le point base. De même, si $\mathcal{M}$ est la catégorie de modèles des complexes d'une catégorie abélienne de Grothendieck et X un complexe, elle signifie que X est acyclique.

Commentary · Examples [ms. 8]

Postface: a two-term complex and the missing filling

Editors' postface, printed p. 8. The counterexample is especially transparent when every map can be written as a scalar. Let k be a nonzero field and use unbounded cochain complexes, with quasi-isomorphisms as weak equivalences and degreewise surjections as fibrations (Hovey, 1999b,

Theorem 2.3.11, with degrees reversed). Our shift convention is $(V[r])^n = V^{n+r}$, with differential $(-1)^r d_V$.

Take $X = k[0]$ and the acyclic complex $C = (k \xrightarrow{1} k)$ in degrees $0, 1$. Let $p : C \to X$ be the identity in degree 0 and zero in degree 1. This is a surjective chain map. Its kernel P is $k[-1]$, concentrated in degree 1. Thus $0 \xrightarrow{\sim} C \xrightarrow{p} X$ is the editors' factorization and

$$\begin{array}{ccc} C & \xleftarrow{\ i\ } & P \\ {\scriptstyle p}\downarrow & & \downarrow \\ X & \longleftarrow & 0 \end{array}$$

is both an ordinary and a homotopy pullback. The contraction $s^1 : C^1 \to C^0$ is the identity, and $d_C s + s d_C = 1_C$. In $D(k)$, therefore, $C \cong 0$, and the underlying square is isomorphic to the square with apex P, base X, and all edges zero.

That latter square, taken *strictly* in complexes, has comparison $s_3 = 0_P$ to the displayed fibrational replacement: commutativity requires $i s_3 = 0$, and i is injective. The comparison induces zero on $H^1(P) = k$, so it is not a quasi-isomorphism. This computes the dotted arrow in the postface and disproves the necessary direction of Proposition 1.

To locate the information lost, write down a homotopy-pullback model for $f : A \to Z \leftarrow B : g$:

$$\begin{aligned} H(f,g)^n &= A^n \oplus B^n \oplus Z^{n-1}, \\ d(a,b,z) &= (d_A a, d_B b, fa - gb - d_Z z). \end{aligned}$$

The chain-map identities imply $d^2 = 0$. This is a shifted mapping cone of $f - g$, with the last coordinate negated relative to one common convention. A cone with maps $u : T \to A$, $v : T \to B$ and a specified degree -1 homotopy h satisfying

$$d_Z h + h d_T = fu - gv$$

has comparison $c_h = (u, v, h) : T \to H(f,g)$. The displayed identity is exactly its chain-map condition. The coherent square is cartesian precisely when this comparison is a quasi-isomorphism.

For $A = B = 0$, $Z = X = k[0]$, and $T = P = k[-1]$, the four edges are zero and $H(0,0) = P$. Every scalar $\lambda \in k$ specifies a filling $h^1_\lambda = \lambda$, and c_{h_λ} is multiplication by λ on P. It is a quasi-isomorphism exactly when $\lambda \neq 0$. Its mapping cone is the two-term complex

$$k \xrightarrow{\lambda} k \quad \text{in degrees } 0, 1,$$

which is acyclic for $\lambda \neq 0$ and has k in both cohomology degrees for $\lambda = 0$. Thus identical vertices and edges support both a cartesian and a noncartesian coherent filling.

We can check the transport sign as well. Put $t = ps$, so $d_X t + t d_C = p$. The map

$$H(p,0) \longrightarrow X[-1], \qquad (c, z) \longmapsto z - tc$$

is a chain map with acyclic kernel, the diagonal copy of C. Composing with $P \to H(p,0)$, $a \mapsto (i(a), 0)$, gives -1_P. The strict pullback transported through this contraction has filling h_{-1}, whereas the strict zero-edge square has filling h_0. The sign depends on the displayed cone convention; its being nonzero does not. With the boundary and its identifications fixed, the classes of fillings are indexed by k, because $\underline{\mathrm{Hom}}(P, X)$ is concentrated in degree -1 and has no degree -2 boundaries. Allowing scalar automorphisms of the apex identifies all nonzero fillings, while the zero filling remains separate.

The editors' other interpretations agree with this computation. In pointed spaces, $X = S^1$ gives $\pi_0 \Omega X = \mathbb{Z}$, so the zero self-map cannot be a weak equivalence. For a CW complex in general, the homotopy groups of its loop space detect all positive homotopy groups of the base component; Whitehead's theorem then makes exactly that component contractible (Hatcher, 2002, Theorem 4.5 and §4.3). Other components are unrestricted. For unbounded complexes in a Grothendieck abelian category, an acyclic middle term in $0 \to P \to C \to X \to 0$ gives $H^n(P) \cong H^{n-1}(X)$, so P is acyclic exactly when X is. The standard injective model structure supplies this setting (Hovey, 2001, Theorem 2.2 and Proposition 2.12 of the preprint); no assertion that acyclic complexes are chain-contractible is needed.

Des considérations analogues montrent que les carrés h-cartésiens de $\mathcal{M}W^{-1}$, définis dans la section 2 comme étant les carrés commutatifs de $\mathcal{M}W^{-1}$ qui sont isomorphes dans $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1,\ \mathcal{M}W^{-1})$ à un carré W-cartésien, ne satisfont pas à toutes les conditions de Cart (3) et Cart (5) de la section 1. En effet, supposons toujours que $\mathcal{M}$ soit ponctuée, et gardons les notations ci-dessus. Considérons le diagramme commutatif dans $\mathcal{M}W^{-1}$

$$\begin{array}{ccccc} * & \longleftarrow & \Omega X & \xleftarrow{*_{\Omega X}} & \Omega X \\ \downarrow & & \downarrow & & \downarrow \\ X & \longleftarrow & * & \longleftarrow & * \end{array} \quad ,$$

où $*_{\Omega X}$ désigne l'unique endomorphisme de ΩX se factorisant par $*$. Il résulte de ce qui précède que le carré de gauche et le carré composé sont h-cartésiens. En revanche, le carré de droite ne l'est pas en général. En effet, si ce carré était isomorphe dans $\underline{\mathrm{Hom}}(\mathbf{\Delta}_1 \times \mathbf{\Delta}_1,\ \mathcal{M}W^{-1})$ à un carré W-cartésien, la flèche $*_{\Omega X}$ serait un isomorphisme

p. 9 de $\mathcal{M}W^{-1}$, donc une équivalence faible de $\mathcal{M}$, ce qui impliquerait les mêmes conditions très restrictives que ci-dessus. Ainsi l'une des implications de l'axiome Cart 3 n'est pas satisfaite.

De même le cube commutatif dans $\mathcal{M}W^{-1}$

$$\begin{array}{ccccc} & & * & \longleftarrow & \Omega X \\ & \swarrow & \downarrow & \swarrow & \downarrow{\scriptstyle *_{\Omega X}} \\ X & \longleftarrow & * & & \\ \downarrow{\scriptstyle =} & & \downarrow & & \\ & & * & \longleftarrow & \Omega X \\ & \swarrow & & \swarrow & \\ X & \longleftarrow & * & & \end{array} \quad ,$$

dont les faces horizontales sont h-cartésiennes, montre que la condition (b) de l'axiome Cart (5) n'est pas satisfaite en général.

Commentary · Present state [ms. 8]

Postface: the two failed quantifiers

Editors' postface, printed pp. 8–9. The two final counterexamples use the same object $P = \Omega X$ and the same underlying zero-edge square Q. They apply whenever P is not isomorphic to zero, a condition realized by both worked examples above. In the horizontal pair, the left square and outer rectangle are Q, hence belong to $\mathrm{Cart}_{\mathrm{im}}$. In the right square the bottom edge is 1_0 and the top edge is 0_P. A homotopy pullback of an equivalence has an equivalence as opposite edge, so this right square cannot belong to $\mathrm{Cart}_{\mathrm{im}}$. This is exactly the implication "I and III cartesian imply II cartesian" that fails.

For Cart (5)(b), use the endomorphism of Q that is the identity at the three cospan vertices and zero at P. It is a commuting cube in the ordinary homotopy category, but its fourth component is not invertible. The positive existence statement in (a), and the failure of uniqueness already noticed in Corollary 2, should not be conflated with this false assertion about *every* fourth component. As the formal deduction above shows, (b) would have followed from the full pasting axiom anyway.

The implication $0_P \in W \Rightarrow P \to 0 \in W$ used in the postface needs no cofibrancy assumption. Writing $r : P \to 0$ and $s : 0 \to P$, the arrow r is a retract, in the arrow category, of $sr = 0_P$, using components $(1_P, s)$ and $(1_P, r)$. Weak equivalences are closed under retracts. The converse follows from two-out-of-three. Equivalently, an invertible zero endomorphism makes the object zero in the homotopy category. These are settled counterexamples, not conjectures awaiting a stronger model-category theorem.

Commentary · Exposition [ms. 8]

Why composition nevertheless survives

The failure of cancellation leaves a useful positive statement: for every Quillen model category, $\mathrm{Cart}_{\mathrm{im}}$ is closed under composition. Two adjacent cartesian witnesses can be made compatible along their shared edge. A left square and an outer rectangle, as in the counterexample, are different data. We give the rectification argument to keep this distinction precise.

For any model category $\mathcal{A}$, the arrow comparison

$$U_{\mathcal{A}} : \mathrm{Ho}(\mathcal{A}^{[1]}) \longrightarrow \mathrm{Ho}(\mathcal{A})^{[1]}$$

is full, essentially surjective, and conservative. The first two properties are the arrow-shape lifting property used in derivator strength (Groth, 2013, Lemma 1.9). To verify fullness directly, take a Reedy-cofibrant source arrow $f : X_0 \to X_1$ and a Reedy-fibrant target arrow $g : Y_0 \to Y_1$. Thus X_0 is cofibrant, f is a cofibration, and Y_0, Y_1 are fibrant. Represent a square in the homotopy category by maps a_0, a_1 and a right homotopy between $a_1 f$ and $g a_0$. The endpoint map $\mathrm{ev}_0 : \mathrm{Path}(Y_1) \to Y_1$ is a trivial fibration. Lifting against f extends that homotopy from X_0 to X_1, replacing a_1 by a homotopic a_1' with $a_1' f = g a_0$ strictly. This gives the required coherent-arrow morphism. Any arrow in the homotopy category has an actual representative between cofibrant-fibrant objects, proving essential surjectivity. Finally, pointwise weak equivalences and saturation imply conservativity. In particular, an isomorphism of underlying arrows lifts to an isomorphism of coherent arrows.

Now choose cartesian strict lifts of the two adjacent squares. Their common columns may differ, but the given underlying identifications specify an isomorphism between these columns in $\mathrm{Ho}(\mathcal{M})^{[1]}$. Apply the preceding result for $\mathcal{A} = \mathcal{M}$ to lift it. The two squares can then be regarded as composable morphisms in $\mathrm{Ho}(\mathcal{M}^{[1]})$. Choose bifibrant representatives for the three column objects in the arrow model category, with a single shared middle representative, and represent the two morphisms by actual maps. They form one strict rectangle in $\mathcal{M}$.

Apply the arrow comparison a second time, now to $\mathcal{A} = \mathcal{M}^{[1]}$. Each new small square has an underlying arrow in $\mathrm{Ho}(\mathcal{A})$ isomorphic to that of its original witness. Fullness lifts this isomorphism and conservativity makes the lift invertible in $\mathrm{Ho}(\mathcal{M}^{\square})$. Thus the two new squares are cartesian as coherent squares. Coherent pasting makes their outer rectangle cartesian, and its underlying square is isomorphic to the required composite. This proves the assertion without a combinatorial or stability assumption, and without lifting an arbitrary incoherent cube.

In the stable setting, Christensen and Frankland (2022, Proposition 6.11, pp. 17–18 of the 7 June 2021 author version) prove the corresponding pasting statement even for homotopy-cartesian squares in an arbitrary triangulated category. The valid remnant of the proposed calculus is therefore substantial: symmetry, the isomorphism test, completion of cospans, weak universality, and positive composition survive for the homotopy-image class. Cancellation and Cart (5)(b) do not.

Commentary · Later developments [ms. 8]

The coherent replacement of the square axioms

After the editors' postface. The construction Grothendieck names on manuscript page 2 gives the appropriate replacement. Let $\mathbb{D}$ be a derivator and $j : \Phi \hookrightarrow \square$ the full inclusion omitting the prospective pullback vertex. A coherent square $Q \in \mathbb{D}(\square)$ is cartesian when the adjunction unit

$$Q \longrightarrow j_* j^* Q$$

is invertible. Right Kan extension along j is fully faithful; consequently

$$j^* : \mathbb{D}(\square)_{\mathrm{cart}} \simeq \mathbb{D}(\Phi)$$

is an equivalence, with inverse j_* (Groth, 2013, Proposition 1.20 and Definition 3.9). A coherent cospan therefore has a cartesian completion, and a morphism of coherent cospans has a unique extension between these completions once their identifications are fixed. If its three components are isomorphisms, pointwise conservativity makes it an isomorphism in $\mathbb{D}(\Phi)$; the equivalence makes the extended square morphism invertible. This proves the correct fourth-vertex assertion. Its input is a morphism in the coherent category, not an arbitrary cube in $\mathbb{D}(e)$.

The full pasting-and-cancellation law is a statement about one coherent rectangle. To see the mechanism in a model or higher-category enhancement, write it as

$$\begin{array}{ccccc} A & \longleftarrow & B & \longleftarrow & C \\ \downarrow & & \downarrow & & \downarrow \\ D & \longleftarrow & E & \longleftarrow & F. \end{array}$$

If the left square is cartesian, $B \simeq A \times^h_D E$. Associativity of the homotopy limit gives

$$B \times^h_E F \simeq (A \times^h_D E) \times^h_E F \simeq A \times^h_D F.$$

Coherence identifies the comparison from C to the first expression with its comparison to the last. One is an equivalence exactly when the other is. For derivators this is the right-Kan-extension pasting statement of Groth (2013, Proposition 3.13); the higher-categorical proof is given, dually, by Lurie (2009, Lemma 4.4.2.1). The editors' rectangle loses the compatibility needed to make those two comparison maps agree.

In a stable enhancement there is a useful translation into the underlying triangulated category. A coherent cartesian square with projections $u : P \to A$, $v : P \to B$ and base maps $f : A \to C$, $g : B \to C$ supplies a distinguished triangle

$$P \xrightarrow{(u,-v)} A \oplus B \xrightarrow{(f,g)} C \xrightarrow{\delta} \Sigma P$$

(Groth et al., 2014a, Theorem 6.1, arXiv v2). The connecting morphism is part of this conclusion. In the zero-edge loop example it is an isomorphism $X \to \Sigma P$, with the sign dictated by conventions. The cube with fourth component 0_P and base component 1_X cannot preserve that morphism, since it would require $\delta = (\Sigma 0_P)\delta = 0$. The triangle therefore diagnoses exactly why that cube is incoherent, even though its four visible faces commute in the homotopy category.

The relation with higher categories is a comparison of enhanced diagram theories. For a suitable model presentation, localizing diagram categories gives the homotopy categories of coherent diagrams; precise comparisons appear in Lurie (2017, Propositions 1.3.4.24–1.3.4.25). It is not necessary here to identify every abstract derivator with an infinity category. The correct conclusion is narrower and sufficient: the familiar homotopy theories retain the diagram information on which the failed inference depended.

Overview · XIV

Chapter XIV is a short experiment in reducing homotopy theory to a calculus of squares in a single category. Its eight manuscript pages introduce five proposed axioms and begin the examples. The editors' postface, which has no manuscript pagination, explains why the intended model-category example fails. The fragment is especially instructive because Grothendieck identifies the necessary finer setting before attempting the reduction: square diagrams must be localized as diagrams, together with their maps, rather than reconstructed from four arrows in the localized category.

The mathematical object under discussion can be described without ambiguity. For $\mathcal{H} = \mathcal{M}W^{-1}$, let $\mathrm{Cart}_{\mathrm{im}}$ consist of those commutative squares in $\mathcal{H}$ that are isomorphic to the underlying images of homotopy-cartesian strict squares in $\mathcal{M}$. With $\square$ denoting the walking commutative square, the relevant functor is

$$\mathrm{dia}_{\square} : \mathcal{M}^{\square}(W^{\square})^{-1} \longrightarrow \mathcal{H}^{\square}.$$

The domain retains coherent diagrams. The target retains ordinary commutativity after localization. Membership in $\mathrm{Cart}_{\mathrm{im}}$ is an existential statement about a coherent realization. Proposition 1 would promote it to a statement about every strict realization, and this is the false inference.

There is a specific historical reason for wanting the larger diagram theory. In *Pursuing Stacks*, §69, Grothendieck connects it with the trace and determinant problems that motivated him in the period of SGA 5; the letter to Thomason of 2 April 1991 again stresses derived diagram categories and mapping cones (Grothendieck, 1983, 1991a). The present chapter tests whether one can retain a useful part of their calculus in a simpler language. The editors' preliminary notice suggests that recognition of the failed example explains the abrupt ending. That suggestion is conjectural; the postface establishes the mathematical failure, not the author's reason for interrupting the manuscript.

The formal axioms are consistent: any category with pullbacks, equipped with its ordinary pullback squares, satisfies them. Cart (1) gives symmetry, Cart (2) tests trivial squares against isomorphisms, and Cart (3) combines pasting with cancellation. Cart (4) requires a completion of every cospan. Cart (5)(a) extends a map between the three-vertex boundaries of two distinguished squares; (b) asserts that every such extension is invertible whenever the boundary map is invertible. The commentary supplies the cube proof, including the stronger three-face hypothesis in the footnote, and proves that (b) already follows from Cart (1)–(3).

The source's second corollary isolates the weak universal property that does survive in homotopy theory. For a homotopy pullback P of $A \to C \leftarrow B$, there is a surjection

$$[T, P] \longrightarrow [T, A] \times_{[T,C]} [T, B].$$

A compatible pair in the target admits a homotopy between its composites; a lift remembers a choice of that homotopy. Passing to components forgets the choice, so the map need not be injective. In the loop square for S^1, with $T = S^0$ in pointed spaces, it is the map $\mathbb{Z} \to \{*\}$. The surjection is equivalent to Cart (5)(a) for a class containing the constant squares. The much stronger assertion in (b) does not follow from this weak property alone.

Positive composition does hold for the homotopy-image class of every Quillen model category. The commentary proves this by applying fullness and conservativity of the arrow comparison twice, first to the model category and then to its arrow category, so that two cartesian witnesses acquire a single shared middle column. This is compatible with the postface: its counterexample concerns cancellation.

The editors' example distinguishes the underlying square from its realization. Factor the basepoint of a fibrant object as

$$0 \xrightarrow{\sim} C \twoheadrightarrow X, \qquad P = C \times_X 0.$$

The resulting strict pullback is homotopy cartesian. Its image in $\mathcal{H}^{\square}$ is isomorphic to the square with apex P, base X, the other vertices zero, and all edges zero. But that zero-edge square, regarded strictly in $\mathcal{M}$, has comparison $0_P : P \to P$ to the fibrational replacement. It is homotopy cartesian exactly when P is weakly zero. This proves the failure of Proposition 1 whenever the loop object is nontrivial. The same underlying square gives the two final counterexamples: a horizontal rectangle with left and outer squares distinguished but right square not distinguished, and a cube whose first three components are identities while the fourth is zero.

The worked algebraic example takes $X = k[0]$ and $C = (k \xrightarrow{1} k)$ in degrees $0, 1$. Then $P = k[-1]$. A specified filling of the fixed zero-edge square is a scalar λ; the homotopy-pullback comparison is multiplication by λ on P. Its cone is $k \xrightarrow{\lambda} k$, so the coherent square is cartesian precisely for $\lambda \neq 0$. The commentary computes the transport through a contraction and its sign explicitly. It also checks the editors' topological qualification: for a CW complex, weak triviality of the loop object means contractibility of the base component, with no restriction on other components. For unbounded complexes in a Grothendieck abelian category it means acyclicity.

The literal axioms have a stronger limitation than the displayed counterexample alone reveals. Our development proves that, if $\mathcal{H}$ has binary products, the axioms force all ordinary pullbacks to exist and force the distinguished class to be exactly their class. The proof first compares a distinguished weak pullback with an existing ordinary one: a section and the invertibility of a cone-preserving idempotent make the comparison an isomorphism. This is the minimality argument familiar for weak kernels (Krause, 2016, §1, p. 6 of the 2014 manuscript). Pasting a distinguished square with a weak kernel pair then shows that pullbacks along monomorphisms are ordinary. Finally one pulls back the diagonal $C \to C \times C$ along $A \times B \to C \times C$. The complete argument is given in the marked development block; its application to these axioms was not located in the bounded literature search, and no priority is claimed.

Additive categories satisfy the binary-products hypothesis. Moreover, even without products, the literal loop object in a pointed category must be zero, because $0 \to X \leftarrow 0$ already has ordinary pullback zero. If the dual structure also exists, its suspension is zero. If the two classes coincide, the square with base X and three zero vertices makes X itself zero. Thus Grothendieck's additive coincidence speculation is false for the literal structures: ordinary pullbacks and pushouts in vector spaces give an immediate counterexample.

The modern positive statement belongs to coherent squares. For the inclusion $j : \Phi \hookrightarrow \square$ of the cospan, cartesian coherent squares are the essential image of the fully faithful right Kan extension j_*. Restriction consequently identifies their category with $\mathbb{D}(\Phi)$. This makes the completion functorial and proves the correct fourth-vertex assertion for coherent morphisms. Coherent rectangles admit pasting and cancellation. In a pointed derivator the suspension–loop adjunction exists; stability, rather than additivity, is the condition under which cartesian and cocartesian coherent squares agree, equivalently that adjunction is an equivalence (Groth, 2013, Proposition 3.17; Groth et al., 2014a, Theorem 7.1, arXiv v2). External derived Hom has the expected continuity, with the usual enrichment hypotheses for an internal version (Cisinski, 2003, Proposition 6.13). None of these assertions makes the forgetful functor reflect the property disproved in the postface.

The proposed main example and Proposition 1 are therefore settled negatively, while the coherent replacements are established theorems. The manuscript's broad request for further compatibility axioms does not by itself specify a present open problem. This commentary does not classify all literal quadrangulated categories without binary products or produce a nonordinary example in that generality. Its audit keeps that limit separate from the explicit counterexamples and the proved structural deductions.

1 Construction fondamentale : la suite transfinie de factorisation d'une flèche f.

p. 1
[page 1]

Soit $\mathcal{M}$ une $\mathfrak{U}$-catégorie, stable par "petites" (*i.e.* $\mathfrak{U}$-petites) $\varinjlim$ filtrantes. Soit

$$C_0 \subset \mathrm{Fl}(\mathcal{M}) \tag{1.1}$$

un *petit* ensemble de flèches, on se propose de construire pour toute flèche f de $\mathcal{M}$, une factorisation

$$f = p\,i\,, \qquad i \in \widetilde{C_0} = ((C_0)_*)^*\,,\ p \in (C_0)_*\,. \tag{1.2}$$

Pour ceci, on va construire une suite ordinale de foncteurs

$$\left\{\begin{array}{rcl} f & \longmapsto & X_\alpha(f) = X_\alpha(C_0, f) \\ X_\alpha : \underline{\mathrm{Fl}}(\mathcal{M}) & \longrightarrow & \mathcal{M} \end{array}\right. \tag{1.3}$$

et des homomorphismes fonctoriels

$$i_\alpha(f) : \mathrm{source}\, f \longrightarrow X_\alpha(f)\,, \tag{1.4}$$

$$p_\alpha(f) : X_\alpha(f) \longrightarrow \mathrm{but}\, f\,, \tag{1.5}$$

de sorte qu'on aura le diagramme (où $X = \mathrm{source}\, f$, $Y = \mathrm{but}\, f$)

$$\begin{array}{ccc} X & \xrightarrow{\quad f \quad} & Y \\ & {\scriptstyle i_\alpha(f)}\searrow \quad \nearrow{\scriptstyle p_\alpha(f)} & \\ & X_\alpha(f) & \end{array}\,, \tag{1.6}$$

ce diagramme étant commutatif

$$f = p_\alpha(f) i_\alpha(f)\,. \tag{1.7}$$

On peut dire aussi qu'on a une section du foncteur canonique de "composition", transposé de $\mathbf{\Delta}_1 \longrightarrow \mathbf{\Delta}_2$, donné par $0 \longmapsto 0$, $1 \longmapsto 2$:

$$\left\{\begin{array}{l} \underline{\mathrm{Nerf}}_2(\mathcal{M}) \underset{\Phi_\alpha}{\overset{\gamma}{\rightleftarrows}} \underline{\mathrm{Nerf}}_1(\mathcal{M}) = \underline{\mathrm{Fl}}(\mathcal{M})\,, \\ \\ \end{array}\right. \tag{1.8}$$

Φ comme "factorisation", où

p. 2
[page 2]

$$\Phi_\alpha(f) = \{\, X \xrightarrow{i_\alpha(f)} X_\alpha(f) \xrightarrow{p_\alpha(f)} Y \,\} \tag{1.9}$$

avec $p_\alpha(f) i_\alpha(f) = f$. La fonctorialité de 1.4 et 1.5, ou celle de Φ_α, *i.e.* de 1.9, s'exprime par le fait que tout carré commutatif

$$\begin{array}{ccc} X & \xrightarrow{\quad f \quad} & Y \\ {\scriptstyle u_X}\downarrow & & \downarrow{\scriptstyle u_Y} \\ X' & \xrightarrow{\quad f' \quad} & Y' \end{array} \tag{1.10}$$

dans $\mathcal{M}$, interprété comme flèche $u = (u_X, u_Y)$ de f dans f' dans $\underline{\mathrm{Fl}}(\mathcal{M})$, donne naissance au double carré commutatif

$$\begin{array}{ccccc} X & \xrightarrow{i_\alpha(f)} & X_\alpha(f) & \xrightarrow{p_\alpha(f)} & Y \\ \downarrow{\scriptstyle u_X} & & \downarrow{\scriptstyle X_\alpha(u)} & & \downarrow{\scriptstyle u_Y} \\ X' & \xrightarrow{i_\alpha(f')} & X_\alpha(f') & \xrightarrow{p_\alpha(f')} & Y' \,. \end{array} \tag{1.11}$$

N.B. Quand on voudra expliciter la dépendance de ces constructions par rapport à C_0, on écrira

$$X_\alpha(C_0, f)\,, \qquad i_\alpha(C_0, f)\,, \qquad p_\alpha(C_0, f)\,, \qquad \Phi_\alpha(C_0, f)\,,$$

ou

$$X_\alpha(C_0, -) \text{ ou } X_\alpha^{C_0}\,, \qquad i_\alpha(C_0, -) \text{ ou } i_\alpha^{C_0} \qquad \textit{etc.}\,,$$

au lieu de $X_\alpha(f)$, $i_\alpha(f)$, …

Commentary · Context [ms. 1]

Why this construction belongs in a theory of derivators

Grothendieck needs factorizations which can be used uniformly across a category of coefficients. A construction for isolated arrows would not supply the functorial replacements needed when those coefficients occur in diagrams. The emphasis on an endofunctor of the arrow category, and then on an entire transfinite sequence of such endofunctors, should be read with that purpose in view.

Two strands of the chapter have different origins. Its language of lifting and factorization is that of homotopical algebra; its treatment of size continues the cardinal filtrations and accessibility developed in (Artin et al., 1972, Exposé I, §9). A filtration does more than assign a cardinal label to an object: it specifies presentations, closure under controlled colimits, and the bounds within which represented functors commute with those colimits. Here that apparatus will turn an unbounded repetition of a local operation into a uniform existence theorem.

The commentary on Chapter VI already discusses the two forms of the replacement axiom, by a functorial replacement and by a factorization “à la Quillen”, at manuscript p. 108, and the distinction between replacements at manuscript p. 180. The present pages address the additional existence problem: how to manufacture the replacements from a set of maps. They should therefore be read as preparation for the diagram theory, rather than as another formulation of its axioms. The modern account of the same small object mechanism in (Riehl, 2014, Chapter 12) makes this separation of construction and use especially clear.

Commentary · Exposition [ms. 1]

Factorization by adjoining solutions

Grothendieck wants a construction which can be used uniformly for every arrow and subsequently compared as its generators vary. The object to be constructed is therefore more than an isolated factorization. It is a section of the composition functor

$$\mathcal{M}^{[2]} \longrightarrow \mathcal{M}^{[1]}, \qquad (X \longrightarrow E \longrightarrow Y) \longmapsto (X \longrightarrow Y),$$

where $[n] = \{0 < \cdots < n\}$. This explains the apparently leisurely passage through the arrow category: naturality in a commutative square will eventually supply natural replacements and comparisons between them.

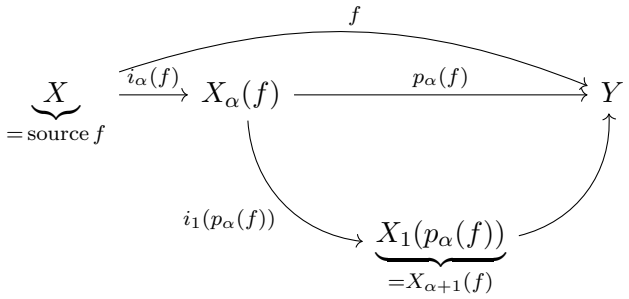
Write $I = C_0$. In modern lifting notation the two desired classes are

$$R = I^{\perp}, \qquad L = {}^{\perp}R.$$

Here $j \perp p$ means that every commutative square with j on the left and p on the right admits a diagonal filler; uniqueness is not required. Thus Grothendieck's $(C_0)_*$ is R, and $\widetilde{C_0}$ is L. The

construction will first produce a much more concrete subclass of L, consisting of maps built by attaching copies of the generators. Retracts enter only when one identifies all of L.

There are two independent tasks. Adjoining a cell for every lifting problem makes all problems present at one stage solvable at the next. Smallness of the domains then ensures that a problem appearing at a sufficiently long limit was already present earlier. Neither task asserts that one application solves every problem in its newly enlarged domain. This distinction is the reason for the transfinite sequence.

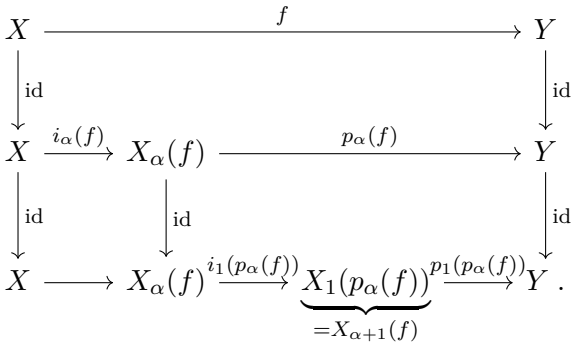


The resulting argument is the classical small object argument, whose modern formulation and retract conclusion are given in Riehl (2014, Theorem 12.2.2 and Corollary 12.2.4). Grothendieck isolates a useful economy in its hypotheses: arbitrary coproducts in $\mathcal{M}$ are unnecessary. Pushouts of the generating arrows, together with filtered colimits, suffice to form all the amalgamated sums under the fixed source. The word "accessible" concerns objects as tested by their covariant representable functors; in the proof below, only factorization of maps from the generating domains through stages is used. The categorical accessibility assumptions later in this chapter are a way of obtaining a uniform bound for that property.

Voici les propriétés essentielles du système inductif ordinal des $X_\alpha(f)$ ou $\Phi_\alpha(f)$.

1. $X_0(f) = X$, $i_0(f) = \mathrm{id}_X$, $p_0(f) = f$ (*i.e.* la factorisation $\Phi_0(f)$ de f est la factorisation triviale $X \xrightarrow{\mathrm{id}_X} X \xrightarrow{f} Y$). [page 3]

2.



$$\begin{aligned} X_{\alpha+1}(f) &= X_1(p_\alpha(f)) \\ i_{\alpha+1}(f) &= i_1(p_\alpha(f)) \circ i_\alpha(f) \\ p_{\alpha+1}(f) &= p_1(p_\alpha(f)) \end{aligned}$$

p. 3

ou mieux

(1.12)

Le morphisme de transition $X_\alpha(f) \longrightarrow X_{\alpha+1}(f)$ est

$$X_\alpha(f) \xrightarrow{\ i_1(p_\alpha(f))\ } X_1(p_\alpha(f)) \;=\; X_{\alpha+1}(f)\,.$$

3. Si α est un ordinal limite, on a

$$\begin{cases} X_\alpha(f) &= \varinjlim_{\alpha'<\alpha} X_{\alpha'}(f). \\ i_\alpha(f) &= \text{morphisme canonique de } X = X_0(f) \text{ dans la limite inductive.} \\ p_\alpha(f) &= \text{limite projective des } p_{\alpha'}(f) : X_{\alpha'}(f) \longrightarrow Y. \end{cases}$$

(On peut considérer la limite inductive définissant $X_\alpha(f)$ comme une limite dans $X\backslash\mathcal{M}/Y\ldots$)

Les morphismes de transition

$$X_{\alpha'}(f) \longrightarrow X_\alpha(f) \qquad (\,\alpha' < \alpha\,)$$

sont les morphismes canoniques relatifs au système inductif des $X_{\alpha'}(f)$.

On peut donc dire que la suite ordinale des factorisations fonctorielles $\Phi_\alpha(f)$ de f variable, [page 4] se déduit de la factorisation fonctorielle $\Phi_1(f)$ de f en

$$X \xrightarrow{\ i_1(f)\ } X_1(f) \xrightarrow{\ p_1(f)\ } Y \qquad (f : X \to Y)$$

par "itération transfinie à droite", *i.e.* en regardant les opérations Φ_α comme des foncteurs

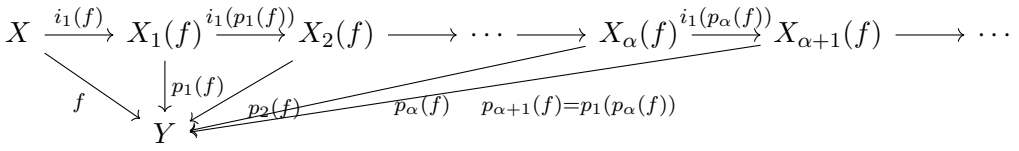
$$\begin{cases} p_\alpha : \underline{\mathrm{Fl}}(\mathcal{M}) \longrightarrow \underline{\mathrm{Fl}}(\mathcal{M}) \\ f \longmapsto p_\alpha(f)\,, \end{cases}$$ [1]

munis d'homomorphismes fonctoriels (au-dessus de $\mathcal{M}$)

$$\mathrm{id}_{\underline{\mathrm{Fl}}(\mathcal{M})} \longrightarrow p_\alpha\,.$$

Ainsi, si on considère

p. 4



$$\begin{cases} \underline{\mathrm{Fl}}(\mathcal{M}) & \text{comme objet de CAT}/\mathcal{M} \text{ par le foncteur } f \longmapsto \text{but } f \\ \text{où} & \text{CAT est la catégorie des catégories } \textit{éléments de } \mathfrak{V}\text{, univers} \\ & \text{tel que } \mathfrak{U} \in \mathfrak{V}\text{, d'où Cat} \overset{(\text{déf})}{=} \mathrm{Cat}^{\mathfrak{U}},\ \mathcal{M},\ \underline{\mathrm{Fl}}(\mathcal{M}) \in \mathrm{CAT}, \end{cases}$$

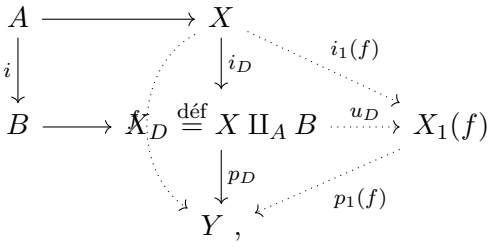
1. **N.B.** p_α respecte les structures de catégories *sur* $\mathcal{M}$, via les foncteurs but : $\underline{\mathrm{Fl}}(\mathcal{M}) \longrightarrow \mathcal{M}$, *i.e.* $\underline{\mathrm{Fl}}(\mathcal{M})$ est considérée comme objet de CAT$/\mathcal{M}$.

on a un endofoncteur p_1 de $\underline{\mathrm{Fl}}(\mathcal{M})$ sur $\mathcal{M}$, et un homomorphisme fonctoriel

(1.13) $$i_1 \ : \ \mathrm{id}_{\underline{\mathrm{Fl}}(\mathcal{M})/\mathcal{M}} \longrightarrow p_1 \ , \qquad \textit{i.e.} \qquad \begin{array}{ccccc} X & & \xrightarrow{\quad f \quad} & & Y \\ & {\scriptstyle i_1(f)}\searrow & & \nearrow{\scriptstyle p_1(f)} & \\ & & \underbrace{X_1(f)}_{=\,\mathrm{source}\,p_1(f)} & & \end{array} \ ,$$

et la description de la suite ordinale des endofoncteurs p_α de $\underline{\mathrm{Fl}}\,\mathcal{M}/\mathcal{M}$ résulte de cette seule donnée, compte tenu que les petites limites filtrantes existent dans les fibres de $\underline{\mathrm{Fl}}\,\mathcal{M} \xrightarrow{\text{but}} \mathcal{M}$. [page 5]

(1.14)



Donc, pour achever de définir la suite ordinale des $X_\alpha(f)$ (munie des $i_\alpha(f)$, $p_\alpha(f)$), ou des $p_\alpha(f)$ (munie des $i_\alpha(f)$), il reste à décrire $X_1(f)$, $i_1(f)$, $p_1(f)$.

La propriété essentielle de ce triple dont nous aurons besoin est la suivante :

(1.15) **Fact**(C_0) (propriété de factorisation par rapport à C_0).
Pour tout diagramme commutatif

$$D : \qquad \begin{array}{ccc} A & \longrightarrow & X \\ {\scriptstyle i}\downarrow & & \downarrow{\scriptstyle f} \\ B & \longrightarrow & Y \end{array} \qquad \text{avec } i \in C_0 \ ,$$

d'où un diagramme traits pleins

il existe un homomorphisme de la factorisation $f = p_D i_D$ de f dans la factorisation $f = p_1(f)i_1(f)$. p. 5

Pour formuler cette condition, j'ai utilisé l'existence des sommes amalgamées X_D, *i.e.* la condition sur C_0 : [page 6]

Commentary · Exposition [ms. 5]

A single stage and the colimits it needs

The first stage is arranged to solve every prescribed extension problem without choosing one problem in preference to another. For $f : X \to Y$, its indexing set can be written explicitly as

$$\Delta(I, f) = \coprod_{(j:A\to B)\in I} \{(a, b) \in \mathrm{Hom}(A, X) \times \mathrm{Hom}(B, Y) \mid fa = bj\}.$$

This is a small set: I is small and the category is locally small in the chosen universe. Each triple $D = (j, a, b)$ gives the pushout $X_D = X \amalg_A B$, together with its induced map to Y. In the category

of objects under X, take their coproduct. This gives exactly (1.23), and the inclusion of the Dth cell supplies the map $B \to X_1(f)$ required by (1.17).

The existence argument deserves to be explicit because the stated assumptions do not include all small colimits. A pushout of a pushout of j is again a pushout of j: this is the pasting property of pushout squares. Consequently every map $X \to X_D$ is itself pushoutable along every map out of X. Any finite family of these objects therefore has an amalgamated sum under X, built by repeated binary pushouts. For a finite subset $F \subseteq \Delta(I, f)$, write this sum as X_F, and set $X_\varnothing = X$. Chosen colimit cocones give transition maps for inclusions $F \subseteq G$. The poset of finite subsets is filtered, and

$$X_1(f) = \operatorname*{colim}_{F \subseteq \Delta(I,f),\ F \text{ finite}} X_F.$$

To verify its universal property, a map from this colimit to an object under X is a compatible family of maps from the finite amalgamations. Restriction to singleton subsets identifies such a family with precisely one compatible map from each X_D. This proves the required coproduct property in the undercategory, including the case $\Delta(I, f) = \varnothing$.

If ordinary coproducts also exist, the same object is the pushout

$$\begin{array}{ccc} \coprod_{D \in \Delta(I,f)} A_D & \longrightarrow & X \\ \downarrow & & \downarrow{\scriptstyle i_1(f)} \\ \coprod_{D \in \Delta(I,f)} B_D & \longrightarrow & X_1(f). \end{array}$$

This familiar presentation is convenient for calculations; the preceding finite-subset construction explains why it is not an additional assumption in Theorem 1. The construction of a stage uses the codomains B_D, but the eventual lifting argument will require smallness only of the domains A_D.

(1.16) Les flèches $i \in C_0$ sont coquarrables, *i.e.* pour un diagramme

$$\begin{array}{ccc} A & \xrightarrow{u} & X \\ {\scriptstyle i}\downarrow & & \\ B & & \end{array}$$

avec $i \in C_0$, la somme amalgamée existe.

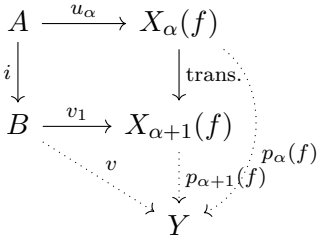
Mais on peut formuler 1.15 aussi ainsi, indépendamment de l'hypothèse (1.16) :

(1.17) Pour tout carré commutatif

$$\begin{array}{ccc} A & \xrightarrow{u} & X \\ {\scriptstyle i}\downarrow & & \downarrow{\scriptstyle f} \\ B & \xrightarrow{v} & Y \end{array} \quad ,$$

avec $i \in C_0$, il existe un carré commutatif traits pleins

$$\begin{array}{ccc} A & \xrightarrow{u} & X \\ {\scriptstyle i}\downarrow & & \downarrow{\scriptstyle i_1(f)} \\ B & \xrightarrow{v_1} & X_1(f) \\ & {\scriptstyle v}\searrow & \downarrow{\scriptstyle p_1(f)} \\ & & Y \end{array}$$



tel que $v = p_1(f) v_1$.

Ceci a pour conséquence le

Corollaire 1 (de 1.17). *Soit $f \in \mathrm{Fl}(\mathcal{M})$, et α un ordinal ($\in \mathfrak{U}$). Pour tout carré commutatif*

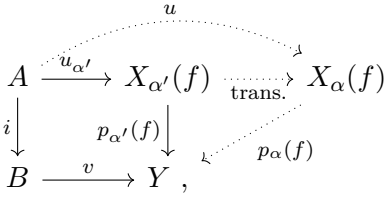
$$\begin{array}{ccc} A & \xrightarrow{u_\alpha} & X_\alpha(f) \\ {\scriptstyle i}\downarrow & & \downarrow{\scriptstyle p_\alpha(f)} \\ B & \xrightarrow{v} & Y \end{array}$$

il existe un carré commutatif p. 6

tel que

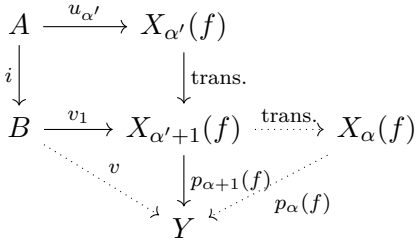
$$v \;=\; p_{\alpha+1}(f)\; v_1 \;.$$

Corollaire 2. *Soit π un cardinal ($\in \mathfrak{U}$) tel que pour toute flèche $i : A \longrightarrow B$ dans C_0, la source A soit π-accessible. Soit α un ordinal grand devant π* (i.e. *tel que l'ensemble ordonné I_α des ordinaux $\alpha' < \alpha$ soit grand devant π*) *– p. ex. α le premier ordinal dont le cardinal soit $> \pi$. Alors pour toute flèche $f \in \mathrm{Fl}(\mathcal{M})$, on a $p_\alpha(f) \in (C_0)_*$.* [page 7]



DÉMONSTRATION. Cela signifie que pour tout carré commutatif

$$(*) \qquad \begin{array}{ccc} A & \xrightarrow{u} & X_\alpha(f) \\ {\scriptstyle i}\downarrow & \overset{w}{\nearrow} & \downarrow{\scriptstyle p_\alpha(f)} \\ B & \xrightarrow{v} & Y \end{array},$$



avec $i \in C_0$, la flèche pointillée w (avec $wi = u$, $p_\alpha(f)w = v$) existe. Or

$$X_\alpha(f) = \varinjlim_{\alpha' \in I_\alpha} X_{\alpha'}(f) \;,$$

donc A étant π-accessible et I_α grand devant π, u provient d'une flèche $u_{\alpha'} : A \longrightarrow X_{\alpha'}(f)$, et (quitte à remplacer α' par $\alpha'' > \alpha'$ et $u_{\alpha'}$ par le composé $u_{\alpha''} : A \longrightarrow X_{\alpha'}(f) \longrightarrow X_{\alpha''}(f)$) on peut supposer $p_{\alpha'}(f)u_{\alpha'} = vi$, *i.e.* que $(*)$ provient d'un carré commutatif

et appliquant le corollaire 1, on trouve p. 7

[page 8]

avec $v = p_{\alpha+1}(f)v_1$, et on prendra

$$w \;=\; \mathrm{trans}_{\alpha,\alpha'+1} \circ v_1 \ .$$

Commentary · Exposition [ms. 7]

Why the cofinality bound solves every problem

Grothendieck's Corollary 2 supplies the decisive passage from a succession of partial solutions to an actual right lifting property. The statement needs the additional word *limit*. For a limit ordinal, the condition that every subset of cardinal at most π has an upper bound is equivalent to cofinality greater than π. More invariantly, choose a regular cardinal κ for which every generating domain is κ-presentable, and use a limit ordinal λ with $\mathrm{cf}(\lambda) \geq \kappa$. The ordered set of stages $\beta < \lambda$ is then κ-filtered.

Consider a square $j : A \to B$ against $p_\lambda : X_\lambda \to Y$, with top map $a : A \to X_\lambda$ and bottom map $b : B \to Y$. Since

$$X_\lambda = \operatorname*{colim}_{\beta<\lambda} X_\beta,$$

smallness gives $\beta < \lambda$ and $a_\beta : A \to X_\beta$ representing a. The compatibility of the maps to Y gives

$$p_\beta a_\beta = p_\lambda a = bj.$$

Thus the square already commutes at this stage. The parenthetical suggestion to enlarge β is harmless but unnecessary: the target Y has remained fixed throughout. The corresponding cell at stage $\beta + 1$ provides $h : B \to X_{\beta+1}$ with $hj = t_{\beta+1,\beta}a_\beta$ and $p_{\beta+1}h = b$. Because λ is a limit, $\beta + 1 < \lambda$, and $t_{\lambda,\beta+1}h$ is the desired filler.

No smallness assertion about B was used. In fact the proof needs only the surjectivity of the map from the colimit of the relevant Hom sets, rather than its injectivity. This is why the usual relative-smallness hypothesis, restricted to the cellular chains actually constructed, is sufficient as well. The bound must be common to all generating domains, and the stopping ordinal must be common to all input arrows if one wants a single factorization functor. Since the generators form a set, individual accessibility bounds can be replaced by a common larger one.

The omitted limit condition is a real, although easily repaired, boundary error. In the definition used in Artin et al. (1972, Exposé I, Definition 9.1), a poset with a maximum is "grand devant π" for every π. Thus $I_1 = \{0\}$ satisfies the printed hypothesis. Take sets, generators $\varnothing \to 1$ and the fold $2 \to 1$, and $f = 1_1$. The first generator adds one point; the square for the fold identifies no distinct old points. Hence $X_1(f) = 2$ and $p_1(f) : 2 \to 1$ is not injective. Since the right class for these two generators consists of bijections, Corollary 2 would be false at $\alpha = 1$. Its proof itself shows the repair: choose a limit ordinal with the indicated cofinality, as in the successor-cardinal example given in the text. The same qualification is required in (1.22) and Theorem 1(b).

The two printed labels $p_{\alpha+1}$ at the end of the proof, on printed page 7, omit the prime on α. Their intended value is $p_{\alpha'+1}$. The displayed source of that arrow determines the correction; the edition's readings are retained in the French text and registered in the corrections table.

Mais on veut une factorisation de f, flèche quelconque dans $\mathcal{M}$, en

$$f \;=\; p\ i\ , \qquad \text{avec}\ \ p \in (C_0)_*\ \ \textit{et}\ \ i \in \widetilde{C_0}\ ,$$

donc il faut encore énoncer une propriété, assurant que les $i_\alpha(f)$ sont dans $\widetilde{C_0}$. On aura même quelque chose de plus précis. Introduisons

(1.18) $C_0' \;=\;$ plus petit sous-ensemble de $\mathrm{Fl}(\mathcal{M})$ contenant C_0, stable par cochangement de base (chaque fois qu'il existe).

$C_0'' \;=\;$ ensemble des flèches qui sont soit dans C_0', soit des sommes amalgamées d'une famille *non vide* de telles flèches $A \xrightarrow{i_\alpha} B_\alpha$ de même source A, $i_\alpha \in C_0'$; la flèche $A \longrightarrow B = \coprod_\alpha {}_{(A)}B_\alpha$ est dans C_0''.

(La condition 1.16 implique que les éléments de C_0' sont coquarrables, et cela suffit, avec la condition de stabilité de $\mathcal{M}$ par $\varinjlim$ filtrantes, à assurer que les sommes amalgamées infinies envisagées existent dans $\mathcal{M}$.)

N.B. C_0'' est *égal* au plus petit ensemble de flèches contenant C_0 et stable par cochangement de base et par petites sommes amalgamées. `[Si les petites sommes existent dans` $\mathcal{M}$`, alors` C_0'' `est aussi l'ensemble des flèches obtenues par cochangement de base à partir de sommes de flèches de` C_0`.]`

(1.19) $C_0''' =$ plus petit sous-ensemble de $\mathrm{Fl}(\mathcal{M})$ contenant C_0'', et stable de plus par limites inductives ordinales strictes, *i.e.* pour un système inductif ordinal $(A_\alpha)_{\alpha<\alpha_0}$, tel que pour α ordinal limite on ait $A_\alpha \xleftarrow{\sim} \varinjlim_{\alpha'\in I_\alpha} A_{\alpha'}$, si les morphismes de transition $i_{\beta,\alpha} : A_\alpha \longrightarrow A_\beta$ sont dans C_0''', de même les morphismes canoniques

$$A_\alpha \xrightarrow{i_\alpha} \varinjlim_{\beta\in I_{\alpha_0}} A_\beta \ .^{2}$$

Commentary · Examples [ms. 8] p. 8 [page 9]

Empty families and a complete calculation in sets

Grothendieck has now separated attachment from lifting, and the simplest generator makes both operations visible. Work in sets and let $I = \{\varnothing \to \{*\}\}$. For $f : X \to Y$, a lifting problem is exactly an element of Y. Hence

$$X_1(f) = X \amalg Y, \qquad i_1(f) = \mathrm{in}_X, \qquad p_1(f) = [f, 1_Y].$$

The right class is the class of surjections, because a lift against $\varnothing \to \{*\}$ is a preimage of one specified element. With the usual axiom of choice, the left class is the class of injections. An injection lifts against a surjection by extending the prescribed map over its complement. Conversely, if $g : A \to B$ is not injective, choose distinct a, a' with $g(a) = g(a')$, map A to $\{0, 1\}$ with different values at these points, and use the surjection $\{0, 1\} \to \{*\}$. A filler would factor that map through g, which is impossible.

The whole transfinite construction can be calculated, with the obvious compatible choices of coproducts:

$$X_\alpha(f) = X \amalg (Y \times \alpha), \qquad p_\alpha(x) = f(x), \qquad p_\alpha(y, \beta) = y.$$

At a successor one adds another copy of Y; at a limit one takes the union of the earlier copies. For every $\alpha > 0$, p_α is already a surjection, but if $Y \neq \varnothing$ every transition to the next stage adds elements. Success in the lifting problem therefore does not mean that the unmodified construction has stabilized.

There is also a small literal omission in (1.18)–(1.20). The definition of C_0'' expressly allows only *nonempty* amalgamated families. In this example C_0' consists of the injections which add one element, and C_0'' consists of the injections with nonempty complement. For $f : \varnothing \to \varnothing$, however, $\Delta(I, f)$ is empty and (1.23) gives $i_1(f) = 1_\varnothing$. Thus (1.20), read with the printed definition, is false in this boundary case. The minimal repair is to permit the empty amalgamated family, whose structural map is the identity, or explicitly to adjoin identities to C_0''. Under the printed convention the always valid assertion is $i_1(f) \in C_0'' \cup \mathrm{Iso}(\mathcal{M})$. This is a convention repair in the source, not a transcription correction, and it does not affect the resulting weak factorization theorem. Zero-length cellular compositions must in any event include identities.

La proposition 2, p. 4 de XIII assure que l'on a

$$C_0''' \ \subset \ \widetilde{C_0} \ .$$

Ceci posé, voici la deuxième propriété essentielle de la factorisation $f = p_1(f)i_1(f)$ (la première étant 1.17) :

2. $C_0 \subset C_0' \subset C_0'' \subset C_0'''$

(1.20) Pour toute flèche $f \in \mathrm{Fl}(\mathcal{M})$, on a $i_1(f) \in C_0''$.

Il en résulte aussitôt, par récurrence ordinale :

Commentary · Exposition [ms. 9]

The cellular closure and its successive steps

The finer class C_0''' records how a map was constructed, before retracts erase that information. Its intended modern description is the class of relative I-cell maps: continuous transfinite composites in which every successor map is a pushout of an amalgamated family of copies of generators. Identities are allowed, and all diagrams are small in the chosen universe. The separate stages C_0' and C_0'' distinguish one attachment from simultaneous attachment of a family.

The assertion that these maps lie in ${}^{\perp}(I^{\perp})$ has a direct proof. Fix $q : U \to V$ in $I^{\perp}$. A lifting problem for a pushout of $j \in I$ reduces, by the pushout property, to one for j. For an amalgamated family of such maps, choose a filler for each member with the common prescribed value on the source; the resulting maps agree there and therefore induce a filler on the amalgamation. For a continuous chain $(Z_\beta)_{\beta \le \lambda}$, construct the lift on Z_β by transfinite recursion. At a successor extend the lift already constructed using the lifting property of $Z_\beta \to Z_{\beta+1}$. At a limit the compatible lifts determine a map from the colimit. This proves the lifting property for $Z_0 \to Z_\lambda$. It uses existence of fillers, together with the ordinary choice principle, and no uniqueness.

The word "successor" is essential in this formulation. In the explanatory sentence of (1.19), the displayed symbols $i_{\beta,\alpha}$ can be read as demanding that *every* transition already belong to the class. That condition by itself would not imply closure under finite composition. For example, in the poset category $0 < 1 < 2$, take $I = \{0 \to 1, 1 \to 2\}$. Pushouts and amalgamations give these two arrows and identities, but not $0 \to 2$. A chain all of whose transitions lie in this class cannot contain both 0 and 2; its colimit introduces no missing arrow. Nevertheless two successive cell attachments factor $0 \to 2$ through 1. Thus the induction in (1.21) requires the usual successorwise interpretation of "limites inductives ordinales strictes", or an explicit additional closure under composition. We adopt that intended interpretation throughout; the claim about the lifting class is valid independently of this notational compression.

(1.21) Pour toute flèche $f \in \mathrm{Fl}(\mathcal{M})$ et tout ordinal $\alpha \in \mathfrak{U}$, on a $i_\alpha(f) \in C_0'''$, a fortiori $i_\alpha(f) \in \widetilde{C_0}$.

Donc si α est grand devant π (*cf.* cor. 2, page 7), la factorisation $f = p_\alpha(f) i_\alpha(f)$ satisfait

(1.22) $\left\{ \begin{array}{l} f = p_\alpha(f) i_\alpha(f), \text{ avec } i_\alpha(f) \in C_0''' \subset \widetilde{C_0} = \Phi \texttt{ [à ne pas} \\ \texttt{confondre avec } \Phi_\alpha\texttt{]}, \ p_\alpha(f) \in C_{0*} = \Psi, \text{ lorsque } \alpha \text{ est} \\ \text{grand devant } \pi, \text{ les sources des } i \in C_0 \ \pi\text{-accessibles.} \end{array} \right.$

Il reste à construire le foncteur $f \longmapsto X_1(f)$, avec $i_1(f)$, $p_1(f)$, satisfaisant les conditions (1.17) et (1.20), sous l'hypothèse (1.16) que les $i \in C_0$ sont coquarrables. On considère alors, pour $f \in \mathrm{Fl}(\mathcal{M})$ fixé, l'ensemble $\Delta(f)$ (ou $\Delta(C_0, f)$) de *tous* les diagrammes D de la forme (1.15), avec $i \in C_0$, et on pose

(1.23) $$X_1(f) \ = \ \coprod_{D \in \Delta(f)} {}_{(X)}X_D$$

(somme amalgamée sous X, *i.e.* somme indexée par $\Delta(f)$ dans $X \backslash \mathcal{M}$), le morphisme $X \xrightarrow{i_1(f)}$ [page 10] $X_1(f)$ étant le morphisme costructural, et le morphisme $X_1(f) \xrightarrow{p_1(f)} Y$ étant celui ayant pour composantes les p_D. En somme, on fait "au plus économique" (et au plus naturel) pour assurer la validité de (1.17), sous la forme équivalente (1.15). D'autre part, par définition de C_0', C_0'', les i_D sont dans C_0', et $i_1(f)$ est dans C_0'', ce qui est (1.20) [3].

3. Il faudrait quand même expliciter la dépendance fonctorielle de $X_1(f)$ par rapport à f !!!

Commentary · Exposition [ms. 10]

The omitted functoriality in the input arrow

The footnote asks for the functorial dependence which makes Theorem 1 usable. Its proof is short once the indexing squares are retained as data. A morphism $(u, v) : f \to f'$ in the arrow category consists of $u : X \to X'$ and $v : Y \to Y'$ with $vf = f'u$. It sends

$$(j, a, b) \longmapsto (j, ua, vb)$$

to a well-defined member of $\Delta(I, f')$. For this image D', the pair of maps $X \xrightarrow{u} X'$ and 1_B induces a map

$$X_D = X \amalg_A B \longrightarrow X' \amalg_A B = X'_{D'}.$$

These maps respect the structural maps from X and the maps to the target. Composing them with the inclusions into $X_1(f')$ gives a cocone over the family defining $X_1(f)$, hence a unique map $X_1(u, v) : X_1(f) \to X_1(f')$.

Identity and composition laws follow by restricting to X and to each copy of B: there the asserted equalities are the identity and composition laws for u and v, and the universal property makes their extensions unique. The same argument proves the naturality of i_1 and p_1. At successor ordinals one applies this functor to the already constructed square between $p_\alpha(f)$ and $p_\alpha(f')$; at limits one takes the map of colimits. Transfinite induction gives all of (1.10)–(1.14), including compatibility with every transition map.

One must fix the relevant colimit cocones to obtain literal functors. Another choice gives canonically isomorphic functors by the same universal properties. There is no need to choose fillers in arbitrary lifting problems: the attached cell itself supplies the particular solution required at each stage. This distinction explains why the factorization is functorial even when the fillers subsequently used to characterize the left or right class are highly nonunique.

Pour résumer :

Théorème 1. *Soient $\mathcal{M}$ une $\mathfrak{U}$-catégorie stable par $\mathfrak{U}$-limites inductives filtrantes, $C_0 \subset \mathrm{Fl}(\mathcal{M})$ un petit ensemble de flèches de $\mathcal{M}$. On suppose les flèches $i \in C_0$ coquarrables. Cela assure la définition d'un endofoncteur $f \longmapsto p_1(f)$ de $\underline{\mathrm{Fl}}(\mathcal{M})$, et d'un homomorphisme fonctoriel $i_1 : \mathrm{id}_{\underline{\mathrm{Fl}}(\mathcal{M})} \longrightarrow p_1$,* i.e. *$i_1(f) : f \longrightarrow p_1(f)$, induisant l'identité sur les objets buts de f et de $p_1(f)$,*

$$\begin{array}{ccc} X & \xrightarrow{i_1(f)} & X_1(f) \\ & {\scriptstyle f}\searrow \quad \swarrow{\scriptstyle p_1(f)} & \\ & Y\,, & \end{array}$$

d'où par itération un système inductif ordinal d'endofoncteurs $f \longmapsto p_\alpha(f)$ de $\underline{\mathrm{Fl}}(\mathcal{M})$, et p. 9
d'homomorphismes $i_\alpha : \mathrm{id}_{\underline{\mathrm{Fl}}(\mathcal{M})} \longrightarrow p_\alpha$, i.e.

$$\begin{array}{ccc} X & \xrightarrow{i_\alpha(f)} & X_\alpha(f) \\ & {\scriptstyle f}\searrow \quad \swarrow{\scriptstyle p_\alpha(f)} & \\ & Y\,, & \end{array}$$

formant un système inductif ordinal de factorisations de f fonctorielles en f.

Ceci posé, on a : [page 11]

a) *Pour tout ordinal α, on a $i_\alpha(f) \in \Phi$.*

b) *Supposons que les sources des $i \in C_0$ soient accessibles et soit alors π un cardinal dans $\mathfrak{U}$ tel qu'elles soient π-accessibles. Alors pour tout nombre ordinal α grand devant π, on a $p_\alpha(f) \in C_{0*}$, donc*

$$f \;=\; p_\alpha(f)\, i_\alpha(f) \qquad \textit{avec} \qquad i_\alpha(f) \in \Phi\,, \qquad p_\alpha(f) \in \Psi\,.$$

On a un résultat légèrement plus précis, que voici :

Corollaire 1. *Soit* Φ_0 *une partie de* $\mathrm{Fl}(\mathcal{M})$ *telle que*

$$C_0''' \subset \Phi_0 \subset \Phi \qquad (d'où\ C_0 \subset \Phi_0 \subset \Phi)\,, \tag{1.24}$$

où $C_0''' \subset \Phi$ *est définie dans* 1.19, *p.* 8. *Par exemple, si* Φ_0 *est une partie de* $\mathrm{Fl}(\mathcal{M})$ *satisfaisant*

$$C_0 \subset \Phi_0 \subset \Phi\,,$$

et stable par cochangement de base, par petites sommes amalgamées (*cf.* (1.18), p. 8), *par* $\varinjlim$ *ordinales strictes* (*cf.* (1.19), p. 8), *elle satisfait* (1.24). (**N.B.** *Si* $\mathcal{M}$ *admet des sommes amalgamées simples, de tels* Φ_0 *existent trivialement, il suffit de prendre* $\Phi_0 = \Phi$.)

Ceci posé, pour toute flèche f *dans* $\mathcal{M}$, *et tout ordinal* α, *on a* [page 12]

$$i_\alpha(f) \in \Phi_0\,.$$

Corollaire 2. *Supposons que les sources des flèches* $i \in C_0$ *soient accessibles, et soit* Φ_0 *comme dans le corollaire* 1 (p. ex. $\Phi_0 = C_0'''$). *Alors le couple* (Φ_0, Ψ) *est un précouple de Quillen,* i.e.

a) $\Phi_0 \longleftrightarrow \Psi$, i.e. $\Psi \subset \Phi_{0*}$ (*ou ce qui revient au même,* $\Phi_0 \subset \Psi^*$), *et*

b) *on a la propriété de factorisation de Quillen.*

Cela implique donc que Φ $(= \widetilde{C_0} = \widetilde{\Phi_0})$ *est formé des flèches qui sont facteurs directs de flèches de* Φ_0. *Donc si* Φ_0 *est stable par facteurs directs, on a* $\Phi_0 = \Phi$, i.e. Φ_0 *est clos à gauche.*

Commentary · Exposition [ms. 12]

Why the retract conclusion is exact

The corollary identifies the amount of closure required after the cellular construction. Put $R = I^{\perp}$ and $L = {}^{\perp}R$. If $I \subseteq \Phi_0 \subseteq L$, then $\Phi_0^{\perp} = R$: the inclusion $I \subseteq \Phi_0$ gives one containment, and $\Phi_0 \subseteq {}^{\perp}R$ gives the other. Assume, as in the corollary, that every map factors as a map in Φ_0 followed by a map in R.

Take $g : A \to B$ in L and choose a factorization

$$A \xrightarrow{j} E \xrightarrow{q} B, \qquad j \in \Phi_0, \quad q \in R, \quad qj = g.$$

The square with left map g, top map j, right map q and bottom map 1_B admits a filler $s : B \to E$. It satisfies $sg = j$ and $qs = 1_B$. In the arrow category the maps

$$g \xrightarrow{(1_A, s)} j \xrightarrow{(1_A, q)} g$$

compose to the identity. Thus g is a retract of a member of Φ_0, with the source held fixed. Conversely a retract of a map with the left lifting property has that property: insert the retract maps into a lifting square, solve the resulting square, and compose back. Therefore L is exactly the retract closure of Φ_0.

The cellular class and its retract closure consequently have different jobs. Cellular maps are the output of the explicit construction; the retract closure is the class characterized purely by lifting. In particular, if Φ_0 is retract closed then it is already L. The stronger description using C_0''' follows from the transfinite attachment construction, with identities included as explained above. This is the content, rather than an additional hypothesis, of the assertion that (Φ_0, R) is a Quillen precouple. Section 4 will isolate the same retract mechanism without any reference to the particular generating set.

Commentary · Later developments [ms. 12]

From a pointed endofunctor to algebraic factorization

Grothendieck's emphasis on $1 \to p_1$ makes the construction especially close to the later algebraic treatment. It should not, however, be read as already providing a monad: a pointed endofunctor comes with a unit but has no specified multiplication or associativity law. The set example above exhibits the difference concretely, since the ordinary iteration keeps adding solutions to problems which have already been solved.

Garner (2009, Theorem 4.4) constructs an algebraically free natural weak factorization system on a small category of generating arrows under specified cocompleteness and smallness hypotheses, in particular for a locally presentable category. Its right factor carries a monad and its left factor a comonad. For a discrete generating category, the algebras on a right map encode chosen solutions of the generating lifting problems; morphisms preserve those choices. The added algebraic structure gives a universal property to the construction. It is stronger than the existence of the functorial factorization obtained here.

This places the chapter's two concerns in their subsequent setting. The transfinite argument proves that the required lifting classes form a weak factorization system, while the algebraic refinement controls the choices of solutions and their compatibility. A functorial section of composition, an algebraic weak factorization system, and an orthogonal factorization system with unique fillers are three distinct structures. Nothing in Theorem 1 requires unique fillers.

p. 10

2 Variation des factorisations $f = p_\alpha i_\alpha$ avec la partie C_0 génératrice

Je dis que le système inductif ordinal de foncteurs $p_\alpha = p_\alpha^{C_0} : \underline{\mathrm{Fl}}(\mathcal{M}) \longrightarrow \underline{\mathrm{Fl}}(\mathcal{M})$, muni [page 13]
des flèches

$$i_\alpha^{C_0} \ : \ \mathrm{id}_{\underline{\mathrm{Fl}}(\mathcal{M})} \longrightarrow p_\alpha^{C_0}\,,$$

dépend fonctoriellement de C_0, quand on considère C_0 comme un élément de l'ensemble ordonné des *petites* parties de $\mathrm{Fl}(\mathcal{M})$, formées de flèches coquarrables (donc de l'ensemble ordonné

$$\mathfrak{P}_{\mathfrak{U}\text{-petites}}(\mathrm{Fl}_{\mathrm{coquar.}}(\mathcal{M}))\quad).$$

Si on a une inclusion

$$C_0 \ \hookrightarrow \ C_1\,, \tag{2.1}$$

on en déduit pour tout ordinal α un homomorphisme fonctoriel

$$u_\alpha \ = \ u_\alpha^{C_1,C_0} \ : \ X_\alpha^{C_0} \ \longrightarrow \ X_\alpha^{C_1}\,, \tag{2.2}$$

rendant commutatifs les carrés déduits de $f : X \longrightarrow Y$ dans $\mathcal{M}$,

$$\begin{array}{ccccc} X & \xrightarrow{i_\alpha^{C_0}(f)} & X_\alpha^{C_0}(f) & \xrightarrow{p_\alpha^{C_0}(f)} & Y \\ {\scriptstyle \mathrm{id}}\downarrow & & \downarrow{\scriptstyle u_\alpha(f)} & & \downarrow{\scriptstyle \mathrm{id}} \\ X & \xrightarrow{i_\alpha^{C_1}(f)} & X_\alpha^{C_1}(f) & \xrightarrow{p_\alpha^{C_1}(f)} & Y\,, \end{array} \tag{2.3}$$

et compatible avec les morphismes de transition pour α variable,

$$\begin{array}{ccc} X_\alpha^{C_0} & \xrightarrow{\mathrm{trans}_{\beta,\alpha}^{C_0}} & X_\beta^{C_0} \\ {\scriptstyle u_\alpha}\downarrow & & \downarrow{\scriptstyle u_\beta} \\ X_\alpha^{C_1} & \xrightarrow{\mathrm{trans}_{\beta,\alpha}^{C_1}} & X_\beta^{C_1}\,. \end{array} \tag{2.4}$$

[page 14]

Pour définir les u_α, satisfaisant aux conditions précédentes, il suffit de les définir pour $\alpha = 1$ "et d'itérer" :

(2.5)
$$\begin{array}{ccccc} & & X_1^{C_0}(f) & & \\ & {\scriptstyle i_1^{C_0}(f)}\nearrow & \downarrow & \searrow{\scriptstyle p_1^{C_0}(f)} & \\ X & & {\scriptstyle u_1(f)} & & Y \\ & {\scriptstyle i_1^{C_1}(f)}\searrow & \downarrow & \nearrow{\scriptstyle p_1^{C_1}(f)} & \\ & & X_1^{C_1}(f) & & \end{array} .$$

Or $X_1^{C_0}(f)$ est défini comme une somme directe dans $X\backslash\mathcal{M}/Y$, relative à un ensemble d'indices $\Delta(C_0, f)$ *contenu* dans $\Delta(C_1, f)$ – et la famille d'objets dont on prend la somme directe étant induite d'une famille (non petite) dont l'ensemble d'indices serait $\Delta(\mathrm{Fl}_{\mathrm{coquar.}}(\mathcal{M}), f)$, savoir formé de *tous* les diagrammes carrés p. 11

$$D : \quad \begin{array}{ccc} A & \xrightarrow{u} & X \\ {\scriptstyle i}\downarrow & & \downarrow{\scriptstyle f} \\ B & \xrightarrow{v} & Y \end{array} \qquad \text{avec } i \text{ coquarrable sans plus ,}$$

la définition des X_D, i_D, p_D associés à D ne dépendant que de D, et non de l'ensemble C_0 ou C_1 de flèches coquarrables qui contient i. Ceci dit, la flèche $u_1(f)$ dans (2.5) n'est autre que l'inclusion canonique d'une somme amalgamée partielle, indexée par $\Delta(C_0, f)$, dans la somme amalgamée correspondante à l'ensemble d'indices plus grand. La fonctorialité de cette flèche $u_1(f)$, pour f variable, "est immédiate", elle résulte de la commutativité du carré, associé à un morphisme $v = (v_X, v_Y)$ de flèches [page 15]

(2.6)
$$\begin{array}{ccc} X & \xrightarrow{f} & Y \\ {\scriptstyle v_X}\downarrow & & \downarrow{\scriptstyle v_Y} \\ X' & \xrightarrow{f'} & Y' , \end{array}$$

savoir le diagramme d'applications entre ensembles d'indices

(2.7)
$$\begin{array}{ccc} \Delta(C_0, f) & \xrightarrow{u_1(f)} & \Delta(C_1, f) \\ {\scriptstyle \text{dépendance fonctorielle en } f \text{ de } \Delta(C_0,f)}\downarrow & & \downarrow{\scriptstyle \text{dépendance fonctorielle en } f \text{ de } \Delta(C_1,f)} \\ \Delta(C_0, f') & \xrightarrow{u_1(f')} & \Delta(C_1, f') \end{array}$$

(commutativité qui revient à dire que $\Delta(C_0, f)$ peut être considéré comme un foncteur en le couple (C_0, f) comme objet de la catégorie produit $\mathfrak{P}_{\mathrm{pet.}}(\mathrm{Fl}_{\mathrm{coquar.}}(\mathcal{M})) \times \underline{\mathrm{Fl}}(\mathcal{M})$ …). Le carré commutatif (2.7) est la partie "indices" d'un carré commutatif entre familles d'objets $\mathscr{X}(C_0, f)$, $\mathscr{X}(C_0, f')$, $\mathscr{X}(C_1, f)$, $\mathscr{X}(C_1, f')$, indexés par ces ensembles, savoir les $X_D^{C_0}$ et les $X_D^{C_1}$ relatifs aux diagrammes D impliquant, soit la flèche f, soit la flèche f' … [page 16]

Commentary · Exposition [ms. 15]

Functoriality in the generators, including limit stages

Grothendieck next keeps track of what happens when more lifting problems are declared relevant. The one-stage comparison is induced by the inclusion of indexing sets, but at later stages the input to the attachment functor has also changed. Writing the recursive formula makes the joint naturality precise.

Let $I \subseteq J$, put $P_I = p_1^I$ and $P_J = p_1^J$, and let $\tau : P_I \to P_J$ be the natural transformation constructed from the inclusion of squares. Both endofunctors lie over the codomain functor, and

their units satisfy $\tau\eta_I = \eta_J$. Let $u_\alpha : P_I^\alpha \to P_J^\alpha$ denote the comparison at stage α, where the superscript means the continuous iteration used in the text, not ordinary iteration at a limit. Then

$$u_0 = 1, \qquad u_{\alpha+1} = P_J(u_\alpha)\,\tau_{P_I^\alpha}, \qquad u_\lambda = \operatorname*{colim}_{\alpha<\lambda} u_\alpha \quad (\lambda \text{ a limit}).$$

The successor formula starts with $P_I(P_I^\alpha f)$, changes the outer attachment functor to P_J, and then changes its input to $P_J^\alpha f$. Naturality of τ allows these two operations in the opposite order as well.

Here is the compatibility with a successor transition, which is the point needed to make the limit formula meaningful. Naturality of η_J and the equation $\tau\eta_I = \eta_J$ give

$$\begin{aligned} u_{\alpha+1}\eta_{I,P_I^\alpha} &= P_J(u_\alpha)\eta_{J,P_I^\alpha} \\ &= \eta_{J,P_J^\alpha} u_\alpha. \end{aligned}$$

Compatibility with all transitions follows by composition and the defining colimit property at limits. Each u_α is natural in f by the same induction. For $I \subseteq J \subseteq K$, the equation $u_\alpha^{K,I} = u_\alpha^{K,J} u_\alpha^{J,I}$ holds at stage one because both maps restrict to the same inclusions of cells. At successors it follows by naturality of the one-stage transformations, and at limits by equality on every colimit component. Identity inclusions are handled identically. This proves the functoriality on the product of the poset of generating sets with the arrow category that the final paragraph of Section 2 leaves unexpanded.

The term "inclusion" describes the indexing sets. It does not by itself assert that the resulting morphism of objects is a monomorphism in an arbitrary category. The following elementary refinement explains when the same word can also be used for the actual stages.

Or la construction canonique du système inductif ordinal p_α, avec les $i_\alpha : \mathrm{id}_{\underline{\mathrm{Fl}}(\mathcal{M})} \longrightarrow p_\alpha$, est fonctorielle par rapport à la donnée initiale p_1, i_1 – je n'explicite pas le détail de la fonctorialité, bien que je devrais …

Commentary · Development (commentators') [ms. 16]

Comparisons which are monomorphisms

The parameter dependence in Section 2 is useful when a family of generators is enlarged gradually. For presheaves, monomorphic generators give a stronger conclusion: an enlargement can be seen stage by stage inside the resulting objects. We record the precise two-variable statement, with its proof, for this construction. We checked the small object construction in Riehl (2014, Section 12.2) and the algebraic comparison in Garner (2009, Sections 3–4); we did not find this particular formulation there. The statement below is an elementary elaboration of the displayed construction, with no claim of priority.

Proposition (monomorphic comparison). [ours] Let $\mathcal{E} = \mathbf{Set}^{\mathcal{A}^{\mathrm{op}}}$ for a small category $\mathcal{A}$. Let $I \subseteq J$ be small sets of monomorphisms in $\mathcal{E}$. Suppose $(u, v) : f \to f'$ is a commutative square whose source map $u : X \to X'$ and target map $v : Y \to Y'$ are both monomorphisms. For every ordinal α for which the construction is performed, the jointly natural comparison

$$X_\alpha^I(f) \longrightarrow X_\alpha^J(f')$$

is a monomorphism. In particular, at a fixed input f, enlargement of a set of monomorphic generators gives monomorphisms at every stage.

Proof. First consider one stage. The map

$$\Delta(I, f) \longrightarrow \Delta(J, f'), \qquad (j, a, b) \longmapsto (j, ua, vb)$$

is injective. Indeed equal images have the same generator j, and cancellation of the monomorphisms u and v gives equality of both maps a and b. Evaluate the pushout formula at an object $c \in \mathcal{A}$. Evaluation preserves colimits, and every $j : A_j \to B_j$ is pointwise injective. Thus, as sets,

$$X_1^I(f)(c) \cong X(c) \amalg \coprod_{(j,a,b)\in\Delta(I,f)} \big(B_j(c) \setminus j(A_j(c))\big).$$

This decomposition is only used at the level of sets; the complements need not form subpresheaves. On the first summand the comparison is $u(c)$, which is injective. On each remaining summand it is

the identity on the same complement, placed in the summand with image index. Injectivity of the indexing map shows that distinct summands remain distinct. Hence the one-stage comparison is pointwise injective.

At stage zero the assertion is the hypothesis on u. If it holds at stage α, apply the one-stage result to the square between $p^I_\alpha(f)$ and $p^J_\alpha(f')$; its source map is monic by induction and its target map is still v. This proves the successor step. At a limit λ, evaluate at c and use the two compatible diagrams of sets. If two representatives in the first colimit have equal images in the second, they become equal at a common later stage of the second diagram. The injectivity of the comparison at that stage makes their images in the first diagram equal there as well. They therefore represent the same element of the first colimit. This proves the limit step and the proposition. □

The assumption on the target map carries real information. With $I = J = \{\varnothing \to \{*\}\}$, take $f : \varnothing \to \{0,1\}$ and $f' : \varnothing \to \{*\}$, the identity on the empty source and the constant map on targets. The induced map between first stages is $\{0,1\} \to \{*\}$, so it is not monic. The construction distinguishes lifting problems by their target component as well as their boundary map.

3 Majoration des cardinaux

Je suppose à présent que $\mathcal{M}$ est muni d'une *filtration cardinale*

$$(\mathrm{Filt}^\pi)_{\pi \geq \pi_0} \qquad (\pi_0,\ \pi \text{ cardinaux dans } \mathfrak{U}) \tag{3.1}$$

(SGA 4 I 9.12, p. 149), les Filt^π stables par sommes amalgamées simples (chaque fois qu'elles existent), donc aussi par sommes amalgamées infinies indexées par des ensembles d'indices de cardinal $\leq \pi$. On suppose de plus que tout objet de Filt^{π_0} soit accessible, et on désigne par π_1 le plus petit cardinal tel que $\pi_1 \geq \pi_0$ et que les objets de Filt^{π_0} soient π_1-accessibles. Désignant, pour tout cardinal, par $\mathcal{M}_\pi$ le sous-ensemble de $\mathrm{Ob}\,\mathcal{M}$ formé des objets π-accessibles, on aura alors pour tout $\pi \geq \pi_1$ (*loc. cit.* 9.16)

p. 12

$$\mathcal{M}_\pi \ \subset\ \mathrm{Filt}^\pi \ \subset\ \mathcal{M}_{(\pi^{\pi_0})} \qquad (\text{si } \pi \geq \pi_1)\,, \tag{3.2}$$

[page 17]

Commentary · Exposition [ms. 16]

A filtration measures the cost of a construction

Grothendieck now asks for more than the existence of a factorization. He wants to perform the construction inside a bounded part of the category, uniformly for every arrow in that part. This is what will eventually let a small amount of data control a model structure. The three quantities to keep separate are the size of the domains and codomains of the generators, the number of generators actually used, and the length of the construction. Isomorphic generators have the same lifting property, but the unmodified construction attaches a cell for each of them.

The terminology comes from Artin et al. (1972, Exposé I, Definitions 9.1–9.3 and 9.12). A partially ordered set is *large relative to* an infinite cardinal π if each of its subsets of cardinality at most π has an upper bound. Thus the modern directedness index is π^+. An object called π-accessible here has a representable functor preserving such colimits; in the usual setting this is π^+-presentability, not presentability at the cardinal π. The filtration is additional structure: its levels are essentially small, are increasing, admit bounded presentations of objects at larger levels, and have specified closure properties. Membership in a filtration level should therefore not be replaced by an informal assertion that an object has at most π elements.

For the calculation ahead we need the following concrete consequences. Put $\mathcal{M}^\pi = \mathrm{Filt}^\pi$. If $A \in \mathcal{M}^r$, it has a filtered presentation by objects of $\mathcal{M}^{\pi_0}$ with at most r^{π_0} indices. If $X \in \mathcal{M}^s$ and $s \geq \pi_1$, it has a presentation by objects of $\mathcal{M}^{\pi_1}$ over a π_1^+-directed poset with at most s^{π_1} indices. These are the presentations used on ms. 20. The stronger closure condition (3.13), which is explicitly assumed below, includes *all* filtered diagrams of cardinality at most the level, not only those large relative to π_0.

This stronger closure also supplies the retract argument in (3.2). If X is a retract of $Y \in \mathcal{M}^\pi$, with idempotent $e : Y \to Y$, the countable chain

$$Y \xrightarrow{e} Y \xrightarrow{e} Y \xrightarrow{e} \cdots$$

has colimit X, so $X \in \mathcal{M}^\pi$. If X is π-accessible, factor its identity through a stage of its π^+-directed presentation by $\mathcal{M}^\pi$-objects. This makes it such a retract. In the other direction, a presentation with at most π^{π_0} arrows expresses $\mathrm{Hom}(X, -)$ as a limit of that many representables. Directed colimits of sets with index larger than this bound commute with those limits. This proves the inclusions in (3.2) under the closure hypotheses used here and explains why their equality at suitable cardinals is useful.

donc si $\pi^{\pi_0} = \pi$, p. ex. si $\pi = 2^c$ avec $c \geq \pi_0$, on aura

$$\mathrm{Filt}^\pi \;=\; \mathcal{M}_\pi\,. \tag{3.2 bis}$$

(Si on admet l'hypothèse du continu généralisée, on a $\pi^{\pi_0} = \pi$ pour tout $\pi > \pi_0$, donc $\mathrm{Filt}^\pi = \mathcal{M}_\pi$ si $\pi \geq \pi_1$ et $\pi > \pi_0$.)

Je pose, pour tout cardinal $\pi \geq \pi_0$,

$$\mathrm{Fl}^\pi(\mathcal{M}) \;=\; \{\; f \in \mathrm{Fl}(\mathcal{M}) \mid \text{source et but de } f \text{ sont dans } \mathrm{Filt}^\pi \;\} \tag{3.3}$$

– ce qui sans doute donne une filtration cardinale sur $\underline{\mathrm{Fl}}(\mathcal{M})$ (mais ce n'est pas là notre souci …). Mon but à présent, c'est de dégager des conditions sur $C_0 \subset \mathrm{Fl}_{\mathrm{coquar.}}(\mathcal{M})$ (petite partie de $\mathrm{Fl}(\mathcal{M})$) et sur le cardinal π, et l'ordinal α, pour que l'on ait

$$\begin{aligned} f \in \mathrm{Fl}^\pi(\mathcal{M}) \;&\overset{?}{\Longrightarrow}\; X_\alpha(f) \in \mathrm{Filt}^\pi \\ &\quad (\textit{i.e. } p_\alpha(f) \in \mathrm{Fl}^\pi(\mathcal{M}),\ \text{ou encore } i_\alpha(f) \in \mathrm{Fl}^\pi(\mathcal{M}))\,. \end{aligned} \tag{3.4}$$

Plus généralement, je me propose de donner une estimation de la "cardinalité" de $X_\alpha(f)$, pour C_0 fixé, en fonction de C_0, de f, de α, plus exactement, en fonction des trois cardinaux $\pi(C_0)$, $\pi(f)$, $\pi(\alpha)$ définis comme

$$\left\{\begin{array}{rcl} \pi(C_0) &=& \text{plus petit cardinal tel que } C_0 \subset \mathrm{Fl}^\pi(\mathcal{M}) \\ \pi(f) &=& \pi(\{f\}) \;=\; \text{plus petit cardinal tel que } f \in \mathrm{Fl}^\pi(\mathcal{M}) \\ \pi(\alpha) &=& \mathrm{card}\,\alpha\,. \end{array}\right. \tag{3.5}$$

Donc je cherche une fonction cardinale de variables cardinales φ, telle que l'on ait

$$X_\alpha(f) \;\in\; \mathrm{Filt}^\pi \qquad \text{si} \qquad \pi \;=\; \varphi(\underbrace{\pi(C_0)}_{r}, \underbrace{\pi(f)}_{s}, \underbrace{\pi(\alpha)}_{t})\,. \tag{3.6}$$

[page 18]

L'estimation cruciale concernera sûrement le cas $\alpha = 1$. Notons que $X_1^{C_0}(f) = X_1(f)$ est défini comme une somme amalgamée (en général infinie) d'objets X_D, pour un ensemble $\Delta(C_0, f) = \Delta(f)$ de diagrammes, savoir les diagrammes commutatifs

$$\begin{array}{ccc} A & \longrightarrow & X \\ {\scriptstyle i}\downarrow & & \downarrow{\scriptstyle f} \\ B & \longrightarrow & Y \end{array}$$

avec $i \in C_0$. Pour un i fixé, et un f fixé, le cardinal de l'ensemble des diagrammes de ce type est majoré par celui de $\mathrm{Hom}(A, X) \times \mathrm{Hom}(B, Y)$. On a $A, B \in \mathrm{Filt}^r$, $X, Y \in \mathrm{Filt}^s$, donc il nous faut une majoration de

$$\mathrm{card}\,\mathrm{Hom}_{\mathcal{M}}(A, X)\,, \qquad A \;\in\; \mathrm{Filt}^r\,, \qquad X \;\in\; \mathrm{Filt}^s\,.$$

p. 13

Commentary · Exposition [ms. 17]

The cofinality qualification in the cardinal arithmetic

Grothendieck looks for cardinals at which the estimate stops growing. The unconditional choice $\pi = 2^c$, $c \geq \pi_0$, works because

$$(2^c)^{\pi_0} = 2^{c\pi_0} = 2^c.$$

The parenthetical appeal to the generalized continuum hypothesis has a different status. Even under GCH, $\pi > \pi_0$ does not imply $\pi^{\pi_0} = \pi$. For example, $\pi = \aleph_\omega$ and $\pi_0 = \aleph_0$ give $\pi^{\pi_0} > \pi$. More generally, König's theorem gives $\pi^{\operatorname{cf}\pi} > \pi$ for every infinite π. A direct proof of the case just used is instructive: if $(f_\xi)_{\xi<\aleph_\omega}$ enumerated all maps $\mathbb{N} \to \aleph_\omega$, choose $g(n)$ outside the set $\{f_\xi(n) : \xi < \aleph_n\}$. For every ξ some n satisfies $\xi < \aleph_n$, and then $g(n) \neq f_\xi(n)$, a contradiction.

Under GCH the additional condition $\pi_0 < \operatorname{cf}\pi$ is sufficient. The general exponentiation rule and its cofinality qualification are recorded in Marks (2026, Theorems 10.12 and 11.7, Exercise 11.8). Nothing in the factorization theorem requires GCH: the fixed exponent identity above is all that is needed. The same correction applies to the repeated GCH assertion on ms. 19.

The sentence about the arrow category immediately before (3.4) should also be read with its size threshold in view. Pointwise filtered colimits and essential smallness of the bounded arrow categories are immediate. Uniformly bounded presentations of arrows require control of the Hom sets between small objects and simultaneous realization of the arrow in two presentations. At a sufficiently enlarged initial level this is the usual accessibility theorem for a finite diagram category. The text does not supply that extra argument at the original π_0, and does not use the assertion in its proof.

[page 19]

Voici les majorations essentielles dans ce sens :

Proposition 3.1. *Soit π_0 le cardinal initial de la filtration cardinale $(\mathrm{Filt}^\pi)_{\pi\geq\pi_0}$ envisagé, π_1 le plus petit cardinal $\geq \pi_0$ tel que les objets de Filt^{π_0} soient π_1-accessibles, $C_1 = \operatorname{card} \underbrace{\widetilde{\underline{\mathrm{Fl}}^{\pi_1}(\mathcal{M})}}_{=\underline{\mathrm{Fl}}(\mathcal{M}^{\pi_1})}$[4]. Pour tout cardinal $\pi \geq \pi_0$, je désigne par $\mathcal{M}^\pi$ la sous-catégorie strictement pleine de $\mathcal{M}$ dont l'ensemble des objets est Filt^π. Enfin, si $\mathcal{C}$ est une catégorie, je désigne par $\widetilde{\mathcal{C}}$ l'ensemble des classes d'isomorphie d'objets de $\mathcal{C}$.*[5]

1°) *Si $r \geq \sup(\pi_1, C_1)$, on a*

$$\operatorname{card}\big(\underbrace{\widetilde{\underline{\mathrm{Fl}}^r(\mathcal{M})}}_{=\underline{\mathrm{Fl}}(\mathcal{M}^r)}\big) \leq 2^{(r^{\pi_0})} \quad (= 2^r, \text{ si } r = 2^c, \text{ avec } c \geq \pi_0)\,. \tag{3.7}$$

2°) *Si $r, s \geq \sup(\pi_1, C_1)$, et si $A \in \mathrm{Filt}^r$, $X \in \mathrm{Filt}^s$, on a*

$$\operatorname{card}\operatorname{Hom}_{\mathcal{M}}(A, X) \leq s^{(r^{\pi_0})} \tag{3.8}$$

$$\operatorname{card}\underline{\mathrm{Fl}}(\widetilde{\mathcal{M}^r/X}) \leq s^{(r^{\pi_0})} \tag{3.9}$$

$$\begin{cases} = s^r & \text{si } r = 2^c, \text{ avec } c \geq \pi_0\,, \\ = s & \text{si } s = 2^{c'}, \text{ avec } c' \geq r^{\pi_0}\,. \end{cases}$$

N.B. Si on admet l'hypothèse du continu généralisée, qui implique que $\pi^{\pi'} = \pi$ si $\pi > \pi'$ (π cardinal infini, $\pi' \geq 1$), alors prenant r tel que $r > \pi_0$, les formules précédentes donnent (avec de plus $r \geq \sup(\pi_1, C_1)$) :

$$\operatorname{card}\widetilde{\underline{\mathrm{Fl}}^r(\mathcal{M})} \leq 2^r\,, \tag{3.7 bis}$$

$$\operatorname{card}\operatorname{Hom}_{\mathcal{M}}(A, X) \leq s^r \qquad (\text{si } A \in \mathrm{Filt}^r,\ X \in \mathrm{Filt}^s)\,, \tag{3.8 bis}$$

$$\operatorname{card}\underline{\mathrm{Fl}}(\widetilde{\mathcal{M}^r/X}) \leq s^r \qquad (\text{si } X \in \mathrm{Filt}^s)\,. \tag{3.9 bis}$$

4. *cf.* plus bas la notation $\widetilde{\mathcal{C}}$.

5. Signalons qu'on a toujours $\operatorname{card}\widetilde{\underline{\mathrm{Fl}}(\mathcal{C})} \geq \operatorname{card}\widetilde{\mathcal{C}}$ car $\widetilde{\mathcal{C}} \hookrightarrow \widetilde{\underline{\mathrm{Fl}}(\mathcal{C})}$ via $\mathrm{cl}(X) \longmapsto \mathrm{cl}(\mathrm{id}_X)$.

Sans hypothèse du continu, ces formules sont aussi valables pour r de la forme 2^c, avec $c \geq \pi_0$. Ce sont ces dernières formules qui on l'air les plus naturelles. Pour (3.8 bis) et (3.9 bis), je signale que le deuxième membre s^r est le cardinal de l'ensemble $\mathrm{Hom}_{\mathrm{Ens}}(A, X)$, où A, X sont deux ensembles tels que $\mathrm{card}\, A = r$, $\mathrm{card}\, X = s$. On ne peut donc espérer améliorer (3.8 bis) ! Pour la

première formule (3.7 bis), notons que l'on a égalité lorsque $\mathcal{M}$ est la catégorie des couples (A, B), A un ensemble et B une partie de A, avec les flèches évidentes, et qu'on définit $\mathcal{M}^\pi$ (pour $\pi \geq \pi_0$) comme la sous-catégorie strictement pleine formée des (A, B) tels que $\mathrm{card}\, A \geq \pi$. p. 14 [page 20]

Commentary · Examples [ms. 19]

An orbit count is not a bound on a Hom set

The purpose of C_1 is to pay for every choice of a map between the small objects. As printed, however, it counts isomorphism classes of objects of the arrow category. These two numbers can be very different. This is a mathematical issue in the edition, not an error introduced by the transcription.

Let G be any small group and let BG have one object $*$, with $\mathrm{Hom}(*, *) = G$. Give BG the constant filtration $\mathcal{M}^\pi = BG$, with $\pi_0 = \pi_1 = \aleph_0$. Every filtered diagram in BG is isomorphic to the constant diagram: transport from a fixed index to another through a common upper bound; a further common upper bound shows that transport does not depend on the choices. Consequently filtered colimits exist, and $\mathrm{Hom}(*, -)$ preserves them. Pushouts of spans of isomorphisms exist as well. The constant filtration has all the presentation and closure properties needed here.

Every two arrows g, h are isomorphic as objects of $\mathrm{Fl}(BG)$: take the square with vertical maps 1 and hg^{-1}. Thus the printed constant is $C_1 = 1$, whereas $|\mathrm{Hom}(*, *)| = |G|$. Take $r = s = \aleph_0$ and a group of cardinality greater than $\aleph_0^{(\aleph_0^{\aleph_0})}$. Formula (3.8), with the printed C_1, is false. The example also identifies precisely the invalid step on ms. 20: the indicated bound $|\mathrm{Hom}(A_i, X_j)| \leq C_1$ does not follow from the definition of C_1.

There is a straightforward repair. Choose a small full skeleton K_1 of $\mathcal{M}^{\pi_1}$, choosing its representatives compatibly with those at level π_0, and use

$$\chi = \max\{\aleph_0, \pi_1, |\mathrm{Mor}(K_1)|\}$$

as the threshold for r and s. It counts actual maps between representatives, including automorphisms. This change is also the natural reading of the lowercase c_1 in Theorem 2: the entire strictly full level need not be a small category, so its raw collection of arrows cannot serve as a small cardinal. The choice of skeleton affects a numerical bound, not the factorization or the lifting classes.

Démonstration de 3.1. Prouvons d'abord la formule (3.8),

$$\mathrm{card}\,\mathrm{Hom}(A, X) \;\leq\; s^{(r^{\pi_0})} \qquad \begin{cases} \text{si } A \in \mathrm{Filt}^r,\ X \in \mathrm{Filt}^s, \\ r \geq \pi_1,\ s \geq \sup(\pi_1, C_1). \end{cases}$$

(**N.B.** Je n'utiliserai pas $r \geq C_1$, postulé dans 3.1 1°.) J'écris `[<<J'écris>> rayé]`

$$A \;=\; \varinjlim_I A_i\ , \quad \mathrm{card}\, I \;\leq\; r^{\pi_0}\ , \quad A_i \;\in\; \mathrm{Filt}^{\pi_0}\ ,$$
$$X \;=\; \varinjlim_J X_j\ , \quad \mathrm{card}\, J \;\leq\; s^{\pi_1}\ , \quad X_j \;\in\; \mathrm{Filt}^{\pi_1}\ , \qquad\qquad J \text{ grand devant } \pi_1\ .$$

On aura

$$\mathrm{Hom}(A, X) \;\simeq\; \varprojlim_{i \in I} \underbrace{\mathrm{Hom}(A_i, \varinjlim_J X_j)}_{\overset{(6)}{\simeq} \varinjlim_{j \in J} \underbrace{\mathrm{Hom}(A_i, X_j)}_{\text{de cardinal } \leq C_1}}\ ,$$

donc pour tout $i \in I$

$$\mathrm{Hom}(A_i, X) \;\leq\; \mathrm{card}(J) \times C_1 \;\leq\; s^{\pi_1} \times C_1 \;=\; s^{\pi_1} \;,$$

car $s \geq C_1$, donc $s^{\pi_1} \geq C_1$, d'où

$$\mathrm{card}(\varprojlim_{j \in I} \mathrm{Hom}(A_i, X)) \;\leq\; (s^{\pi_1})^{\mathrm{card}\, I} \;\leq\; \underbrace{(s^{\pi_1})^{(r^{\pi_0})}}_{s^{\pi_1 r^{\pi_0}}} \;.$$

Comme $r \geq \pi_1$, on a $r^{\pi_0} \geq \pi_1$, donc $r^{\pi_0}\pi_1 = r^{\pi_0}$, d'où

$$\mathrm{card}\,\mathrm{Hom}(A, X) \;\leq\; s^{(r^{\pi_0})} \;,$$

c'est bien la formule (3.8). Pour en tirer une estimation pour $\mathcal{M}^r/X$ (avec $X \in \mathrm{Filt}^s$), je vais d'abord majorer le cardinal des classes d'isomorphie d'objets de $\mathcal{M}^r/X$, *i.e.* des flèches à isomorphisme près (dans $\mathcal{M}^r$) [page 21]

$$A \;\longrightarrow\; X \;, \qquad X \text{ fixé dans } \mathrm{Filt}^s,\; A \text{ variable dans } \mathcal{M}^r \;.$$

On aura

$$A \;=\; \varinjlim_{i \in I} A_i \qquad \text{avec } A_i \in \mathrm{Filt}^{\pi_0},\; I \text{ ensemble ordonné de cardinal} \leq r^{\pi_0} \;.$$

Pour I fixé, le cardinal de l'ensemble des systèmes inductifs indexés par I, dans $\mathcal{M}^{\pi_0}/X$, à isomorphisme près, peut se majorer ainsi : pour tout $i \in I$, il faut choisir A_i dans $\mathcal{M}^{\pi_0}$ p. 15
(mais seule sa classe dans $\widetilde{\mathcal{M}^{\pi_0}}$ importe), donc c'est majoré par $\mathrm{card}\,\widetilde{\mathcal{M}^{\pi_0}} \leq C_0$ [(7)], et pour tous les i, par $\mathrm{card}\, I \times C_0 \leq r^{\pi_0} \times C_0$, et si $r \geq C_0$, donc $r^{\pi_0} \geq C_0$, on trouve une majoration des choix possibles du système des *objets* A_i dans $\mathcal{M}^{\pi}$, à isomorphisme près, par r^{π_0}. Si on se donne de plus les morphismes de transition $A_i \longrightarrow A_j$ pour $i < j$, cela fait pour chaque paire comparable, élément de $I \times I$, un choix majoré par C_0, donc encore une majoration par $\underbrace{\mathrm{card}(I \times I)}_{=(\mathrm{card}\, I)^2 = \mathrm{card}\, I} \cdot C_0 \leq r^{\pi_0} \cdot C_0 = r^{\pi_0}$. Donc l'ensemble des systèmes inductifs en question, à isomorphisme près, pour I fixé, est de cardinal $\leq r^{\pi_0} \cdot r^{\pi_0} = r^{\pi_0}$. Enfin, les *homomorphismes* d'un système inductif donné dans X sont majorés par $\mathrm{card}\, I \times s^{(r^{\pi_0})}$ (par (3.8) déjà prouvé), donc par

$$r^{\pi_0} \cdot s^{(r^{\pi_0})} \;=\; s^{(r^{\pi_0})} \qquad (\text{puisque } r^{\pi_0} \leq s^{(r^{\pi_0})}) \;.$$

Au total, pour I fixé, l'ensemble des systèmes inductifs à isomorphisme près, indexés par I, à valeurs dans $\mathcal{M}^r/X$, est de cardinal majoré par $\underbrace{r^{\pi_0}}_{\substack{\text{nombre des}\\ \text{systèmes inductifs}\\ \text{dans } \mathcal{M}^{\pi}, \text{ à}\\ \text{isomorphisme près}}} \cdot \underbrace{s^{(r^{\pi_0})}}_{\substack{\text{nombre des}\\ \text{flèches d'un}\\ \text{tel système inductif}\\ \text{dans } X}} =$

$s^{(r^{\pi_0})}$. [page 22]

Mais il faut maintenant faire varier I, à isomorphisme près, dans la catégorie des ensembles ordonnés (filtrants *etc.*) de cardinal $\leq \lambda = r^{\pi_0}$. On voit de suite que cet ensemble de classes d'isomorphie (qui peut s'interpréter comme un ensemble quotient d'un certain ensemble de parties d'un ensemble fixe I_0 de cardinal λ) est de cardinal $\leq 2^{\lambda}$. On trouve donc finalement

$$\mathrm{card}\,\widetilde{\mathcal{M}^r/X} \;\leq\; s^{(r^{\pi_0})} \cdot 2^{(r^{\pi_0})} \;=\; s^{(r^{\pi_0})} \;,$$

sous condition que

$$r \;\geq\; \sup(\pi_1, C_0) \;, \qquad s \;\geq\; \sup(\pi_1, C_1) \;.$$

6. car les $A \in \mathrm{Filt}^{\pi_0}$ sont π_1-accessibles.

7. On a posé ici $C_0 = \mathrm{card}\,\widetilde{\mathrm{Fl}^{\pi_0}}$, donc $C_0 \leq C_1$.

Il faut prouver l'inégalité similaire pour card $\widetilde{\underline{\mathrm{Fl}}^r\,\mathcal{M}}$ (3.9). Or, comme pour A, B dans $\mathcal{M}^r$, on a, si $r \geq \sup(\pi_1, C_1)$,

$$\operatorname{card} \operatorname{Hom}_{\mathcal{M}}(A,B) \;\leq\; r^{(r^{\pi_0})}$$

en vertu de (3.8) où on fait $s = r$, on trouve que

$$\begin{aligned} \operatorname{card} \underline{\mathrm{Fl}}(\widetilde{\mathcal{M}^r/X}) \;&\leq\; \Big(\operatorname{card} \widetilde{\mathcal{M}^r/X}\Big)^2 \cdot r^{(r^{\pi_0})} \\ &\leq\; s^{(r^{\pi_0})} \cdot r^{(r^{\pi_0})} \\ &=\; s^{(r^{\pi_0})} \qquad \text{si } s \geq r\ . \end{aligned}$$

(On va regarder plus bas les cas $s \leq r$ [8]). C'est bien la formule (3.9).

Venons-en à la catégorie $\mathcal{M}^r$ elle-même. L'argument de la page 21 montre que l'ensemble des classes d'isomorphie d'objets de $\mathcal{M}^r$ indexés par un I fixé, de cardinal $\leq r^{\pi_0}$, comme $A = \varinjlim_i A_i$ avec $A_i \in \mathrm{Filt}^{\pi_0}$, est de cardinal majoré par r^{π_0} (si $r \geq C_0$). Si on fait varier I, on trouve une majoration par $r^{\pi_0} \cdot 2^{(r^{\pi_0})} = 2^{(r^{\pi_0})}$. On en conclut comme tantôt que l'ensemble $\widetilde{\mathrm{Fl}\,\mathcal{M}^r}$ est de cardinal majoré par

p. 16 [page 23]

$$(2^{(r^{\pi_0})})^2 \times r^{(r^{\pi_0})} \qquad (\text{si } r \geq \sup(\pi_1, C_1))\ ,$$

donc par $r^{(r^{\pi_0})}$. Je dis qu'on a

$$r^{(r^{\pi_0})} \;=\; 2^{(r^{\pi_0})}\ ,$$

en effet, on a $\geq$, et pour prouver $\leq$, on note que $r < 2^r$, donc $r^{(r^{\pi_0})} \leq (2^r)^{(r^{\pi_0})} = 2^{r \cdot r^{\pi_0}} = 2^{(r^{\pi_0})}$, O.K.! Cela établit donc 3.7. Cet argument prouve en fait le

Commentary · Exposition [ms. 22]

The estimates survive the corrected counting argument

Grothendieck's desired bound has enough room to absorb the choices that were omitted in the displayed counting. We give the calculation with the corrected threshold $r, s \geq \chi$ of the preceding block. Write $\mu = r^{\pi_0}$. For the presentations on ms. 20, accessibility gives

$$\operatorname{Hom}(A_i, X) \cong \varinjlim_j \operatorname{Hom}(A_i, X_j), \qquad |\operatorname{Hom}(A_i, X)| \leq s^{\pi_1}.$$

Taking a limit over the presentation of A then yields

$$|\operatorname{Hom}(A, X)| \leq (s^{\pi_1})^{|I|} \leq s^{\pi_1 \mu} = s^{\mu}.$$

This proves the repaired (3.8). The last equality uses $\pi_1 \leq r \leq \mu$ and infinite cardinal arithmetic.

The choices of all the objects A_i must be counted by a product, not by $|I|$ times the number of possibilities at one index. The same applies to the transition arrows. A poset with at most μ objects has at most μ arrows; a diagram on it with values in a fixed small skeleton at level π_0 can therefore be specified in at most $\chi^{\mu} \leq 2^{\mu}$ ways. The requirements of identity and composition merely reduce this number. There are at most 2^{μ} isomorphism types of posets of size at most μ, since both their underlying sets and their order relations can be coded inside a fixed set of size μ and its square. Taking colimits gives

$$|\operatorname{IsoOb}(\mathcal{M}^r)| \leq 2^{\mu}.$$

This replaces the unsupported fixed-index bound r^{π_0} on ms. 21 and 23 by 2^{μ}; the eventual bound is unchanged.

For a fixed $X \in \mathcal{M}^s$, choose one representative of each object at level r. There are at most s^{μ} arrows from any such representative to X, hence at most $2^{\mu} s^{\mu} = s^{\mu}$ objects of $\mathcal{M}^r/X$ up to isomorphism. Between two of them there are at most $r^{\mu} = 2^{\mu}$ morphisms, because a morphism in the slice is a particular underlying morphism in $\mathcal{M}$. Consequently

$$|\operatorname{IsoOb}(\mathrm{Fl}(\mathcal{M}^r/X))| \leq (s^{\mu})^2 2^{\mu} = s^{\mu}.$$

8. *cf.* cor. 2, page 23.

This is (3.9), including the case $s < r$. Finally, applying the same argument to the arrow category without a fixed target gives (3.7). In particular the appearance of products where exponential counts are required is a false intermediate inference, but it does not force a worse final estimate once the small skeleton has been counted correctly.

The elementary identity used here is $a^b = 2^b$ for infinite b and $2 \leq a \leq b$: one has $2^b \leq a^b \leq (2^b)^b = 2^b$. These are the hypotheses under which Lemma 3.2 is used. Its unqualified wording should not be extended to arbitrary finite cardinals, for which, for example, $3^3 \neq 2^3$.

Lemme 3.2. *Soient r un cardinal, r' un cardinal $\geq r$. Alors on a*

$$r^{r'} \;=\; 2^{r'} \qquad (= s^{r'} \text{ pour tout } 2 \leq s \leq r)\ .$$

Corollaire 1. *Soient $r \geq \sup(\pi_1, C_1)$, et $A, X \in \mathrm{Filt}^{\pi}$. Alors*

$$\operatorname{card} \mathrm{Hom}_{\mathcal{M}}(A, X) \;\leq\; 2^{(r^{\pi_0})} \qquad (= 2^r \text{ si } r = 2^c,\ \text{avec } c \geq \pi_0)\ . \tag{3.10}$$

On applique (3.8), qui donne la majoration $r^{(r^{\pi_0})}$, et le lemme 3.2.

On notera qu'on trouve la même majoration pour le cardinal de $\underline{\mathrm{Fl}}(\widetilde{\mathcal{M}^r})$ tout entier (3.7)! De même, (3.9) donne :

Corollaire 2. *Soit $r \geq \sup(\pi_1, C_1)$, et $X \in \mathrm{Ob}\, \mathcal{M}^r$. Alors*

$$\operatorname{card} \underline{\mathrm{Fl}}(\widetilde{\mathcal{M}^r/X}) \;\leq\; 2^{(r^{\pi_0})} \qquad (= 2^r \text{ si } r = 2^c,\ \text{avec } c \geq \pi_0)\ . \tag{3.11}$$

c'est donc la formule (3.9) pour $s \leq r$, laissée en suspens.

Revenons à la majoration cardinale des $X_\alpha(f)$, où $f : X \longrightarrow Y$ est dans $\mathrm{Fl}^s(\mathcal{M})$, *i.e.* $X, Y \in \mathrm{Filt}^s$. On suppose de plus $C_0 \subset \mathrm{Fl}^r(\mathcal{M})$, [page 24]

$$\begin{aligned} &C_0 \;\subset\; \mathrm{Fl}^r(\mathcal{M}) \;=\; \mathrm{Fl}(\mathcal{M}^r)\ , \qquad (f : X \longrightarrow Y) \in \mathrm{Fl}^s(\mathcal{M})\ , \quad \textit{i.e. } X, Y \in \mathrm{Filt}^s\ , \\ &\text{avec } s \geq r\ . \end{aligned} \tag{3.10}$$

Commentary · Examples [ms. 23]

What the proposed sharpness example does show

Grothendieck rightly observes that the Hom bound cannot improve on the elementary set-theoretic exponent s^r: sets of cardinalities r and s have exactly that many functions. The claim that the category of pairs (A, B), $B \subseteq A$, attains the arrow-isomorphism bound 2^r at every allowed r needs a separate check. First, the printed inequality $|A| \geq \pi$ on ms. 20 must be $|A| \leq \pi$ to describe the intended increasing bounded filtration; the original sign remains in the source text and is recorded in the corrections register.

Even after that change, equality does not hold at every cardinal. Assume GCH and take $r = \aleph_1$, $\pi_0 = \pi_1 = \aleph_0$. A map of such pairs is a function between sets with two colours, required to preserve the distinguished colour. Its isomorphism type is determined by the colour of a target element, the two cardinalities of its source fibre, and the multiplicity of each such fibre type. Among cardinalities at most $\aleph_1$ there are only countably many choices. Thus there are countably many fibre types, and at most

$$\aleph_1^{\aleph_0} = \aleph_1$$

possible multiplicity lists. The count of arrow-isomorphism types is therefore at most $\aleph_1$, strictly less than $2^{\aleph_1} = \aleph_2$. The threshold involving the printed C_1 is met: arrows between countable coloured sets have at most $2^{\aleph_0} = \aleph_1$ isomorphism types.

The same example does attain $2^{\aleph_0}$ at the countable level. For each subset S of the positive integers, take one fibre of size n for each $n \in S$, and add a countably infinite fibre so that the source remains countable. Distinct S give nonisomorphic arrows. This is an orbit-count example at a level below the proposition's threshold $C_1 = 2^{\aleph_0}$, rather than an admissible equality case for that proposition. These calculations retain the useful point of the example while separating a genuine sharp Hom estimate from a stronger, false, universal sharpness assertion about arrow orbits.

[Deux fois (3.10).] Il y a une difficulté idiote, c'est que $\mathcal{M}^r$ est équivalente à une petite catégorie, mais n'est pas elle-même petite. Même si C_0 ne contenait qu'une seule classe d'isomorphie de flèches de $\mathcal{M}^r$, son cardinal pourrait être (pour r fixé) arbitrairement élevé. Aussi, dans ce qui suit, je dois supposer la condition de "non pléthoricité cardinale" pour C_0 :

(3.11) $\forall\, i \in C_0$, désignant par $C_0(i)$ l'ensemble des $i' \in C_0$ telles que $i \simeq i'$ dans $\mathrm{Fl}(\mathcal{M})$, j'impose que $\operatorname{card} C_0(i) \leq 2^{(r^{\pi_0})}$ (ce qui est aussi la valeur de la majoration pour le cardinal de $\widetilde{\underline{\mathrm{Fl}}^r(\mathcal{M})} = \widetilde{\underline{\mathrm{Fl}}(\mathcal{M}^r)}$).

[Deux fois (3.11).] Cela implique donc que l'on a $\operatorname{card} C_0 \leq (2^{(r^{\pi_0})})^2 = 2^{(r^{\pi_0})}$, p. 17

$$\operatorname{card} C_0 \;\leq\; 2^{(r^{\pi_0})}\ , \tag{3.12}$$

qui est équivalente à (3.11) (moyennant $C_0 \subset \mathrm{Fl}^r(\mathcal{M})$, postulé dans (3.10)).

Il s'ensuit par (3.8) que l'on a

$$\operatorname{card} \Delta(C_0, f) \;\leq\; \underbrace{\operatorname{card}(C_0)}_{\leq 2^{(r^{\pi_0})}} \cdot s^{(r^{\pi_0})} \cdot s^{(r^{\pi_0})} \;\leq\; s^{(r^{\pi_0})}\ .$$

D'autre part, les X_D dont on prend la somme amalgamée sous X, pour obtenir $X_1(f)$, sont dans $\mathcal{M}^s$, si on fait l'hypothèse suivante. [page 25]

(3.13) Les $\mathcal{M}^\pi = \underline{\mathrm{Filt}}^\pi$ sont stables par sommes amalgamées simples, et par $\varinjlim_{\pi_0}$ filtrantes de cardinal $\leq \pi$ (pas nécessairement grandes devant π_0) ,

compte tenu que $r \leq s$, donc $\mathcal{M}^r \subset \mathcal{M}^s$, donc A, B, X dans $X_D = B \amalg_A X$ sont dans $\mathcal{M}^s$. Les sommes amalgamées partielles *finies* des X_D sont donc aussi dans $\mathcal{M}^s$, par récurrence sur le cardinal de l'ensemble d'indices. La somme amalgamée infinie apparaît ainsi comme $\varinjlim$ filtrante d'objets de $\mathcal{M}^s$, l'ensemble d'indices étant l'ensemble $\mathfrak{P}_f^*\Delta(C_0, f)$ des parties finies non vides de $\Delta(C_0, f)$. Cet ensemble est de cardinal majoré par s', si s' est un cardinal *infini* tel que $\operatorname{card} \Delta(C_0, f) \leq s'$. On peut donc prendre $s' = s^{(r^{\pi_0})}$. On a donc prouvé, compte tenu de (3.13) appliqué à $\mathcal{M}^{s'}$, le

Lemme 3.3. *On suppose* (3.10), i.e. $C_0 \subset \mathrm{Fl}^r(\mathcal{M})$, $f \in \mathrm{Fl}^s(\mathcal{M})$, *avec* $s \geq r \geq \sup(\pi_1, C_1)$, *et de plus que* C_0 *satisfait la condition de non-pléthoricité* (3.11) (*ce qu'on peut toujours supposer, quitte à réduire* C_0 *sans changer* $\widetilde{C_0} = \Phi$ *et* $C_{0*} = \Psi$), *et que la filtration cardinale satisfait la condition de stabilité (anodine!)* (3.13). *Posons*

$$s' \;=\; s^{(r^{\pi_0})}\ . \tag{3.14}$$

Alors $X_1(C_0, f)$ *est dans* $\mathcal{M}^{s'}$. *Plus généralement et plus joliment, pour* C_0 *et* r *fixés* (*avec* $C_0 \subset \mathrm{Fl}^r(\mathcal{M})$ *et satisfaisant la condition de non-pléthoricité* (3.11) *relativement à* r), *pour tout cardinal de la forme* [page 26]

$$s' \;=\; s^t\ , \qquad \text{avec } t \geq r^{\pi_0},\ s \geq 2 \tag{3.15}$$

(d'où $s' \geq 2^{(r^{\pi_0})} > r^{\pi_0} \geq r$), $\underline{\mathrm{Fl}}^{s'}(\mathcal{M})$ *est stable sous le foncteur* $p_1^{C_0} : \underline{\mathrm{Fl}}(\mathcal{M}) \longrightarrow \underline{\mathrm{Fl}}(\mathcal{M})$.

En effet, si on applique la première partie du lemme au couple (r, s'), on trouve que $X_1(f)$ est dans $\mathcal{M}^{s''}$, avec $s'' = s'^{(r^{\pi_0})}$. Mais

$$s'' \;=\; s'^{(r^{\pi_0})} \;=\; (s^t)^{(r^{\pi_0})} \;=\; s^{tr^{\pi_0}} \underset{\substack{| \\ \text{car } t \geq r^{\pi_0}, \\ \text{donc } tr^{\pi_0} = t}}{=} s^t \;=\; s'\ ,$$

donc on voit que $f \in \mathrm{Fl}^{s'}$ implique $X_1(f) \in \mathcal{M}^{s'}$, ou ce qui revient au même, $p_1(f) \in \mathrm{Fl}^{s'}$. p. 18

Corollaire. *Soient C_0, r, $s' = s^t$ ($t \geq r^{\pi_0}$, $s \geq 2$) comme dessus, et soit α un nombre ordinal tel que*

$$\operatorname{card} \alpha \ \leq \ s' \ = \ s^t \ .$$

Alors $\underline{\mathrm{Fl}}^{s'}(\mathcal{M})$ est stable par le foncteur $p_\alpha = p_\alpha^{C_0}$.

On le voit aussitôt par récurrence transfinie, compte tenu du lemme 3.3, et de l'hypothèse de stabilité (3.13).

Pour résumer :

Théorème 2. *Soit $\mathcal{M}$ une catégorie stable par petites $\varinjlim$ filtrantes, et munie d'une filtration cardinale $(\mathrm{Filt}^\pi)_{\pi \geq \pi_0}$, telle que les Filt^π soient stables par $\varinjlim$ filtrantes de cardinal $\leq \pi$ (pas forcément grandes devant π_0), et par les sommes amalgamées simples qui existent dans $\mathcal{M}$. On suppose que les éléments de Filt^{π_0} soient accessibles, et on désigne par π_1 le plus petit cardinal $\geq \pi_0$, tel que les objets de Filt^{π_0} soient π_1-accessibles. On pose* [page 27]

$$c_1 \ = \ \operatorname{card} \mathrm{Fl}(\mathcal{M}^{\pi_1}) \ = \ \operatorname{card} \mathrm{Fl}^{\pi_1}(\mathcal{M})$$

(où pour tout $\pi \geq \pi_0$, $\mathcal{M}^\pi$ désigne la sous-catégorie strictement pleine de $\mathcal{M}$ définie par Filt^π, et $\mathrm{Fl}^\pi(\mathcal{M}) = \mathrm{Fl}(\mathcal{M}^\pi)$).

Commentary · Exposition [ms. 26]

One fixed exponent controls every stage

The geometric calculation has now become very simple. If $C_0 \subseteq \mathrm{Fl}(\mathcal{M}^r)$ and there are at most 2^μ generators, where $\mu = r^{\pi_0}$ and $r \geq \chi$, then for an arrow with endpoints in $\mathcal{M}^s$, $s \geq r$, the set of attaching squares has cardinality at most s^μ. Each individual pushout stays in $\mathcal{M}^s$. Their common-source amalgam can be obtained as a filtered colimit of finite partial amalgams, using at most s^μ indices. This proves Lemma 3.3 with the corrected counting constant. If there are no squares, the amalgam is simply the original source; this case is included by allowing the empty finite subset, or by treating it separately.

What matters for iteration is an exponent fixed point. If $S = c^t$ with $c \geq 2$ and $t \geq \mu$, then $S^\mu = c^{t\mu} = c^t = S$. Thus the successor construction preserves $\mathcal{M}^S$. A limit stage indexed by an ordinal of cardinality at most S stays there by (3.13). Transfinite induction proves that every stage up to any ordinal α with $|\alpha| \leq S$ has its middle object in $\mathcal{M}^S$.

To obtain the lifting property at the final stage, the ordinal must also be a limit of cofinality greater than μ. The initial ordinal of μ^+ is a uniform choice: $\mu^+ \leq 2^\mu \leq S$. The assertion in Theorem 2 that the initial ordinal of *any* cardinal $r' > \mu$ will do is too broad as a justification of the cofinality condition; a singular r' may have cofinality at most μ. Choosing the successor cardinal, as the theorem itself suggests, repairs this point. The size estimate and the cofinality test perform different jobs and must both be retained.

Soit C_0 une petite partie de $\mathrm{Fl}(\mathcal{M})$, formée de flèches coquarrables, et posons

$$\Phi \ = \ \widetilde{C_0} \ = \ \Psi^* \ , \qquad \text{où} \ \ \Psi = C_{0*} = \Phi_* \ .$$

*Soit r un cardinal $\geq \sup(\pi_1, c_1)$, et tel que l'on ait $C_0 \subset \mathrm{Fl}^r(\mathcal{M})$. On suppose que C_0 est irrédondant (*i.e. *deux objets de C_0 isomorphes sont égaux), ou plus généralement, que C_0 satisfait la très anodine condition de non-pléthoricité* (3.11) *relativement à r. On considère la suite transfinie des foncteurs $p_\alpha = p_\alpha^{C_0}$ sur $\underline{\mathrm{Fl}}(\mathcal{M})$ (cf.* th. 1*), donnant lieu aux factorisations fonctorielles d'une $f \in \underline{\mathrm{Fl}}(\mathcal{M})$, $f : X \longrightarrow Y$, en*

$$X \ \xrightarrow{i_\alpha(f)} \ X_\alpha(f) \ \xrightarrow{p_\alpha(f)} \ Y \ . \tag{3.16}$$

On a alors ce qui suit :

1°) *On a (pour mémoire) $i_\alpha(f) \in \Phi$ pour tout α, et de plus,* si α est grand devant r^{π_0}, *on a aussi $p_\alpha(f) \in \Psi$. Si r' est un cardinal $> r^{\pi_0}$ (p. ex. le cardinal successeur de r^{π_0}), on peut prendre pour α le premier ordinal dont le cardinal soit égal à r'.*

2°) *Pour tout cardinal s de la forme*

$$s \;=\; c^t \qquad \textit{avec}\;\; t \geq r^{\pi_0},\; c \geq 2$$

(donc $s = 2^t$ si on prend $c \leq t$, cf. *lemme 3.2),* $\underline{\mathrm{Fl}}^s(\mathcal{M})$ *est stable sous les p_α tels que* $\operatorname{card}\alpha \leq s$. *Si on prend p. ex. pour α le premier ordinal dont le cardinal soit $> r^{\pi_0}$, alors* $\underline{\mathrm{Fl}}^s(\mathcal{M})$ *est stable par p_α, qui par 1°) réalise donc une factorisation fonctorielle* (3.16) *avec $i_\alpha(f) \in \Phi$, $p_\alpha(f) \in \Psi$.*

Démonstration. Tout a été prouvé, si on se rappelle que les objets de $\mathcal{M}^r$ sont r^{π_0}-accessibles (*cf.* (3.2)). p. 19 [page 28]

Commentary · Development (commentators') [ms. 27]

Keeping the multiplicity of generators in the estimate

The non-plethoricity hypothesis is convenient when one is free to choose a generating set. In a family of constructions, however, discarding isomorphic copies can obscure the given maps between generating data. We can keep those copies and make their cost explicit. The following is a quantitative completion of the calculation, with no claim of priority. We checked the cardinal-filtration argument in SGA 4 and the accessibility bounds for functorial factorizations in Low (2016, Theorem 4.4); neither is cited as asserting this exact formula with the raw multiplicity parameter.

A uniform bound with multiplicities. [ours] Assume the filtered-colimit, pushout and cardinal-filtration hypotheses of Section 3, including (3.13). Choose χ by counting the actual arrows of a small full skeleton of $\mathcal{M}^{\pi_1}$. Let C_0 be any small set of coquarrable arrows whose endpoints lie in $\mathcal{M}^r$, where $r \geq \chi$. Let f have endpoints in $\mathcal{M}^s$, and let α be any small ordinal. Put

$$\mu = r^{\pi_0}, \qquad q = \max\{2, r, s, |C_0|, |\alpha|\}, \qquad B = q^\mu.$$

Then $X_\beta(C_0, f) \in \mathcal{M}^B$ for every $\beta \leq \alpha$. If α is a limit with $\mathrm{cf}(\alpha) > \mu$, the terminal factor $p_\alpha(f)$ has the right lifting property against C_0.

Proof. The cardinal μ is infinite, $B \geq q \geq r, s$, and

$$B^\mu = q^{\mu\mu} = q^\mu = B.$$

At stage zero the assertion follows from monotonicity of the filtration. Suppose it is true at β. The repaired Hom estimate applies to each endpoint of a generator and to each endpoint of $p_\beta(f)$, and gives at most $B^\mu = B$ possibilities for either side of an attaching square. There are therefore at most $|C_0|B^2 \leq B$ squares. Each of their pushouts belongs to $\mathcal{M}^B$. A finite partial amalgam also belongs to $\mathcal{M}^B$, by induction on the number of its terms; the empty one is X_β. The poset of finite subsets of the set of squares is filtered and has cardinality at most B. Condition (3.13) puts its colimit, which is $X_{\beta+1}$, in the same level.

If $0 < \lambda \leq \alpha$ is a limit, its diagram has cardinality $|\lambda| \leq |\alpha| \leq B$. Again (3.13) puts $X_\lambda = \varinjlim_{\beta<\lambda} X_\beta$ in $\mathcal{M}^B$. This completes the induction. Finally, a generator domain is μ-accessible by (3.2), so any map from it to X_α factors through some X_β, $\beta < \alpha$. The prescribed map from the generator codomain to the fixed target then determines a square at that stage, solved at $\beta + 1 < \alpha$. Its image in X_α is the required lift. □

In particular take α to be the initial ordinal of μ^+. The formula gives an explicit answer to the size question (3.6) for the unaltered generating set. The extra parameter $|C_0|$ is necessary in this formulation: in Set, arbitrarily many distinct copies of the isomorphism class $\varnothing \to \{*\}$ attach arbitrarily many points to $\varnothing \to \{*\}$ at the first stage, while the filtration levels of the generator endpoints remain fixed.

Commentary · Later developments [ms. 28]

From bounded factorizations to small model structures

Theorem 2 addresses a question that remains useful long after the existence of the small object argument is understood: can a chosen factorization be performed inside a controlled small part of the ambient category? In the locally presentable setting, Low (2016, Theorem 4.4) gives a functorial weak factorization system whose functors preserve specified presentable objects under explicit bounds

on the generators, their Hom sets and two regular cardinals. His Theorem 5.9 then tests when two such systems form a model structure by restricting them to an appropriate small full subcategory; Proposition 5.12 gives the corresponding statement for an arbitrary combinatorial model category.

These results use regular presentability indices and the relation of one cardinal being sharply below another. The numerical dictionary is therefore not obtained by replacing every Filt^{π} with the modern class of π-presentable objects. What is common is the argument's architecture: control one stage, choose a cardinal stable under its operations, and keep the entire factorization within that bound. This is the immediate background for the model-structure criteria that Grothendieck develops in Section 4.

4 Compléments sur les structures de Quillen

Définition 4.1. Soit $\mathcal{M}$ une catégorie. On appelle *précouple de Quillen* dans $\mathcal{M}$ un couple (Φ, Ψ) de parties de $\mathrm{Fl}(\mathcal{M})$, satisfaisant les deux conditions suivantes.

a) On a $\Phi \longleftrightarrow \Psi$, *i.e.* $\Psi \subset \Phi_*$, ou ce qui revient au même, $\Phi \subset \Psi^*$ – soit encore : pour tout carré commutatif dans $\mathcal{M}$

(4.1.1)
$$\begin{array}{ccc} A & \xrightarrow{u} & X \\ {\scriptstyle i}\downarrow & \overset{w}{\nearrow} & \downarrow{\scriptstyle p} \\ B & \xrightarrow{v} & Y\ , \end{array}$$

avec $i \in \Phi$, $p \in \Psi$, il existe w telle que $wi = u$, $pw = v$.

b) Toute $f \in \mathrm{Fl}(\mathcal{M})$ se factorise en

$$f \;=\; p\,i\ , \qquad \text{avec } i \in \Phi,\ p \in \Psi\ .$$

On écrit

(4.1.2)
$$\Phi \;\leftrightarrows\; \Psi$$

pour indiquer que (Φ, Ψ) est un précouple de Quillen.

On dit que le précouple de Quillen est *clos*, si Φ est clos à gauche, Ψ clos à droit. On va voir plus bas (cor. 2, page 31) que cela implique (donc équivaut à)

(4.1.3)
$$\Phi \;=\; \Psi^*\ , \qquad \Psi \;=\; \Phi_*\ .$$

Un précouple de Quillen clos est aussi appelé un couple de Quillen. [page 29]

Commentary · Exposition [ms. 28]

From a factorization procedure to its two lifting classes

Grothendieck has constructed factorizations from a set of generators. He now asks which parts of that construction survive when the generators and their cardinal estimates are forgotten. This change of viewpoint explains the apparently elementary opening of Section 4: the next existence argument will need to recognize a model structure from two factorization procedures, and a factorization procedure does not by itself determine the classes of maps which ought to be called cofibrations and fibrations.

Write $L^{\square}$ for the maps having the right lifting property against every member of L, and ${}^{\square}R$ for the corresponding left lifting class. Grothendieck's notation is $L_* = L^{\square}$ and $R^* = {}^{\square}R$. A *précouple* supplies factorizations and the inclusion $L \subset {}^{\square}R$. A *couple* supplies the equalities

$$L = {}^{\square}R, \qquad R = L^{\square}.$$

Thus a couple is what is now called a weak factorization system. Neither uniqueness of the diagonal filler nor a functorial choice of factorization belongs to this definition. The constructions of Section 1 provide functoriality under their additional smallness hypotheses. Modern definitions and the retract argument can be compared directly in Riehl (2014, Definition 11.2.1 and Lemma 11.2.3).

The word *clos* concerns equality with a lifting class. It must be distinguished from closure under the operations listed later in (4.4.3). Those operations preserve a left lifting class, but the converse requires an existence theorem. Section 1 furnishes that converse for classes generated by a small set of sufficiently small maps. This distinction will become decisive when the class $C \cap W$ is known to have the expected stability properties but no generating set has yet been found.

The expression "facteur direct" also has a categorical meaning here. It is a retract in the arrow category, without any additive direct-sum decomposition. For arrows $j : A \to B$ and $i : A' \to B'$, it means that there are morphisms of arrows $j \to i \to j$ whose composite is the identity of j. Proposition 4.2 shows that a factorization of j lets us keep its source fixed. That stronger form is why one diagonal filler is enough to turn a lifting condition into a retract statement.

Proposition 4.2. *Soit* (Φ, Ψ) *un précouple de Quillen dans* $\mathcal{M}$*, et soit* $j \in \mathrm{Fl}(\mathcal{M})$ [9]*. On a alors les conditions équivalentes sur* j *:*

a) $j \in \widetilde{\Phi}$.

b) $j \in \Psi^*$.

c) j *est facteur direct d'un* $i \in \Phi$.

c′) j *est facteur direct d'un* $i \in \Phi$ *ayant même source que* j*, plus précisément, il existe un diagramme*

(4.2.1)
$$\begin{array}{ccc} A & \xrightarrow{\ j\ } & B \\ {\scriptstyle \mathrm{id}_A}\downarrow\uparrow{\scriptstyle \mathrm{id}_A} & & {\scriptstyle q}\downarrow\uparrow{\scriptstyle p} \\ A & \xrightarrow{\ i\ } & B' \end{array},$$

avec $i \in \Phi$*, et* p. 20

(4.2.2)
$$qj \;=\; i\,, \qquad pi \;=\; j\,, \qquad pq \;=\; \mathrm{id}_B\,,$$

de sorte que j *est un facteur direct de* $i \in \Phi$*, par* (id_A, q)*, admettant la rétraction* (id_A, p).

d) *Pour tout diagramme commutatif traits pleins*

(4.2.3)
$$\begin{array}{ccc} A & \xrightarrow{\ j\ } & B \\ & {\scriptstyle i}\searrow \quad \nearrow{\scriptstyle p} \quad \curvearrowleft{\scriptstyle q} & \\ & B' & \end{array},$$

i.e. *toute factorisation de* j *en* pi*, si on a* $p \in \Psi$*, il existe une section* q *de* B' *sur* B *dans* $A\backslash\mathcal{M}$, i.e. *une flèche* $q : B \longrightarrow B'$ *telle que*

$$pq \;=\; \mathrm{id}_B \qquad et \qquad qj \;=\; i\,.$$
